Emery Walker Ltd., ph. sc.

THE JOURNAL OF

The Institution of Electrical Engineers

VOL. 63.

INAUGURAL ADDRESS

By WILLIAM B. WOODHOUSE, President.

(*Address delivered before* THE INSTITUTION, *23rd October*, 1924.)

To be elected President of the Institution of Electrical Engineers is an honour carrying with it a measure of responsibility, of which I am deeply conscious. It is an honour which I value not only as a personal one but as, in some degree, a recognition of the importance of the branch of electrical engineering in which I am engaged. I thank you very much.

THE INSTITUTION.

The Institution, to be fully representative of the activities of its members, must engage in numerous and diverse works. Its rapid growth in recent years has been due, I think, to the appreciation of this necessity and to the policy of the Council of aiding, by a frank and helpful recognition of sectional interests, the creation of other organizations to meet new needs as they arise.

Amongst such bodies may be mentioned the British Engineering Standards Association, whose good work is yearly showing itself to be of more and more value; the Electrical Research Association, whose contributions to knowledge will, I hope, continue to flow in an increasing volume; and the Electrical Development Association, whose mission is not only to educate the public in matters electrical but to emphasize the mutual interdependence of various sectional interests on one another.

The Wireless Section of the Institution, the Local Centres, the Centres overseas and the numerous special Committees of the Council all indicate a policy of enlisting the active support and direct efforts of as large a number of members as possible in the great work of development which the Institution has undertaken.

The continued work of the body of members in the past has resulted in a general increase of knowledge, in which the whole world shares, and in a variety of ways has helped to improve the status of the electrical engineer. Our duty each in turn is to repay, so far as we can by working for the common good, the benefits which we have received from the work of others.

The granting of the Royal Charter to the Institution was a gracious recognition by His Majesty the King of the distinguished position which the Institution now holds. During the past year, in connection with the World Power Conference, a further mark of Royal favour was shown, by the Garden Party given by His Majesty to representatives of the Institution and of the foreign delegates to the Conference. I am sure that all members will value this additional recognition.

EDUCATION.

The electricity supply industry, the branch of electrical engineering in which I have spent the greater part of my professional life, is now reaching a stage of development at which the magnitude and nature of the problems to be dealt with are becoming more clearly defined. One of these problems is that of the training necessary to fit the younger men to carry on the growing work before them; and the rapid growth of the industry makes the problem of more than usual importance.

In any industry the men employed may be divided into three main groups: the general body of employees, the executive officials and the administrative officials. The ideal system of training is one which, whilst establishing a regular curriculum for each class of worker, allows sufficient latitude to permit the advancement of men whose ability and character show them deserving of transfer to higher positions, even though the regular course of training has not been followed.

The problem is not a new one, and the most successful solutions appear to be those which are flexible enough to meet the steadily changing conditions that arise. My own view of the most suitable general training of the officials is that it should include not only technical

instruction and practical experience in the supply industry, but also experience in one or more sections of the manufacturing industry. A system of interchange between manufacturers and supply undertakings should be of value to both sections of the industry, and in many cases benefit would, I think, arise by periodical interchanges of staff between supply undertakings. In this connection my view is that such a course of training should include not only the technical but also the accountancy side of the business. Familiarity with the ordinary methods of accountancy is somehow quite unusual in young engineers whose mathematical abilities go far beyond the simple but important arithmetical processes of the bookkeeper.

The whole subject is one which, I think, should repay discussion, bearing in mind that although the system of scholarships at universities and technical schools helps to keep open the career to the talents, there is a direct obligation on the industry to bear the cost of post-graduate training by providing salaries for those young men who show the necessary ability and energy which are sufficient to encourage them to continue this widening of experience beyond the normal period of their training. Were such a system generally adopted, I believe that the industry would benefit largely.

Progress.

The progress of the electricity supply industry throughout the world during the past 20 years has been so rapid and the developments so numerous that it has almost seemed that no anticipation of its future possibilities could be exaggerated, and, as a consequence, there have been (and are being) made claims for the use of electricity which exceed the present probability of fulfilment. This tendency to overstate the case is likely to be harmful in producing a natural reflex of disappointment when the facts are known. Already we find in various quarters that the developments in this country are compared detrimentally with those made in other countries, without any account being taken of the conditions which would explain the difference. As a consequence, notwithstanding that developments are being made and conceived on a larger and more ambitious scale than ever before, there is further talk of legislative amendments for the purpose of stimulating progress.

The lines which development is following in all parts of the world have been indicated and established principally by British engineers, and there is no evidence that the ability of our engineers in any way falls below that of engineers of other countries. This being so, it savours of the ironic that the electricity supply industry in this country should have become so much the sport of theorists and the victim of legislative experiments.

The development of electricity supply in any country depends on the particular circumstances attending production and use, and comparisons between different countries without considering these circumstances are likely to be, not only valueless, but misleading.

Electricity supply has a great future, but it is not a panacea for industrial and social ills, and it behoves engineers to speak out just as definitely when unjustifiable claims are made for it as when it is unfairly attacked.

The development of the use of electricity is largely due to considerations of convenience in meeting the desired needs of civilized communities. Its development is limited by a consideration of cost in relation to the cost of other means of supplying the same needs. The degree to which convenience can be translated into terms of cost is a measure of the necessity or of the standard of luxury of the community. For example, regarding electricity merely as a means of providing in a convenient form sound, light, power or heat, we see that for signalling or sound-recording at a distance electricity is without a competitor; the consideration of cost for this purpose is confined to that of alternative electrical methods.

Lighting.

For lighting, the convenience, cleanliness, safety and comfort of electrical methods place them in a most favoured position relatively to other illuminants; but the development of electric lighting—limited in the past by the cost of production and at present by other conditions, to which I shall refer later—has been made in competition with gas and oil and has had, in many cases, to oust the older method.

One of the most notable achievements of electrical engineering has been the reduction in the cost of electric light in the present century, by increasing the illumination six-fold for the same amount of electricity. To-day, electricity is the cheapest form of illuminant, and, as a consequence, its use for lighting purposes is growing at a rate never before equalled in the history of the industry.

It is of interest to consider what are the limitations to further use and what is the probable development.

No general statistics are available of the number of dwelling-houses using electric light, but probably less than 20 per cent of the houses in this country are wired and connected to the public supply. This small proportion is due, I think, to considerations other than the cost of producing electricity, the first being the cost of the consumer's installation.

In existing houses, many of which are already supplied with gas, the introduction of electricity involves the expenditure of capital on wiring which, under present conditions, the landlord is not prepared to provide, on account of the Rent Restriction Acts, and the tenant is reluctant to expend on an improvement which may result in an increased rent when restrictions are removed. Assuming that this difficulty can be overcome by arrangement between the landlord, the tenant and the supply undertaking, a considerable addition to the number of consumers may be anticipated.

A second consideration is that in the natural order of development those houses which could be most cheaply supplied have been dealt with first, and the supply to the others, for various reasons, will involve a proportionately greater cost of distribution.

The 1921 census enumerated for the first time the number of rooms in dwellings of various kinds, including flats and those occupied business premises in which the portion used for domestic purposes is not less than three-quarters of the whole. The figures are not yet completed for the whole country, but a consideration

of typical districts is of interest as indicating the possible demand if the whole of the houses were lighted electrically. I have taken as an example the census figures for London, Manchester and the West Riding, and find the following division as to size :—

Census of Dwelling-houses.

	Percentage of total number of houses where number of rooms per house is:			
	1 to 3	4 to 5	6 to 8	9 and more
	per cent	per cent	per cent	per cent
London.. ..	18	27·1	42·4	12·5
Manchester ..	11·8	65·8	20	2·4
West Riding of York.. ..	33·8	48·3	15·5	2·4

It may be assumed, I think, that the majority of existing consumers dwell in houses of 6 or more rooms, and that the untouched field lies principally in the supply to the smaller houses. The extent to which this field varies will be seen in the various districts. In London 45 per cent, in Manchester 77 per cent, and in the West Riding 82 per cent of the houses are of this smaller size. Not only are the dwellers in these smaller houses potentially smaller users of electricity, but the cost of distribution per house is practically as high as for the larger users. It follows that on the one hand the reduction of the cost of distribution is of the utmost importance, and the stimulation of the use of electricity for domestic purposes other than lighting equally so on the other. Here it may be said that the general standard of illumination in dwelling-houses in this country is low, though much above that of 20 years ago. The public have not yet realized the decorative possibilities of electric light, and the unshaded filament—an abomination in the sight of any thoughtful person—is still too frequently seen. We may, however, assume that the tendency to soften and diffuse the light and to harmonize the system with the general decoration of the room will continue to grow, with a consequent increase of consumption in the larger houses.

To use a popular though often untrustworthy basis of comparison, the present-day consumption per head of population for lighting purposes in this country is about 10 units per head, representing a supply to some 20 per cent of the houses. The complete supply should produce figures of 40 to 60 units per head, depending on the proportion of large houses. It should be emphasized that this question is not primarily one of generation but is almost entirely determined by two considerations, the cost of wiring the houses and the cost of distributing the electricity.

Power.

While the cost of electricity for lighting is primarily determined by the cost of distribution, in the case of power supply the cost of generation is the principal part.

The early development of power supply was largely aided by the advantages of subdivided electrical driving by a number of motors, in place of the general method of using line shafting, countershafting and belts driven from a main engine in factories, or small non-condensing engines in large premises such as shipyards. Once the power user purchased electricity and adopted the electrical driving of machinery he was in a position, for the first time, to measure accurately the amount of power required for each machine and to base his future plans on accurate data.

The continued development of the use of the public supply has been maintained only by a continued reduction of the cost as compared with that of individual generation, and the margin has at times been small. The growth of the industry has, however, now reached such a stage of development that the advantages of centralization permit in the majority of cases the supply of electricity at prices which show a definite saving of cost to the user, in addition to the less direct, but important, advantages of convenience. Generally speaking, the possibility of supplying a power user at a price lower than his own cost of production depends on the magnitude of the power plant relative to the central system.

To-day the principal industrial areas of the country are being supplied from stations of from 50 000 to 100 000 kW. Further economies will accrue from the growth and interconnection of these stations and the complete supersession of small stations in industrial areas—a work which is steadily progressing.

Apart from the economies of capital and operating costs inherent in large generating stations, the accumulated experience of the specialists who now control the operation of these stations produces economies in working not otherwise obtainable, and I am confident that we are entering on a new phase in the industry and that the days of the individual industrial plant are numbered. Certain special cases must, however, be regarded; those, for example, in which a large use is made of steam for manufacturing processes and those in which the steam engine on account of its special characteristics is still regarded as more suitable to the work.

A careful study of works using both motive power and steam for process work shows that in many cases the advantages of combining the power plant and the steam-raising plant are illusory and that economies will result from the separation of the two. Accurate records of analysis of industrial operations of this nature are scarce and the industry would be helped by further research of an unbiased nature.

The second case is perhaps best evidenced by the colliery winding-engine, the retention of which is in many cases more a matter of prejudice in favour of a well-tried machine than due to the consideration of the cost of installation of the electrical equipment. A partial solution of the winding-engine problem which has found a considerable amount of favour has been the use of the mixed-pressure turbine in conjunction with the winding engine. The method is falling out of favour because in most cases it perpetuates wasteful machinery and only reduces the waste. Modern centralized production shows, over the partial method, an advantage which is becoming greater as the scale of production increases. In the past, moreover, a public

supply on a sufficiently large scale was rarely available and the special devices necessary to reduce the peak loads were costly. To-day, in all the principal coal fields a public supply is available on a scale which no longer need be concerned with the variations of load, and the simplest type of motor may be fitted and supplied from the general system without difficulty.

The satisfactory experience of electric winding for collieries gives every assurance of a further and rapid extension of use.

Heating.

The use of electricity for heating must take into account the particular requirements and the method of application before it can be said that it is the most suitable or most economical method to be adopted.

The relative price of a heat unit in the form of coal and in the form of electricity—unfavourable as the comparison is to the latter—is, of course, not the criterion of its value unless the efficiency of utilization is taken into account. When this is done it is found that for many purposes electric heating is suitable and economical. For some, its cost is prohibitive.

The adoption of electricity for general heating purposes, apart from special applications to which it is suited, is not probable until substantial and vital changes are made in the methods of production, and the supply-engineer's thoughts must therefore be directed to the most suitable combination of means of heating, lighting and power supply in dwelling-houses and factories.

This consideration leads to the further one of the measure of co-operation which should be established between suppliers of coke, gas or other fuel, and those of electricity, in the best interests of the public. The subject of coal distillation is therefore one of particular interest to the electrical engineer.

Coal.

The principal condition affecting the development of electricity supply in any country is the price of coal. The advantages of centralized power production from coal lie in the better utilization of capital and in the more economical use of coal due to design, skilled operation and diversity of demand.

It is obvious that in a country where coal is dear the advantages of centralization of power production are greater than in a country such as our own where coal has been cheap. As a consequence, the development of electricity supply in countries where water power is available and where coal is dear has been much more rapid than in this country, not, it will be noted, necessarily due to a spirit of greater enterprise, but primarily because it was the best or only economic solution of the power problem.

In the early days of power supply the industry gained a temporary advantage over the generality of power users by their adoption of mechanical grates and the use of small coal, the price of which was low on a heat-value basis. The cost of small coal, however, has gradually risen so that its market price to-day is more in accordance with its heat value, and the supply-engineer's advantage is almost wholly in his more economical methods of use. It is important therefore to consider whether, by the adoption of other methods, the industry can place itself in a position of still greater advantage over the ordinary user, and in this connection the striking world-wide changes which are going on in the demands for fuel must be regarded.

The utilization of water power and the steadily increasing efficiency of power production from coal indicate that the existing demands for mechanical power will be met by a rapidly decreasing consumption of coal. In our own country the pre-war consumption of nearly 200 million tons of coal a year represented a use in many respects wasteful, and the engineering progress of the last 10 years has already made a substantial reduction. The growing use of oil fuel is also in a large measure in substitution for coal.

These considerations tend to reduce the world demand for coal and, were they not qualified by the increasing demand for power, the prospect before coal-producing countries such as our own would be one of unqualified gloom. Whether, or for how long, this country can continue to export large quantities of raw coal seems therefore not so much a question of national resources as one of price and demand.

The most efficient use of coal for power production is measured by the coal consumption per unit of electricity, and with the materials and methods to our hands electrical engineers are rapidly approaching the maximum of economy. On broader grounds it may be considered whether the quantity of coal consumed is the true criterion or whether a process which, whilst consuming more coal, yet produces a greater profit per ton is not to be preferred.

The demands for oil fuel, for light spirits and for artificial fertilizers, all of which can be produced by the distillation of coal, should, if possible, be met by home products; and the distillation processes should, so far as is economical, be carried on in combination with the production of electricity. Coal distillation is a subject which the electrical engineer must regard as within his province and it may be of interest to enumerate some considerations which I think will engage his attention.

There are in commercial use two classes of coal-distillation processes: coking processes, and regulated combustion or producer process. The coking processes are the more important and include those in use by the gas industry and by the coke-oven industry; the producer processes which result in complete distillation of the carbonaceous matter and its conversion to gas are of less importance.

The success of established processes depends on an appreciated or increased value of certain products above their absolute fuel value, due to the existence of a demand for potential energy in a particular form. This increase of value is not obtained if all the fuel products are used for power production, unless the form in which they are obtained—for example, gas or oil—permits the use of more efficient generating plant or, due to the ease of control, results in a more efficient process of generation. If, therefore, a coal distillation plant is worked in conjunction with the production of electricity, commercial success calls for the marketing of the products (such as oil and ammonia) which are not used for the primary business of producing electricity.

The processes at present in use involve the treatment of a much larger quantity of coal than would be required for direct combustion, and the disposal of products the total value of which exceeds that of the coal required for direct combustion. The selling price of these products depends on world-wide competition with products obtained from other sources than coal. In other words, if such a process were adopted primarily for the reduction of the cost of electricity, its success would depend on conditions which make, or may make, the revenue from the sale of fuel to the electricity works a minor matter.

It may be said, therefore, that the adoption of any established commercial process of distillation would introduce into the electricity supply business an element of speculation which is foreign to the industry as it exists to-day, and which might alter substantially the nature of the industry and the security which it at present offers to the investor.

The cost of distribution is so considerable a charge for many uses that cheap electricity depends very largely indeed on the ability of the undertaking to raise capital at a low rate. A low rate of interest or dividends on capital is only consistent with the present faith of the public in the stability and security of the industry; consequently, any speculative element not controlled by the observance of engineering and commercial principles peculiar to the industry might lessen public confidence and make the cost of electricity greater.

Keeping this in mind, it follows that the most suitable process is one in which the quantity and nature of the by-products can be varied most readily to meet changing markets, and one that should be commercially justifiable even when a large proportion of the products is used in the production of electricity. No existing process can be said by the experience of working on a commercial scale to be demonstrated as worthy of adoption principally because of the heat losses in the process, the capital outlay involved and the operating expenses.

The quantity of heat required for the distillation of coal as ascertained by laboratory tests is small, of the order of 2 or 3 per cent, but, in practice, heat losses are considerable. The development of continuous processes and shorter times of distillation seems essential to cheap production.

The utilization of gas from distillation processes is another interesting aspect of the problem. Gas fuel for steam-raising has, from my own experience, proved eminently satisfactory over a period of years; but the special value of gas for distribution offers a market of higher prices, and coal gas such as produced from coke ovens is finding more and more outlet in sale to gas undertakings.

Research is also proceeding for the production of oils from coal by chemical reactions not consequent on distillation, and the progress made suggests many interesting possibilities which may have an important effect on the practice of power engineers.

Generation.

The design and operation of electricity stations, whilst showing progressive development, has undergone no startling changes since the introduction of the steam turbine and, so far as the thermal efficiency of the present type of plant is concerned, we are steadily approaching the limits.

The process of conversion of the heat energy of coal to electricity takes place in three steps: the conversion to steam, from steam to mechanical power, and from mechanical power to electricity. Of the apparatus used as designed for present-day practice the boiler may have an efficiency of 85 per cent, the steam turbine an efficiency ratio of 87 per cent, and the alternator an efficiency of 97 per cent, or an overall figure of 72 per cent.

The serious consideration in this not unsatisfactory ratio is of course that the heat cycle used as a measure of the turbine efficiency-ratio has an absolute efficiency of a low degree, and if we take the real overall efficiency of the best modern station under working conditions we find that it rarely exceeds 20 per cent. This is practically double the efficiency of 20 years ago, during which time the pit price of coal has also practically doubled. In effect, therefore, the engineers responsible for these developments have, by their efforts, discounted in full the increased cost of coal—no mean performance.

It is of interest to consider the possibilities of development in the efficiency of the heat cycle. Improvements can be made by reheating the steam or by the progressive heating of feed water, but the degree of improvement is not large.

The more important possibility is that of increasing the temperature and pressure of the steam. The combustion of coal under properly controlled conditions is such that a flame temperature of several thousand degrees may be attained, and, could steam be produced and utilized at such a temperature on the present heat cycle of operations, a substantial increase of thermal efficiency would be possible. The practical limitations to-day are the nature of the materials used and the design of the apparatus, the latter a minor consideration if suitable materials were available.

The progress of the past 20 years has been a step-by-step improvement in design, construction and methods of operation, and the field for further improvement by a continuation of this work, though not large, is one of considerable promise. It must, however, be borne in mind that the total cost of production includes not only that of fuel but also the cost of providing, operating, and maintaining the plant. It may be assumed that these costs are, in a principal station, divided in the proportion: coal 50 per cent, capital charges 30 per cent, operating costs 20 per cent; from which their relative importance may be judged.

In the total cost of electricity the cost of capital is an item which is second in importance only to that of fuel. The reduction of the capital cost per kilowatt of plant may come about by the adoption of larger units of plant and by the development of design to obtain a greater output of electricity from the same use of material. The size of the generating unit is limited by a consideration of capital investment in spare plant and by a consideration of the load on the station at night times and week-ends. As the demand for electricity increases, the justification for larger units also grows and the cost per kilowatt should fall.

As to the more economical utilization of materials so

as to obtain a greater output from the capital investment, there seems considerable room for improvement. For example, in the steam boiler an average evaporation of 6 lb. of water per square foot of heating surface is a poor utilization of materials when we know that under certain conditions an average of 20 lb. may be obtained.

The consideration of boiler design in relation to heat transfer is a subject of great interest. The transfer of heat from a radiant surface proceeds so much more rapidly than the transfer from the hot gases by conduction, that there has been a natural development of the volume of combustion chambers and a more careful consideration of the amount of surface exposed to radiant heat.

The design of the furnace is limited by the available refractory materials, on which subject kindred scientific institutions have done valuable work. In this direction, interesting developments have taken place in the production of new and more refractory materials and in the design of the boilers and furnaces to reduce the amount of refractory material required.

Reviewing the developments which have been made, it appears that progress has been on right lines and has resulted in reducing substantially the cost of generating electricity. The direction which future developments should take seems clearly indicated and should result in further economies, but not of a revolutionary amount.

Distribution.

So much has been said in the Press about the reduction in the cost of producing electricity that the ordinary consumer of electricity for lighting may be excused for wondering why the price of electricity is so high. The answer is, of course, that the cost of distribution to small users whose use is only intermittent, as is the case with the user of electric light, is governed almost entirely by the cost of distributing mains and apparatus, and if by some means the fuel bill were halved the effect on the price of light would be but trifling.

It may be taken that the cost of distribution for lighting adds some 300 per cent to the cost of production; and it is of interest to note by way of comparison that the distribution of milk, also sold from house to house in small quantities, adds only 100 per cent to the wholesale price. The cost of distributing electricity requires our most careful consideration, more particularly as one finds that the methods adopted differ but little from those of 20 years ago. I believe that a frank interchange of views between supply engineers on these methods would be of great value.

The other line of development, namely, the reduction of the average price by encouraging an increased user of electricity, will naturally not be overlooked, and it is gratifying to find that the work of those engineers who have devoted their energies principally to the development of domestic uses such as cooking is beginning to bear good fruit.

The problem of supply to the small householder, already referred to, and of supply in rural districts with scattered population, is one in which the costs should be examined with particular care so that the supply to these users shall not prove a burden on the undertaking. It is rather generally assumed that the supply undertakers should charge one price for the same service in any part of their area. In a densely populated town this may be justifiable, but the acceptance of the principle for rural districts will result either in penalizing the town dweller or in financial loss on the rural supply.

Tariffs.

The subject of tariffs is of importance in that a greater measure of public goodwill is likely to be obtained by a proper understanding by the consumer of the underlying principles which determine the charges for each particular class of electrical service. The principles are, of course, the common economic principles applicable to the production and distribution of any commodity and are not peculiar except in degree to electrical service.

A closer analysis of costs of each operation not only is of value in determining the possible selling price, but is in the interests of the consumers individually and as a body. The development of an undertaking requires a margin of profit available for fostering new extensions of the system or new applications of use, for research and for advertisement. It is obvious that any arbitrary ruling, such as, for example, that prices shall be determined by cost plus a fixed margin, would prevent the necessary accumulation of a development fund in its widest sense.

The cost of electricity at the station busbars may be expressed with reasonable accuracy in the form of a charge per kilowatt of demand plus a charge per unit; the average cost at main distribution centres may be expressed in the same form, but to express the cost delivered to consumers of different classes we must adopt a division into three parts, which may be expressed approximately as :—

(1) The fixed charges on generation.
(2) The running charges per unit.
(3) The standing charges on distribution.

The principle of averaging these distribution charges has been accepted in the past without question as a sound one, but it is at least questionable whether development is not hampered by this method of selling, for the effect is to penalize the profitable consumer to enable others less profitable to be served. It would, in my view, be unsound to develop undertakings beyond the economic limit, either by penalizing existing consumers or by State aid, in that alternative services exist for most needs, e.g. lighting by gas, power by self-contained plants such as the petrol engine, the oil engine and the steam turbine, heat by gas or coal, and so on.

I believe that there is a very wide field for the further development of electricity supply for all purposes, but I deprecate unprofitable development either at the expense of existing users or the public as a whole.

Interconnection.

The development of the industry commencing by generation on a small scale at separate centres is, by a natural process, now reaching a stage where for various reasons the limit of aggregation of generating plant in a station may be foreseen. As a consequence, the generation of electricity to supply

any considerable area will be carried on at more than one centre.

There are economic advantages in the interconnection of the systems supplied by individual stations, within limits not difficult to decide, the extent to which the interconnection may be justifiably carried being determined by the balance of advantages and disadvantages in any particular case. The advantages are: a reduction in the amount of spare plant, or greater security; more economical loading of plant and greater diversity of demand; the possibility of extensions by larger and more economical steps; and the reduction of capital invested, per kilowatt of plant. In water-power schemes the diversity of water-flow in different watersheds and the pooling of water storage are additional advantages. The disadvantages are principally the capital cost of interconnection and the consequent annual charges for capital and operation.

The economical extent to which interconnection may be carried is largely a matter of the working pressure and amount of energy to be supplied. The limit of working pressure is determined by the system of transmission adopted. It has been assumed in this country that underground mains are essential for this purpose, though in other European countries overhead lines are being generally used. In this connection the pioneer work of the British cable makers is notable, and the prospects of three-core cables at pressures up to 60 000 volts are stated to be favourable.

The use of three-phase alternating current has by general consent proved the most economical of the available methods of transmission at high pressures. In the past, local generation and distribution have been carried out at pressures of 6 600 and 11 000 volts with reliability and, compared with other systems, a saving of cost. Where the systems in a large region are to be interconnected the need arises for higher pressures, and we are now confronted with a new set of problems appertaining to this wide interconnection.

The arguments for interconnection are well known and, due to the undue prominence given to them, the disadvantages of our present methods have been correspondingly placed in the background. Let us consider what are these disadvantages. The first one, inherent in the three-phase alternating-current system, is that the cost of switchgear and protective devices increases rapidly with the size of the supply system. This must be so, when we consider that the switch must be designed not merely to cut off a faulty section of the system but also to stop the flow of power from the system as a whole into the faulty section.

The duty of a switch may be reduced by the introduction at suitable places of additional reactance in the apparatus used. The alternator once designed with the object of maintaining constant pressure is now preferred to have a contrary characteristic; the transformer also is designed to withstand fault currents at the expense of regulation and, in addition to the power current in the system, large magnetizing or idle currents exist and must be controlled. As a consequence, the regulation of pressure at the various main distribution centres and at important sub-centres requires the introduction and use of regulating apparatus, involving further expenditure of capital and increased cost of operation. In this respect the art has not progressed as rapidly as the need.

Fruitful lines of research are the better understanding of the duty and behaviour of oil switches, a work which is being undertaken by the Electrical Research Association, and the possibility of reducing the duty of the switch without unduly affecting pressure conditions. The use of reactors is but a palliative. A switch opening under fault conditions has to deal with the stored energy in the system, its operation is so controlled that the flow of energy into the fault has already grown to a considerable magnitude before the switch opens, and its design is such that if it opened when the fault current was a maximum it would probably prove ineffective, the time delay in opening permitting the absorption of the energy, though usually destructively, in other places than the switch.

The development of electronic valves has introduced a device which is free from friction and from time-lag of operation such as is caused by electrical induction or mechanical inertia. Their application to the control and regulation of electricity supply systems is a promising prospect. If control can anticipate the disturbance caused by a fault, instead of as at present being consequent on it, a great advance will obviously be made.

Another line of research is the application of direct-current transmission, a work with which the name of one of my predecessors in the Presidential Chair, Mr. J. S. Highfield, is closely associated. The reversion to direct current would bring with it many advantages, and one looks forward with interest to the outcome of the work being done.

It is of interest to remember that early systems of supply were developed which were regulated by a variation of pressure from zero to a maximum. Practice of the last 20 years has been almost wholly on the lines of constant pressure, both of steam and of electricity.

The problem of insulation is also a serious one and the three-phase system, though the best available at the present time, cannot be regarded as even approaching the ideal.

High pressures are necessary to enable the concentration of generation and the transmission of electricity over long distances and, this being so, one of the most urgent problems for solution is that of providing a means of transmission at high pressures which is free from the disadvantages of the present system and, in particular, is less costly to install. For example, the carriage of coal from, say, South Wales to London for the purpose of generating electricity at stations in London is more economical than the establishment of generating stations in the coalfield and the transmission of electricity from the coalfield to the metropolis. So long as this is the case it is idle to assume that because in certain countries where water power is used a transmission for 1 000 or even 500 miles is justified, a similar provision would be justified in this country. The solution of this problem is one that it is hoped is not far distant.

Overhead lines are in certain circumstances a means of economy, but in a densely populated country difficulties are met with which in many cases make their use

of doubtful economy. The legislation of the Electricity Supply Acts of 1919 and 1922 have given the suppliers of electricity in this country most valuable powers with regard to overhead lines and it is of interest to see the steady, though slow, increase in the use of such lines. There is still a considerable amount of prejudice to be met and also quite legitimate criticism from those whose amenities are disturbed. A general discussion of these matters, a fuller presentation of the case to the public, and a concerted effort to obtain the most economical design consistent with safety should be of general benefit.

Legislation.

And now, as a somewhat harassed industry is threatened with more legislation, a word as to the legislation of the past.

The first Electric Lighting Act of 1882 contemplated parochial systems of supply with either immediate or ultimate operation by the local authorities individually. This was, as experience has shown, a basic error.

The Power Company Bills at the beginning of the century were framed on broader lines, but, Parliament halting between two opinions, the Acts were so emasculated for the protection of existing undertakings that their value was much reduced.

In the last 5 years we have had two new general Acts which endeavoured to reconcile the conflicting ideas of municipal working and private enterprise under the guidance of a body of Commissioners who were given the task of acting as judges and advocates at the same time.

We are said to be a nation whose genius is compromise; and the national trait, with a good deal of discussion and a considerable and consequential amount of delay, seems to be asserting itself beneficially so that progress, disturbed as it was by the new ideas, is resuming its way. For the work done by the Commissioners in the most difficult circumstances, I believe that the whole industry has a great admiration, but it is to be hoped, for the sake of the industry and the country it serves, that an opportunity will be given to those engaged in it to show what can be done without further legislative interference.

The progress of the industry even in a time of national trade depression is rapid, the technical and commercial difficulties are being overcome and there is, in my view, every prospect of continued development on sound commercial lines if, as in the past, each step stands the test of justification by results. Electricity supply is a beneficial and useful service to the community, but it is unwise and misleading to suggest that its artificial stimulus will prove a solution for all industrial ills. The national need for economy was never more urgent than it is to-day, and I am confident that electrical engineers, with other workers in the field of applied science, will, if permitted to proceed on commercial lines, subject to reasonable control in the public interest, make progress in the next 20 years to a degree even more notable than that of the past 20 years, during which I have seen electric power supply grow from a small and experimental venture to its present importance.

The co-ordination of individual solutions of the problems to our hand is more likely to lead to success than the imposition of a method of production and control which, however decided to-day, must, by the progress of science, be challenged and modified to-morrow. The great progress of engineering goes on at a snowball rate; every extension of the boundaries of knowledge touches a wider field of the unknown and, as surely as one may venture to prophesy anything, it may be said that the practice of a decade hence will differ substantially from that of the present time.

Those of us who have been engaged in the development of electricity supply remember the serious opposition of municipalities who, as owners of gas-works, feared the competition of the new illuminant. History records that the gas engineers experienced in their time the organized opposition of the candle makers.

The very fact of the existence of so large a body of trained engineers as is contained in the membership of the Institution is an assurance of change. Let us hope that when the time comes for our present practice to be met by a new competitor in public service, progress will be permitted to take place on an economic basis and that it will not be hampered because public funds invested in the industry will be jeopardized by the new development.

The industry, like all other human organizations, is changing and must change if progress is made. The changes will be brought about largely by the abilities and inventive powers of engineers, and I feel that it is particularly important that our younger members should not be overawed by the magnitude of the work done in the past but should preserve that spirit of adventurous research which the pioneers of the past possessed in so great a degree.

WESTERN CENTRE: CHAIRMAN'S ADDRESS

By W. NAIRN, Member.

(Address delivered at BRISTOL, *6th October,* 1924.)

In this address I propose to deal principally with the work which lies at my hand—the applications of electricity to the lighter forms of transport.

HISTORICAL.

The earliest application of electricity to the movement of passenger vehicles in this country took place in 1883 and 1884—40 years ago—when electrified lines were laid at Giant's Causeway, Brighton, Blackpool, and Bessbrook-Newry, the promoters being Messrs. Traill, Magnus Volk, Holroyd Smith, and Mather and Platt respectively. Little interest was taken in these lines, but they gave a practical start to the experimental work which was carried on until in 1890 the American companies succeeded in placing on the market single-reduction motors which were so reliable that the doom of the horse for tramways was sounded.

By 1890 the rush to electrify was in full swing in America, but it was not until five years later that a real start was made in this country with the construction of electric tramways as we now know them. In Bristol the line from St. George to Old Market-street was amongst the first, having been built in 1895.

For the original equipments, we in this country were indebted to the experiences gained in the preceding five years in America, and the early struggles of American engineers with open-type motors of 7 h.p. or 8 h.p. were practically unknown to British engineers. The greatest praise that can be given to these early equipments imported from America is that most of them are running to-day and comparatively little improvement on them can be suggested. These motors were rated at 25 h.p. and there were two to each car. Where the weight of the car is increased by adding vestibules and top covers the size for new equipments is about 35 h.p., although the London County Council for their heavy cars and high speeds have recently adopted motors of 63 h.p. The distinction between the old and the new motors is that the latter are fitted with interpoles and are ventilated, bringing the weight per h.p. down from 80 to 40 lb.

The application of roller and ball bearings to electric rolling stock was tried in the early days with little success owing to the frequent breakages. Within recent years, however, further experiments have been made and, owing to the improved materials available and also to improved methods of construction and testing, these bearings now stand well up to their work. The object in using roller and ball bearings is two-fold; first the saving in power, and secondly reduced maintenance charges.

In Bristol three cars were equipped with ball and roller bearings in armatures and car axles, and exhaustive tests were carried out on them to determine the saving in power that might be expected. One of the first points noticed in these tests was that the percentage saving was much greater on level routes than on hilly routes. This is due to two factors. In descending hills with the brakes applied no saving in power takes place, whilst in ascending hills the ratio of the friction current to the total current is small and any saving in friction current results in a small percentage saving. Due to the difference in gradients and also to the number of stops on different systems, there is a wide variation in the results obtained in different towns, but in Bristol the saving in power on hilly routes was found to be 6 per cent and on the level routes 11 per cent. These results call attention to the difference between roller bearings in a workshop shaft and roller bearings on a street car. In the former money is being saved all the time, whereas in the latter there are many periods when the roller or ball bearing is a distinct disadvantage, viz. when descending hills and when accelerating.

Regarding brakes, the earliest cars were fitted with cast-iron shoes acting on the wheels and applied by hand power. This was the service brake, and an emergency brake was provided by short-circuiting the motors when they were acting as generators. This latter brake did no good to the motors and was not agreeable to the passengers; it was therefore replaced by the rheostatic brake, the motors when generating being connected through a resistance which could be varied from the controller. The next step to the rheostatic brake was the magnetic brake acting on the rail, the magnet being energized from the motor current, and the track shoe was sometimes coupled to the set of wheel brakes so that the drag of the magnetic shoe applied them also. In the Edinburgh system—the most modern of our tramway systems, having been equipped only in 1923—the magnetic track brake is used. This acts only on the rails, but is also capable of being applied by compressed air. The compressed air is obtained from an electrically driven compressor installed on the car and driven from the trolley wire.

REGENERATIVE CONTROL.

The question of regenerative control on street tramcars has always been an attractive one to electrical engineers because the electric vehicle is the only vehicle in common use to-day which is reversible. A steam locomotive going down hill cannot return coals to the tender, nor can a petrol vehicle under similar circumstances refill its petrol tank, but it is quite possible for an electric vehicle to return electricity to the line or to

a battery. Unfortunately, regenerative control has not been a commercial success, due to the fact that the saving in power did not pay for the capital and maintenance charges of the regenerative equipment. The Raworth regenerative system made the most headway in this country. In this a shunt-wound motor took the place of the series motor and the driver was given control of the field. One result of this was a tendency for the driver to "race" the car on a weak field, with a consequent rise in current consumption, so that when the regenerated units were subtracted from the used units there was little difference between this figure and the units used by the series motor car. In Bristol four cars were equipped with regenerative control, the results of tests showing a saving in power of less than 3 per cent. With the further cheapening of the cost of electricity the future for regenerative control on either trams or railways is not very bright; I make this statement whilst being fully alive to the fact that in America the latest railway electrification schemes are all equipped for regeneration, even where current is generated from water power. The gradients in that country are, however, very different from those prevailing in England, and regeneration is used more for the purpose of avoiding the wear and tear due to braking than for the saving of power. On the Chicago, Milwaukee and St. Paul Railway there is one run of 200 miles down the side of the Rocky Mountains.

Types of System.

Apart from storage battery cars, the earliest means of applying electricity to street cars was either from an overhead wire using the track as the return, or from a conduit in the track with two insulated conductors. Subsequently a system known as the surface contact system was tried in a few towns. The use of overhead wires is now universal, the exception being the London County Council conduit system. British practice in overhead lines followed the American, except that the lines were built more substantially and were more sightly. Few changes of moment have taken place. Hard-drawn copper is still the most popular conductor but, where the car services are heavy, alloy conductors are used, although their conductivity is as low as 40 per cent of Matthiessen's standard. A new conductor which promises well is a cadmium-copper alloy which combines a conductivity of over 90 per cent of Matthiessen's standard with wearing qualities approaching those of the other alloys. For insulation purposes porcelain is gradually replacing the composition insulations introduced from America. The design of the various wire fittings has been considered recently by a committee appointed by the Municipal Tramways Association. This committee has standardized a complete line of fittings, and a standing committee has been appointed to consider suggested improvements. It is of interest to know that this committee was brought into existence on the suggestion of one of the members of this Centre, Mr. H. I. Rogers.

Electrolysis.

A subject which gave rise to a good deal of discussion in the early days of overhead lines was electrolysis. Here, again, the experiences of American engineers were helpful to us as the first American rails were unbonded and the difference of potential between rails and water pipes often exceeded 20 volts, so that a great deal of experience was gained in a very short time. In fact, the early depredations caused such alarm that one writer of the period foretold that the extensive pipe plants of the gas and water works were doomed to immediate disintegration, with the inevitable result that the unfortunate inhabitants of the cities would be drowned if they were not previously blown up. To safeguard the public the British Board of Trade—which was then responsible for transport problems—framed the regulations which, among other provisions, limited the voltage between rails and pipes to the voltage of one Leclanché cell when the pipe was positive and three Leclanché cells when the pipe was negative. Further, it put on the tramway undertaking the onus of building the tramway so that it was electrically separate from the pipes of other undertakings, but unfortunately there was no similar obligation on authorities laying pipes subsequent to the construction of the tramway, so that this desirable provision was rendered void. The greatest credit is due to those who originally framed the regulations for their masterly handling of what was then a new study, and as a result of their labours the existence of electrolytic action is unknown to the general public. Before the advent of electric tramways or electrical undertakings lead pipes suffered from corrosion in certain soils, and it is to-day a matter of great difficulty to determine whether corrosion is due to electrolytic or chemical action.

Permanent Way.

As regards the permanent way, electricity has come to its aid and the overhead wires provide power for driving concrete mixers, compressors for operating pneumatic picks, rail grinders and—perhaps the most useful of all—the electric welder for welding the fish-plates to the rails instead of bolting them, and also for filling in spooned or hammered joints. Both the carbon arc and the metallic arc welders are used and give good results.

Types of Vehicle.

For rural transport, development in this area has been by petrol omnibus, but in many districts in the Midlands the railless vehicle with two overhead wires is making headway, and has proved itself a practical form of road passenger vehicle using the cheapest power available—electricity. The storage battery vehicle has not made the progress which was expected; this is due not to any inherent engineering defect in the vehicle but to its high first cost and lack of charging facilities. Even where a supply of electricity is available, the price of a motor-generator and switchboard has to be added to the cost of the vehicle, making the price of a single vehicle prohibitive as compared with that of a petrol vehicle. In its proper sphere the storage battery vehicle has no equal; this sphere is where large fleets of vehicles are required, stops are frequent and long mileages per day are not required. The maintenance charges are low, it is silent and clean, and no fire risk attaches to it.

It is unfortunate that prices cannot be brought down to a competitive figure. As a truck for indoor use it is an unqualified success and has no competitor.

Between the purely electric vehicle and the petrol omnibus, there are two distinct types of petrol-electric vehicles. In one the whole power of the engine is converted into electricity which drives a motor or motors connected to the rear wheels. This is the arrangement of the Tilling-Stevens omnibus. In the second system, known as the Entz magnetic system, two d.c. machines are employed. One has its field connected to the engine and its armature to the propeller shaft. The second machine has its field connected to the car frame and its armature to the propeller shaft. The first machine is called the clutch generator and the second machine the motor. On top speed the clutch generator is used as a clutch alone when it is short-circuited on itself; on speeds other than top speed the clutch acts as a generator and supplies power to the motor. Both systems give the advantage of smooth speed control with the elimination of gear-box and clutch, two items of petrol vehicle equipment which are makeshift devices.

On the Tees-side a hybrid vehicle is in use. It is a petrol-electric vehicle wound for 500 volts and fitted in addition with two trolley poles for running as a trackless vehicle where overhead wires exist.

Electric Lighting and Ignition.

Passing to the purely petrol vehicle, the equipment of interest to us is the electric lighting, and starting and ignition outfits. No passenger car is fully equipped without a lighting and starting set, but the starting set is still omitted from most of the heavy petrol vehicles engaged on omnibus or commercial work. It is a curious fact that the development of these sets has been carried out not by the recognized electrical engineering firms of the country but mostly by those who in the past were makers of oil and acetylene head lamps. This, I am afraid, has been due to the low prices available for the equipments, and this low price has also been responsible for many of the early troubles. Much experience has now been gained and good progress has been made by British makers in solving what is really a very difficult problem owing to the variable engine speed and the uncertainty of output. For example, a motor coach doing long day trips in summer would have an engine speed and period of running time ideal for charging the battery, which might not be required owing to the trips being in daylight. The same chassis put on to winter duty as an omnibus would be continually stopping so that the battery would not get properly charged and it would now be called on to deal with the lighting of a saloon body with about 8 additional lights. Having this continually varying demand in mind it is strange that the popular system of charging to-day is the so-called "constant-current" method in which the dynamo endeavours to supply a constant current irrespective of whether the battery requires it or not. This is inherently wrong, as the current passing to the battery should vary with the state of charge of the battery, a large current for a discharged battery and no current for a fully-charged battery. Now this result can be obtained by the constant-potential method of charging, and the reason it has not been adopted is seemingly the inability of British manufacturers to make a practical constant-potential machine. A further advantage of the constant-potential dynamo is that the lamps can be lit without the battery, whereas in the constant-current system the battery and dynamo are one unit and if disconnected from one another the lamps or the dynamo are likely to be burned out due to excess of voltage. Constant-potential machines of foreign manufacture have been available for many years and have recently been brought to a high state of perfection, and I consider it most unfortunate that the experience of the heavy electrical engineering firms with voltage regulators is not available to meet this competition. Until such machines are available we shall have to put up with the annoyance of undercharging or the expense in battery plates due to overcharging.

For ignition in motor vehicles the magneto still holds the field, the proportion of cars fitted with magnetos being 80 per cent, against 16 per cent fitted with coil ignition. The remainder have dual ignition. Coil ignition made considerable headway until last year, but there is now a tendency to revert to the magneto. Coil ignition gives easy starting and perfectly satisfactory running if the battery is looked after, but we as electrical engineers have no right to expect the motor user to take regular readings of specific gravity to ascertain the state of charge of his battery. It is the duty of engineers making lighting sets either to provide a constant-potential dynamo which will keep the battery charged automatically, or else to invent some kind of dash-board indicator which will show the state of charge of the battery.

Aerial Transport.

Passing from the petrol road vehicle to the aeroplane, there is little in the electrical equipment of the latter which differs from motor-car practice. There is, however, one matter in connection with the production of air-cooled aeroplane engines which is of special interest to electrical engineers, and that is the testing of them. Air-cooled engines are usually tested for endurance and brake horse-power by coupling them to a water brake and running them in an air current comparable with the flying conditions, an electric motor being coupled to the shaft for starting up and running in. The fan supplying the air-blast requires about one-half the horse-power output of the engine, so that in a 100 h.p. engine test-stand 50 h.p. is continuously used in providing the blast and 100 h.p. is continuously wasted in the water brake. With the smaller sizes of aeroplane engines there was little to be said against this, but with aeroplane engines now developing 1 000 h.p. the problem is different. The directors of the Bristol Aeroplane Co. considered the problem carefully and decided that the correct course to adopt was to make the test engine provide the power for the blast, and the only method of doing this satisfactorily was to use an electrical dynamometer. The electrical dynamometer adopted is a 500-volt d.c. generator with the fields mounted on trunnion bearings. The field is kept from revolving by being attached to a spring balance which measure

the torque of the engine, and the speed of the engine is measured electrically by a small generator mounted on the end of the shaft, the revolutions being recorded on an instrument of the illuminated-dial type. The engine to be tested is directly coupled to the dynamometer, which is also used for starting up the engine and running it in. The fan for the blast is mounted at the end of the wind tunnel, and a storage battery and booster form part of the equipment. The method of operation is as follows. Current is drawn from the battery to motor the dynamometer and revolve the engine, and current is also drawn from the battery to run the fan for the blast. When the engine fires, the dynamometer generates and charges the battery and drives its own fan, the torque on the dynamometer being adjusted by varying the current passing into the battery. This current is controlled by a regulator on the battery booster field. The battery installed at Filton has 240 cells and a capacity of 1 950 ampere-hours at the 10-hour rate. With this system a plentiful supply of power is available when required for operating the fans, and the output of the engines is not dissipated in heating water but is usefully converted into electrical energy.

General Remarks.

I commenced my remarks by saying that I would deal with the lighter forms of transport and I have just referred to aeroplane engines of 1 000 h.p. Twenty-five years ago we travelled a long way to see an engine of 1 000 h.p. in a power station, and we were duly impressed by its massive construction and substantial foundations. To-day an engine of this horse-power can be mounted on a framework and can rise from the earth.

Those who are not yet very old have seen the coming of electricity to our towns and countrysides and its use for lighting, heating and power. They have seen the coming of the self-propelled road vehicle, the submarine vessel and the aeroplane, in all of which electricity has played a small but essential part. They have seen the development of the telephone to be an essential part of our business lives; the coming of the gramophone, the moving picture and, latterly, wireless. Most probably they have seen a greater change come over the life of the community than has occurred in the whole period since civilized man inhabited the earth.

We are justly proud of the part which electricity has played in this march of progress and we need not be unduly alarmed at the statistics which show that the units used per head of the population in the large cities of this country are only about 200, against 700 in American cities. There is no comparison between the conditions. We have been reared on cheap coal and we are building up our electricity supply industry on strong and substantial British lines under the guidance of the Electricity Commission. Power stations and distribution systems are under continual improvement and extension and only the best practice is being retained. There is only one flaw in the whole structure and that is the non-standardization of frequencies. General experience calls for a frequency of 50, but it is difficult to see how the large systems operating at 25, 33½, and 40 periods can possibly be changed over. The expense would now be so great that I am afraid it could not be justified.

At the moment the electricity supply industry is embarrassed with a plurality of political patrons, patrons as defined by Dr. Johnson in his famous letter to Lord Chesterfield. In that letter Johnson wrote: "Is not a patron, my lord, one who looks with unconcern on a man struggling for life in the water and when he has reached ground encumbers him with help." The electricity supply industry has been struggling for 35 years, it has now reached firm ground and the patrons have arrived.

Electricity, the strong, reliable and indispensable servant of the public, when viewed through political glasses becomes a beautiful fairy endowed with powers to cure unemployment, solve the housing problem and convert the whole nation into a community of restful button-pressers. I do not presume to express any opinion on the desirability or otherwise of the nationalization of electricity supply, but whether the industry is nationalized or not it is a source of great satisfaction to us all to know that nothing can stop its progress, and we foresee a period of continued activity.

In concluding my remarks I should like to remind you that the primary duty of our Institution is to supply its members with the latest information on the various branches of the industry, and that the volumes of the *Journal* form the most valuable collection of information on electrical matters.

I wish also to express to you my thanks for the honour you have conferred on me in appointing me your Chairman for the current session, and I can assure you that I shall use my best endeavours to maintain the traditions of the office and secure a continuance of the respect which the Western Centre has earned for itself in the electrical world.

IRISH CENTRE: CHAIRMAN'S ADDRESS

By C. P. COOTE-CUMMINS, Member.

(ABSTRACT *of Address delivered at* DUBLIN, *9th October,* 1924.)

When the Members of the Irish Centre elected me Chairman for the present Session a wish was expressed that, in my opening address, I should deal with the question of the training of engineers, this matter being of very great importance to our Centre at the present time when Ireland has, so to speak, attained her majority and commenced to manage her own affairs.

In a general sense engineering consists of the intelligent application of scientific facts and principles to the practical requirements of manufacture and industry, and it follows from this that an engineer must possess a thorough knowledge of the underlying scientific principles of the branch of engineering in which he specializes, and must have also a sound general knowledge of other branches of his profession. To be successful he must of course possess other qualifications, such as initiative, vision, knowledge of men, etc., but without the first two he cannot apply scientific principles intelligently, and a man who cannot do so should not be permitted to call himself an engineer, nor should he be allowed to pose as one.

It is an unfortunate fact that, outside the professional Institutions, there is no clear understanding as to what really constitutes engineering or what qualifications really justify the title of engineer, and it is rather remarkable that this should be so in view of the highly specialized engineering courses which have become a necessary part of all modern universities and colleges, and in view also of the large number of highly qualified professional men who are to be found in the different engineering Institutions; but so it is, and I think that few of you will deny that the ignorance of the general public in this respect is very great.

You may perhaps consider that much of the above is not pertinent to the subject of training, except in so far as it may serve as an argument for a fuller and a better training, but I think that it affects fundamentally the whole question of training. The best training that could be devised for doctors and lawyers would be almost completely neutralized if utterly unqualified persons were permitted to practise, and under such conditions both of these professions would fall back to somewhat the same status that the medical profession enjoyed when the local barber was the recognized medical authority in his district.

My contention is that without the protection afforded by "limited practitioners" the medical and legal professions could not get satisfactory results from any system of training, and that the community would suffer owing to the loss of really able men in these professions. This protection is still denied to the engineering profession and I am convinced that the consequent loss to the community is much greater than is generally realized, and that this loss is only tolerated because the community, having never emerged from the barber-doctor period in engineering matters, is not able to appreciate or measure its loss.

The status that the profession of engineering undoubtedly enjoys to-day, in spite of the lack of protection, is a remarkable tribute to the necessity for qualified engineers and is clear evidence that such a body of men is needed in every country for the purposes of national and industrial development; and unless a country realizes this and takes steps to secure the existence of trained men by according them, when trained, the full professional recognition accorded to the other professions, her industrial development must suffer. This is, I believe, true in every country, but is more accentuated in a country which is in the early stages of industrial development than in one in which that development has already reached an advanced stage. Full professional recognition of the engineering profession is, in my opinion, as much needed for the protection of the nation's industries as it is needed by the medical profession for the protection of the nation's health; for, just as the medical profession can, by virtue of its recognized status, influence and direct public opinion in the right direction, so also should the engineering profession be able to influence and direct it as regards engineering matters. It will, however, never be able to do this effectively so long as utterly unqualified men are permitted to pose as engineers. In the interests of the nation I assert that charlatanism in engineering matters, in these days of rapid engineering development, is as dangerous to true industrial development as it would be to the health of the nation if permitted in the medical profession. It is like a parasitic growth which not only hinders the growth of a plant but makes it almost impossible to propagate healthy plants for future needs.

Of course no system of training can be devised unless there is some agreement as to what an engineer should be, but it seems to me to be equally necessary to arrive at some clear understanding as to what an engineer should do, and I feel that the ignorance of the public in this respect exists largely because professional engineers themselves have not made serious efforts to enlighten it, and I think that before they can do so effectively there must be some real agreement within the profession itself.

Trained engineers with high professional qualifications find an outlet for their energies in many directions, viz. manufacturing, designing, contracting, advising, etc., as well as in the service of the Government, municipalities, local authorities and large corporations, and this very wide field of its activities is, in some respects,

detrimental to the interests of the profession because it brings its members into direct intimate association with the commercial world (the world of buying and selling) to a far greater extent than other professions, and consequently some engineers become, to all intents and purposes, traders, whose main interest and occupation is the sale of certain engineering products or the advancement of certain business interests.

This is, of course, a very contentious subject and I should have preferred to ignore it if possible, but having contended for full professional recognition for engineers because I believe this to be a national necessity, I feel compelled to point out that such recognition involves obligations upon the engineering profession, not the least of which is the obligation upon each member to do nothing which might lower the dignity of the profession in the eyes of the public or of his professional brethren, and although a member is, of course, fully entitled to occupy himself in trade or business if he so desires—and the more qualified engineers in trade or business the better—he should be very careful to keep this always in mind.

I have said that I think the engineering profession should be in a position to lead public opinion, and I suggest that this position would be arrived at more quickly if all members who are directly connected with trade or business were to abstain rigidly from acting as advisers to the general public. Such advice, even though it may be quite disinterested and thoroughly sound, is always open to unpleasant criticism and is largely the cause of the opposition which sometimes exists to the admission of what is called the "trading element" to professional Institutions. I believe that it is a cause of division in the engineering profession and that it hinders that unity which is so much needed.

The experience and knowledge of qualified engineers engaged in industrial and commercial pursuits is far too valuable to be wasted, and I do not suggest that it should be wasted. The assistance and advice of such men should be sought and acted upon, but some machinery should be devised by means of which it could be tendered in a general way through the professional Institutions rather than given directly to prospective clients.

It is not easy to arrive at a satisfactory definition of an engineer in modern times, owing to the diverse occupations to which engineers can usefully devote themselves, but if we agree, as I think we must, that both study and practice are essential qualifications for an engineer, we must exclude from professional recognition all who do not possess, in some degree at least, both of these qualifications. A superior knowledge of either is not sufficient without the other. That is, I think, as far as we can go; it is certainly as far as I feel inclined to go, and crude as the definition may appear I cannot see how we can narrow it down without getting into serious difficulties. The tendency of some professional Institutions to exclude men because of the work in which they happen to be engaged is, I think, a mistake. All that should be demanded in this respect is a rigid observance of professional etiquette, which should as far as possible be the same for all branches of the profession and which should aim at preserving the best traditions of the profession. These, as I understand them, consist of the efforts of the great men of the past to exploit the resources of nature for the benefit of humanity.

It will not, I take it, be disputed that early training during the really receptive years of youth is one of the greatest factors, if not the greatest factor, in the shaping of the after life of the individual. I think that such qualities as resourcefulness, thoroughness in small matters, clear thinking, etc., which are, or should be, part of the equipment of all engineers, are very largely a matter of this early training.

I had the good fortune to be trained in a school, the Royal Navy, in which these very qualities are undoubtedly developed to a very marked extent, and this is, I am sure, brought about by the system known as "Catch them early and break them in young." I passed into the "Britannia" at the age of 12½ years and immediately commenced a specialized training. The training was perhaps too severe to suit modern ideas but it produced men of action and resourcefulness who, within the limits of their profession, knew their business from start to finish, who could be depended on in an emergency, and who had learned to pull together and play the game. Now that result was obtained by means of the right kind of training during the receptive years of early youth, and as far as my experience goes it is not always obtained by means of the ordinary systems of education. Qualities of this kind are essential in engineering work, just as they are in the Naval Service; they were obtained in the Navy by placing the specialized training in the hands of Naval officers who knew exactly what they wanted and made the general subjects subservient thereto. I would suggest that similar results can be obtained by the engineering profession in a similar way.

Of the total number of men who lay claim to the title of engineer a comparatively small percentage have received a university or technical college training, and this must necessarily be so, because only a few can afford to devote themselves to unremunerative work for such a lengthy period as is required to secure a university degree as well as the necessary practical experience, and we must therefore recognize that the majority of those who in my opinion must be classified as engineers obtain the necessary theoretical qualifications whilst they are wage-earners, the most usual course being to attend evening technical classes during apprenticeship. These evening classes are usually conducted in the local technical institute, where the pupil attends for two or three evenings per week, for a course of four or more years. Many excellent engineers have to my knowledge been trained in this way, but the effort required is very great. It is no small thing to work hard all day and then in the evening to make a severe mental effort for two or three hours, when the body is fatigued and the brain, in consequence, is not working at its best. In my opinion, the system puts too great a strain upon all except those whose physique is exceptional, and it is questionable whether even they are not overtaxing themselves. Apart from this, however, the best work cannot be obtained from a tired body, and the results must therefore be most

inefficient when compared with those which could be obtained by the same worker making the same mental effort with an untired body, and in this respect the student at day classes has a very great advantage over the night student. Since night classes provide the only opportunity that the majority have of acquiring the necessary theoretical knowledge, it is obvious that our present system is, and must be, extremely inefficient, and as it makes demands upon the worker which may seriously interfere with his physical fitness it may for this reason alone cause him to be less efficient when trained.

I do not see how evening technical classes can ever be completely dispensed with because, so far as I am aware, they constitute the only method by means of which the adult worker can supplement his knowledge and strengthen his weak points. They are very valuable for this, which is, I think, their true function, but they are not suitable for those who are starting a specialized career, such as engineering, with no other knowledge than that acquired in an elementary school, even though the elementary training may have been ideal, because such a student has, after a full day's work, to cram into about 180 hours per annum an amount of work which the day technical school, or university, student spreads over 1 200 hours.

In our present educational system, evening classes constitute the only method of scientifically training the large majority of our future engineers, but they are not suitable for the purpose, they are inefficient, and they make heavy demands upon the youth of the country. Is it a matter for wonder that so many engineers can be found to-day whose elementary knowledge of scientific principles is far from sound? As I have said, these classes are generally conducted in the local technical institute, which is under the control of the local authority, who contribute to its support out of the local rates, the funds being supplemented from Government sources. This municipal control leads to serious anomalies. The managing committee is generally representative of every interest and section except engineering, and although there is a provision for co-opting members representative of special interests there is no provision for ensuring that the co-opted members have any special qualifications. If engineering representatives were co-opted they would almost certainly consist of engineering employers, who are, as often as not, not engineers at all. It is quite common to find that business men whose knowledge is purely commercial, but who are connected with a business in which engineering processes are carried on, are the recognized authorities upon engineering in the minds of local education committees. Surely there is something wrong with a system which permits of the selection of an engineering teacher by men who have never even heard the difference between a corporate and non-corporate member of a professional Institution, to whom a university degree in Arts is just as high a qualification for teaching engineering as a Science or Engineering degree, and who would, with the best intentions, if left to themselves elect the local wireman to teach a class in dynamo design. I say without hesitation that the administration and control of engineering classes by local authorities is a fiasco, and when we give the matter serious consideration and find that these classes form the only channel for providing theoretical training for the majority of our future engineers, we see that it is more than a fiasco: it is a crime.

The efficiency of the teaching is of course essential in any training scheme, and every effort must be made to ensure that the teachers possess the necessary qualifications and also that they have every facility and opportunity for securing the best possible results. Only those who have experience of it can realize the strain that teaching puts upon an enthusiastic teacher—and a teacher who does not possess enthusiasm should occupy himself in other directions. The proper preparation of the lesson involves a very large amount of time and thought, and the arrangement of practical work in the laboratory, or of lecture-table experiments to illustrate the subject of the lecture, can easily occupy the whole day. After the preparation work is done, and during the two hours, or more, of the class meeting, the teacher must give of his best without pause or sensible slackening, for this is the only way to hold the attention of the class.

Now I think that you will admit that work of this nature cannot be done efficiently unless the teacher gives his whole time to it. If his main work lies elsewhere and requires most of his time and energy, and he arrives at the school only a few minutes before the students, he cannot teach engineering subjects with any real success, because it is impossible for him to give his subjects adequate preparation or to devote any time to the arrangement of experimental work; yet this is the state of affairs generally found in connection with evening classes.

If the main function of the school in an engineering training is to provide the theoretical instruction necessary, with the greatest efficiency and economy, the method of teaching requires very careful consideration, but until engineers themselves are prepared to take an active part and interest in the training system and to collaborate with and assist the teachers, who are at present left to shoulder the whole burden, it is scarcely fair to criticize present teaching methods adversely.

The best method of testing the knowledge possessed by an individual is extremely difficult to decide, and so far no really satisfactory method has been devised. Written examinations cannot bring out the full extent of a candidate's knowledge and they have the great disadvantage that they operate most adversely against those who have a nervous temperament or whose power of expressing their ideas on paper is limited, whilst they give an undue advantage to those who happen to possess a good memory. Although written examinations will probably always be necessary, I think that an oral test should also be made use of under conditions which do not tend to make the candidate nervous, and at least as much weight should be given to the oral test as to the written. In addition, the actual work done by the candidate during the course, provided it has been satisfactory and of the right type, should be considered carefully and given even more weight then either of the above. Whatever the method adopted, it is, I think, most important that

it should be conducted by the professional Institutions and should be of such a nature as to make it possible for any candidate possessing the requisite knowledge to be registered as a qualified engineer, regardless of the channels through which he acquired his knowledge. The standard required should be high as regards both theoretical and practical knowledge, but any attempt to specify the particular channel through which a man must pass in order to obtain full professional recognition would be inadvisable, as it might result in the exclusion of men who in all other respects were most desirable.

The forgoing remarks may be summarized somewhat as follows :—

(1) An engineer must be a specialist with extensive theoretical and practical knowledge.

(2) Men without the necessary knowledge must not be recognized as engineers, and must not be permitted to pose as such.

(3) The existence and provision of qualified engineers is a national necessity.

(4) Full professional recognition and status is essential in order to give effect to items (1), (2) and (3).

(5) Agreement and unity between the different branches of the engineering profession is required in order to secure item (4).

(6) The engineering profession must take an active part in arranging for the education and technical training of its members.

(7) In a scheme for training engineers, evening classes under the supervision of the engineering profession are permissible for adults but are not advisable for beginners.

(8) The training of engineers should not be placed under the control of local authorities.

(9) The technical subjects of engineering should be taught by engineers who should give their whole time to the work and receive adequate renumeration.

(10) A satisfactory test as to qualifications should be devised by the engineering institutions, the passing of which should be accepted as sufficient qualification for admission to membership of the engineering profession.

The best method of giving effect to the above desiderata is of course a matter which would have to be discussed at very considerable length, and time will not permit of my doing this ; in any case such a consideration is more a matter for the joint deliberations of the engineering institutions than for the individual. I think, however, that items (4) and (5) are absolutely vital. Item (5) is entirely a matter for the engineering profession itself, and, if full agreement were reached, everything would depend upon item (4). Without full professional recognition it would be impossible to give full effect to the remainder of the programme, because the conditions of items (1), (2) and (3) could not be attained, and, in consequence, there would not be sufficient inducement to attract the right men to the engineering profession ; with it, the rest of the programme would only be a question of time.

This demand for full professional recognition can only be met by suitable legislation, and if the engineering profession were sufficiently united and insistent the legislators would have to yield to its just demands.

My proposals are so far-reaching that I fear that any suggestions I could make for carrying them out would appear to you to be visionary were I to put them forward as such. I have said that an engineer should possess vision and I have often wished that our really able engineers would occasionally visualize their dreams of the future for our edification; they would, I am sure, prove of exceptional interest. I venture to put before you a vision of the condition of Irish engineering at some future period ; an Ireland in which the word " engineering " embraces all branches of the profession and signifies to the public a national service conducted for the true advancement and industrial development of the country on lines which prevent the exploitation of the country or its resources for the benefit of syndicates or capitalists, and which ensure that a sound and consistent national policy is followed, regardless of sinister influences or vested interests ; an engineering profession limited to qualified men and cleansed from all personal rancours and petty jealousies, in which all members are recognized as of equal standing but in which each member is classified according to the particular branch of the profession to which he properly belongs ; a profession ruled by a central council (containing representatives nominated by each of the branches) controlling such matters as education, professional etiquette, rules of conduct, legislation and the directing of public opinion, and endowed with full powers to prevent engineering charlatanism ; a profession in which each branch is distinct in itself and retains its complete independence as regards its own special technical work, but with a very large number of branches, including civil, electrical, mechanical, municipal, educational, heating, and ventilating engineering, etc., with a trading and commercial branch for those engineers devoting their energies to that class of work ; a profession with room within itself for all men doing engineering work, and only asking for adequate qualifications and a high standard of professional conduct, and embracing all those manifold activities which make up the world of engineering proper, and therefore a profession possessing an influence and control sufficient to direct legislation, and consequently a profession able to hold out the prospect of reasonable remuneration to its members, a profession controlling the education of its members ; by requiring for its recruits a definite type of elementary education between the ages of 12 and 14, a specialized type of education between the ages of 14 and 16, and specialized technical instruction (in day classes from 16 to 20, and evening classes from 20 onwards) for the worker students, with all the specialized instruction given by whole-time teaching members of the profession whose work is supervised by the central council ; a profession which, with the assistance and co-operation of those of its members employing engineering assistants, provides carefully arranged and progressive courses in practical work for those assistants attending day classes, and which co-operates with the universities and technical colleges and provides suitable practical training concurrently with the university curriculum ; and lastly, a profession which undertakes the testing of the final qualifications of all applicants for entry and, in doing so, gives full weight to all the work done by the candidate

during his course, whether theoretical or practical, and, having satisfied itself of his fitness, accepts him as a member, whatever his social position.

Such is the dream I present to you; criticize it as you will, but remember that it is only a dream.

You may perhaps consider that in dealing with the subject of the training of engineers I should have gone into more details as to the actual training methods and teaching syllabuses. These are, of course, branches of the subject upon which much might be written and I have very definite views regarding them, but I have purposely not expressed these views because I feel that they are details which must be settled by the engineering profession acting as a whole when it has obtained full professional recognition, just as the training for the medical and legal professions has been arranged and elaborated by those professions.

The whole question of the education of engineers is of such vital importance to the engineering profession that it may finally prove to be the common platform upon which the different branches of the engineering profession will eventually come together.

NORTH-WESTERN CENTRE: CHAIRMAN'S ADDRESS

By H. C. LAMB, Member.

(ABSTRACT *of Address delivered at* MANCHESTER, *4th November*, 1924.)

We meet again at a time when there are several good reasons, I think, to be hopeful about the near future of the electrical industry, one reason being that public opinion has become more convinced than ever before that one of the chief needs of to-day is a greater application of electrical power to the business of life in all its branches. Electrical engineers, of course, have been preaching this doctrine for many years, but the encouraging thing is that writers in the popular Press are now emphasizing this point, and the necessity for a national policy with regard to the development of the electric supply industry is generally realized.

In the public discussion of the subject by laymen, it is too often disappointing to find that those taking part fail altogether to do justice to the good work of British engineers, and that little seems to be known of the sound, though unsensational, progress which has been made. It is, of course, all to the good that the principles underlying the charges for electrical energy should be understood by the general public, and that the great importance of load factor and diversity factor should be appreciated, but, unfortunately, there is a tendency for some of those who take part in the popular discussions on the subject to divide themselves into two camps, one of which says that the comparatively limited development of electrical power in this country is evidence of the failure of private enterprise, while the other is equally positive that the situation indicates the limitations of public ownership. This is an intensely interesting aspect of the subject, but a very thorny one, and it is perhaps unnecessary for me to say that I propose to leave it severely alone to-night.

At the present rate of growth, the output of the public supply stations in the chief towns will double itself in 4 or 5 years—a rate of advance which, in any other industry, would give cause for immense satisfaction, but as ours is expected to grow at a phenomenal pace, something better is demanded.

CHARGES FOR ELECTRICITY.

It is often said that, owing to supply charges being too high, development is slower in this country than it might be. It is hardly necessary for me to call attention to the very great part which water power plays in those countries which are most advanced electrically, and, as the fuel cost is 75 per cent of the total operating cost of a modern power station, it is clear that generation by water power must have a considerable influence on selling price.

On this question of price it is only natural that frequent reference is made to America. It is no easy task to make comparisons between British and American supply tariffs, because no two are alike, but a close scrutiny of the charges in force in the principal towns leads to the definite conclusion that, while the flat rates for lighting are, on the whole, lower in America than here, the rates for power are practically on the same level.

As regards the industrial power supply section, it is, I believe, a fact that the most advanced British municipalities and power companies have secured as great a proportion of the potential demand as have similar undertakings anywhere else, although, of course, there are still vast possibilities in this direction.

DOMESTIC SERVICE LOAD.

It is in the development of the domestic service load that we are behindhand, in spite of the fact that there does not appear to be anything in America so favourable to the consumer as are the two-part tariffs in common use here, with a fixed charge based on the rateable value of the house, plus a low rate for energy consumed; and yet the number of domestic consumers in British towns is only a small fraction of what it should be. In the Manchester area, for instance, electricity is used in 10 000 dwelling houses, which is only 5 per cent of the whole number, and is typical of our own towns.

generally. In the most progressive towns in America a supply is given to 80 per cent, or even more, of the houses, and it must be admitted, I think, that this difference is chiefly due to the much greater enterprise shown there.

One would like to take this opportunity of acknowledging the very generous response which is invariably given by power supply undertakings in the United States for information regarding the methods which have assisted in their rapid progress. Briefly, the problem was the same in the American towns a few years ago as it is here to-day, namely, what can be done with the unwired house. It was solved by the adoption of a deferred payment system for wiring and fittings, financed in some cases by the supply companies themselves, in others by the banks working in conjunction with associations of wiring contractors. The tariffs in force in almost all English towns to-day are sufficiently attractive to ensure that practically all *new* houses of any class are wired for the use of electricity, but it seems impossible to secure the old houses in any great numbers without some scheme of free or assisted wiring.

In the same way, it is the first cost of electric apparatus which prevents its use by the general public. For example, up to a year ago only 100 electric cookers were purchased and installed by consumers on the Manchester mains, whereas in the first year of a public hiring scheme 500 were connected. One great advantage of public hiring and maintenance schemes is that the experience gained rapidly leads to improvements in design. The records of failures show the general weaknesses and make it possible to specify features essential to success. If rapid progress is to be made, it would appear that more apparatus must find its way from the manufacturer to the consumer through the supply authorities. This method inspires confidence, because the consumer knows that untried and untested articles will not be recommended to him, and that, in case of accidents, satisfactory repairs will be carried out at a reasonable cost.

Street Lighting.

Another direction in which the consumption of electricity may well show a considerable increase is in the public lighting of the streets, for in recent years there has been a marked raising of the standard of desirable illumination. This is, no doubt, partly the result of the improved lighting in shops and public buildings, due to the general adoption of lamps of the gas-filled type, and the more effective glassware now available, but it is in a much greater degree the result of the conditions arising from the very pronounced growth of high-speed traffic. It is well recognized, both by motorists and by police authorities, that adequate road-illumination is most effective in reducing the risks inseparable from such traffic.

The most striking difference between old and modern methods of street lighting arises from the fact that the lamps are now regarded as sources of illumination, whereas formerly they were merely beacons placed at intervals for the purpose of indicating, more or less effectively, the line of a roadway, just as buoy lights are used in the channel of an estuary. The following may be regarded as desirable values of the minimum illumination on the horizontal plane at ground-level midway between lamps :—

For important street-crossings and public squares, etc., in cities where traffic is dense
0·5 to 1 foot-candle, or more.
For important main thoroughfares
0·3 to 0·5 foot-candle, or more.
For secondary thoroughfares .. .. 0·1 foot-candle.
For side streets and streets in residential districts
0·05 foot-candle.

Some of these values may appear to be on the high side, but there is little doubt that they will eventually be exceeded.

Despite the relatively high efficiency of flame arc lamps, they are being rapidly superseded by gas-filled incandescent lamps, mainly owing to the lower capital charges and maintenance charges of the latter, but also because they are much more reliable and are more suitable for use with the modern scientifically-designed directive glassware.

As an "all-night" street-lighting load has a load factor of well over 40 per cent, it is obviously a very desirable one, and more particularly so in the case of residential districts. The only disadvantage is that it is essentially a peak load, but there is every indication that the importance of this distinction is rapidly disappearing. Depending upon the standard of illumination adopted, the load will vary from 5 to 25 watts per yard of street.

The announcement that the electrification of the Manchester to Oldham railway line is to be proceeded with, is one which will be welcomed by all electrical engineers, and will, at the same time, bring renewed hope to many thousands of long-suffering suburban travellers, some of whom spend a weary 20 minutes every morning in a railway train, in order to cover a distance of 4 miles.

Nothing would give greater public satisfaction than a sign that a forward policy was to be adopted by the railway companies in respect of railway electrification.

The Super-power Station.

It may be said, without fear of contradiction, that the super-power stations erected in the last few years have fully realized the high expectations of those responsible for them. They contain some of the finest products of British engineering, and are operated in a manner unsurpassed anywhere as regards the care which is taken to secure the highest working efficiency. One sign of the interest they have aroused is in the constant stream of engineering visitors which they attract from all over the world. The high thermal efficiencies predicted, the economy of labour, and low working costs have all been realized.

High Steam Pressures.

The stations now operating at 375 lb. steam pressure have a coal consumption per kilowatt-hour which is about one-half of what was usual 20 years ago; when the steam turbine came into general use. A further gain of 8 per cent can be made by raising the initial pressure to 550 lb. per square inch and reheating the steam once, whereas if, instead of stopping there, the

pressure were raised to 1 200 lb. per square inch, and the steam reheated twice, it is estimated that 20 per cent would be saved, making it possible to obtain station overall thermal efficiencies of 26 per cent when using very large units. Plant of this kind, of course, means high capital cost, and no doubt its justification will depend on the future price of fuel.

It looks as though the ultimate possibilities of high-pressure steam will be explored before very long. Boilers have been ordered for a working pressure of 1 200 lb. per square inch—not, as might be supposed, small experimental units, but, on the contrary, designed on the scale common in big power stations to-day, having steam and water drums of forged steel with walls 4 inches thick.

Benson Boiler.

One of the boldest experiments with high-pressure steam is the Benson boiler, which will have nothing to do with half measures, but goes at one jump to what is called the critical pressure of 3 200 lb. per square inch. It is an arresting fact that, at this pressure, the steam has no latent heat, and its volume is no greater than that of an equal weight of water at the saturation temperature of the steam.

The experimental plant which has been constructed at Rugby consists of small-bore steel tubes, in the form of a number of vertical spirals. Distilled water is continuously fed into the bottom of the spirals at a constant pressure of 3 200 lb. per square inch, and, as it rises in the tubes, its temperature is gradually raised to 706° F., when it passes into steam without any boiling process (in the ordinary sense of the words). I understand that the turbo-plant to operate in conjunction with this boiler has been completed, and the results of the tests which are now in progress will be awaited with much interest.

The raising of steam pressures has brought certain troubles with it, but these are almost entirely confined to the accessories of the main plant, and will soon be overcome. One of the chief difficulties has been the rather serious waste of steam which occurs through the scoring of the faces of safety valves and drain valves, when they are called upon for throttling action at very high temperature and pressure. Unequal expansion and unsuitable materials have been the chief causes of these troubles, but many improvements have recently been made.

Boiler Priming.

The fear was often expressed that high-pressure, high-duty boilers would give serious trouble through priming. Experience with a large battery of boilers worked at 375 lb. per square inch, and having steam and water drums exceptionally small in proportion to the evaporative capacity, goes to show that very little priming takes place so long as proper care is given to the condition of the feed water.

Boiler Feed-water.

The rate of evaporation for a given heating surface is now double what it used to be, and the high-duty boiler of to-day requires water of exceptional purity both as regards soluble matter and dissolved oxygen. Unless the water supply is very good, it is necessary to install evaporators for the make-up water which, in any case, should be kept down to the minimum quantity possible. Every precaution has to be taken to prevent loss of water, and the slightest leakages should be stopped. If once pitting of boiler tubes is allowed to start, it becomes very difficult to arrest, and it is now recognized that the main cause of corrosion in boilers, economizers, and sometimes in turbine blading, is dissolved oxygen in the feed-water. The closed feed-water systems of to-day, designed with the object of rigidly excluding air, are a great contrast to the old method of open tanks with water spraying from a ball valve and assisting to the maximum degree the process of dissolving oxygen from the atmosphere. The new method can be entirely successful, but only if great care is exercised.

In spite of what has sometimes been said to the contrary, a tight surface condenser, working under high vacuum, is an efficient de-aerator, provided that the make-up water is injected in a fine stream. Under these conditions, the amount of dissolved oxygen present when the condensate leaves the condenser can be as low as 0·07 cubic centimetre per litre, and this small proportion is probably harmless.

Condenser-tube Corrosion.

Another problem receiving a great deal of attention in power station laboratories is condenser-tube corrosion. The fear of dirty and corrosive circulating water getting into the boiler feed through a broken condenser tube is somewhat of a nightmare. One of the difficulties is that the problem is usually entirely different at each station, and it is necessary to carry on independent investigation. Most valuable work has been done at many places, and it might help towards a solution of this complicated problem if all the information obtained, where condenser-tube corrosion is experienced, could be collected and published by one of the Institutions.

Experience shows that the forecasted working boiler-efficiency of 85 per cent can be maintained over an indefinite period, but this is only possible when some process is adopted for keeping the heating surfaces continuously clean. In the early days of the steam-jet blowers, much damage was done by improperly directed jets and many tubes were ruined, but this trouble has now been overcome, as well as the difficulty of obtaining material which will live in the first pass of the boiler.

Grit Arresters.

A recent improvement which should always be installed in combination with soot blowers, when solid fuel is used, is the cinder catcher. From the æsthetic point of view, the modern system of fan draft and short steel chimneys is much to be preferred to the old skyscrapers, but there is no doubt that in many cases a nuisance has been caused by the great quantities of grit discharged from such chimneys. The first attempts to overcome this trouble were not altogether successful, but catchers can now be obtained which will eliminate 90 per cent of the solid stuff from the chimney gases, and many tons of gritty dust which would otherwise be deposited in the near neighbourhood of the station are collected and transported to the ash tips.

Air Preheaters.

Another new feature of the boiler house, of which there is comparatively little experience, is the air preheater. Only a few years ago, there was much scepticism regarding the use of air heaters. The first point in doubt was whether the tubes, or other classes of metal channel employed, could withstand the corrosive action of the flue gases for a reasonable length of time, and secondly, whether the calculated economy would be borne out in practice.

With regard to the first of these points, it is well known that the flue gas contains acid sulphates, which readily attack mild steel in the presence of moisture. The important point in the operation of air heaters is, therefore, that the gases should never be cooled to so low a temperature that deposition of moisture takes place. It is, perhaps, too early yet to speak confidently, but the evidence so far goes to show that a life of 10 or 15 years may reasonably be expected for air heaters.

Some trouble, through the burning of grates and the destruction of brickwork, has been experienced when an air temperature of 350° F. has been exceeded. In fact, it is doubtful whether even this temperature will be found to be economical, as it will certainly cause increased furnace maintenance costs, but at moderate temperatures, such as 200° F., air preheating has been an unqualified success, and the expected increase in boiler efficiency has been fully realized. Combustion in the furnace is greatly improved, and the combination of air preheater with the very large furnace volumes of to-day produces an entirely smokeless result. This last point is particularly important, as much in the interest of our own industry as in that of the whole community. The growing pressure of public opinion will some day force smokeless combustion on all industrial concerns, and if the power supply plants lead the way, as they should, the chances of public favour and new business are greatly improved. The public smoke inspector should be an important, though purely honorary, ally of the electricity supply authority.

Super-tension Cables.

An entirely different subject, but one of particularly absorbing interest is the future, or perhaps I should say the present, of the super-tension cable.

The schemes which are developing for distributing power over wide areas from a small number of large plants, depend for their success, in this country at any rate, on underground transmission at high voltage. Interest was undoubtedly stimulated by the announcement of Government intentions to use the powers of the State for the purpose of furthering a scheme of new transmission lines, and one may perhaps be permitted to hope that certain very recent events will not cause any reversal of that policy.

An important question in connection with super-tension transmission is whether single-core or multicore cable should be adopted. In this country multicore cable is chiefly favoured, but on the Continent the tendency has been for a long time, and apparently is still, to use single-core cable. The chief claim made on behalf of single-core cable is one which must appeal strongly to all those who have responsibility for maintaining continuity of supply in large electrical systems. I refer to the claim that, as the insulation of the conductors is subject only to the dielectric stress between phases and earthed neutral, the automatic protective gear will be called upon solely to deal with faults to earth, and not with short-circuits between phases. It has been the custom to think and speak of high-tension cables as never breaking down, except through faults having an external origin. For the higher voltages now coming into use this no longer holds good, and the shock of a short-circuit at a pressure of 33 000 volts or more, even when the fault is several miles from the generating plant, is very severe, especially on a big system with several power stations and a great deal of converting plant feeding into the fault. The claim, therefore, that short-circuits would be eliminated by the use of single-core cable is one which merits the fullest consideration. It should be remembered, however, that two simultaneous earth faults on different phases are quite a possibility, and amount to much the same thing as a short-circuit, and it has been found in practice that, unless great care is exercised, the damage caused by a fault on a single-core system is not confined to the area in which it originated.

Another claim made by the advocates of single-core cable is for increased current-carrying capacity, due to better dissipation of heat and a reduction in the mutual heating between cores; also, that a fourth cable, on a three-phase system, constitutes 100 per cent spare on the assumption that it can be used to take the place of any one of the three cables forming the main.

These claims are of doubtful validity, particularly the last, which would involve switching complications and would prevent the triangular formation of the cables that is so desirable.

With regard to jointing, it is claimed that single-phase joints are less likely to break down than three-phase joints, but this claim is discounted by the fact that there are three times as many of them, which is important in view of the difficulty experienced in maintaining watertightness of the boxes.

One disadvantage of the single-core cable is that, armouring throughout being inadmissible, the cables are more liable to damage during laying than are three-phase armoured cables; and another is that the system is less flexible and not so adaptable to the varied conditions and requirements of an underground transmission line, particularly in cities.

Probably the chief point against the single-core system is the substantially greater cost of manufacture, laying and jointing, as compared with the multicore system.

It may be that consideration of capital charges and eddy-current losses will fix a minimum pressure for the commercial use of single-core cables, and that manufacturing difficulties will fix a maximum for multicore cables, and further, that these two limiting figures will not be very far apart, possibly in the neighbourhood of 50 000 volts.

It is, I believe, a gratifying fact that British makers stand first in the world in the manufacture of super-tension multicore cables, and it is no doubt correct to say that there is more of such cable in use in this country than anywhere else. The 33 000-volt underground line

for connecting the supply systems of Manchester and Salford was not quite the first example of the kind, although it was the first in Great Britain. It has been in continuous use for five years—so far, without a black mark of any sort on its record. Since then, over 60 miles of cable for this pressure have been laid down in Manchester and the immediate neighbourhood, and there are, of course, many other installations—some at even higher voltages—in England and Scotland.

Although there are hundreds of miles of underground cable working at 20 000 and 22 000 volts with entirely satisfactory results, it is no secret that a certain amount of trouble has been experienced, both with joints and with cables, at voltages above 30 000, and that it has been necessary in some instances, alike in this country, on the Continent of Europe and in America, to make temporary reductions in working pressures. This applies both to single-core and multicore systems. It is right to emphasize the fact, however, that practically all manufacturers and users are convinced that such reduction in working voltage is only a temporary measure, pending certain alterations, and in some of these cases the normal pressure has already been restored. Troubles have been due to various causes. In the first place, these main transmission lines have often to be laid very deep in the ground, which increases the difficulty of keeping water out of the joints.

With regard to breakdowns of the cable itself, a striking point is that very slight changes in manufacture appear to make all the difference between failure and success. The absolute exclusion of air, the removal of the last trace of free moisture from the materials, and tightness of the dielectric, are no doubt essential to success. It would appear that changes of temperature, following the rise and fall of the load, cause movement of moisture and of the impregnating oils, which may result in breakdown, even after the cable has stood up to a test far more severe than the normal working pressure.

Owing to the relatively large proportion of dielectric, super-tension cables are somewhat weak mechanically, and require much more careful handling and laying than those for ordinary pressures. It has even been suggested that the cable should be manufactured in straight lengths, and not coiled on to drums; but that, of course, is going to extremes. Electrically, the unbalanced static potentials existent in the usual 3-core formation would appear to present a more difficult problem than the maximum potential gradient on the layers of dielectric immediately adjacent to the conductors.

A great amount of research work has been carried out, and the considerable practical experience recently gained will, it may be said with confidence, soon bring the super-tension cable up to the same high standard of reliability as has been attained by those working at more usual pressures. More than this could not be desired. In the meantime, credit is due both to those manufacturers who have done the pioneering work which has made possible the super-tension cable, now so essential to electrical development, and to those authorities in the electricity supply industry who have not been afraid to shoulder considerable responsibility in its extensive use.

Protective Gear for Large Systems.

The rapid development of large transmission systems has increased the importance of automatic protective apparatus, and the nature of the breakdowns experienced on these systems may have a bearing on the future design of the protective gear.

Practically all failures of cables at pressures up to 11 000 volts have originated as faults to earth, and, for that reason, it has been possible to clear them by means of discriminative protective apparatus before short-circuits between cores have developed. On the other hand, with voltages over 30 000 it has, unfortunately, been the case that breakdowns have been due to short-circuits between two cores, and, in spite of the quick operation of protective gear, it has not always been possible to isolate the faulty feeder with sufficient rapidity to prevent a serious disturbance of the whole system concerned.

The advantages of simplicity and reliability in the design of this protective apparatus are now widely recognized, but there is still room for further improvement, as even the most modern types have not been entirely satisfactory in practice. Much of the trouble has been caused by the weak mechanical construction of the relays, although it is clear that the best possible workmanship is not too good for relays controlling feeders each one of which may have a load of 15 000 or 20 000 kW.

Another point not sufficiently appreciated in the design of protective apparatus has been the extent and effect of the comparatively heavy capacity-currents in 33 000-volt mains, and, consequently, gear of the highest repute has failed to retain its stability under the capacity-current conditions arising from a severe system disturbance. There is, however, every indication that, by rendering the relays partially immune from the effects of currents of abnormal frequency, and, if necessary, reducing the sensitivity of the operating settings, it will be possible to overcome the capacity-current troubles, and the effects of the heavy through-current caused by short-circuits, or excessive overloads, on portions of the system outside the protected zone.

Various systems of generator protective gear have been in successful operation for many years, but the combined protection of generator and step-up transformer, which is now becoming necessary in many cases, has not always been quite so successful, owing to the unbalanced component of the circulating current introduced by the magnetizing current of the transformer.

Outdoor Switchgear.

A good deal of interest attaches to the large 33 000-volt outdoor switching equipment installed in Manchester more than a year ago. So far, the operation of this equipment has been entirely without noteworthy incidents of any kind. There was some natural hesitation, at the time when the installation was designed, as to whether such an experiment could be a success under the peculiar climatic conditions of this city. Now that these fears have proved groundless, it is likely that other similar installations will be used, not so much, perhaps, in cities, as in schemes for rural electrification.

NORTH MIDLAND CENTRE: CHAIRMAN'S ADDRESS

By THOMAS BOYES JOHNSON, Member.

"THE VOCATION OF THE ELECTRICAL ENGINEER."

(ADDRESS *delivered at* LEEDS, 11*th November*, 1924.)

No one can read the reports of the proceedings * at the Commemoration Meetings of this Institution held in February 1922, without being struck by the enormous development of engineering during the last 50 years. Dealing with electrical engineering, it seems incredible that at the time of the birth of many of us electric lighting was practically unknown, the telephone had not been invented, electric trams and railways had not been thought of, whilst wireless telegraphy and telephony—which have now attained such universal prominence—were not even dreamt of. The dynamo entered the area of commercial use less than 50 years ago, and it still seems almost miraculous that the turning of a mass of iron enclosed in wire in an electromagnetic field should give us lighting, heating, traction and power in such various ways and to such an enormous extent as we have to-day.

There is no reason to think that there will be any slackening in the field of discovery or in that of practical application. As Prof. Howe remarked at the meeting of the British Association in August last: † "We can look forward with confidence to an ever-increasing application of electricity to the utilization and distribution of the natural source of energy for the benefit of mankind."

It follows that the world at large must have been profoundly influenced by the engineering achievements of the last half century, and that the engineer must have influenced the conditions and amenities of life to a very great degree. It is certain that he will continue to influence them to an equally great degree in the coming years. Fortunately the work of scientific research is now recognized more generally than was formerly the case, and various administrations and organizations are satisfied that it is worth the cost. On the work of the scientists depend the practical applications which ameliorate the conditions of mankind and the improvement of our industries.

Among the developments lying immediately in front of us is that of the national power resources. To replace the wealth which has been destroyed new wealth must be created, and this can best be done by drawing on the resources of Nature's great treasure house. It is interesting to note that so far back as 1875 Lord Kelvin recommended—as modern investigators and politicians also do—that power stations should be situated near the coal mines, and the power transmitted from there, instead of coal being carried to the places where needed. It is unfortunate that the provision of power on a large scale is largely hampered by what Sir John Snell calls "intense municipal feeling," and, in view of the need of such development and of the great advantages which could be derived from it, it is hoped that the Electricity Commissioners will soon be able to make greater progress than they have hitherto succeeded in doing. The utilization of waste heat and exhaust steam, the most economical methods of using coal, and the use of oil and alcohol—all present opportunities of considerable development in the near future. When the public becomes aware of what a good and cheap supply of electricity for the whole country could do to promote its welfare, it will demand the promised boon and will sweep away obstructions whether these be municipal or the vested interests of companies.

Dr. Landor, the Director of Fuel Research, describes the fuel problems as follows:—"First, the utilization of coal in a manner which will render available the largest possible proportion of the potential heat which it contains; secondly, the obtaining from our coal resources of oil in sufficiently large quantities to render us to some extent independent of imported supplies—this is doubly important since the imported supplies are in the main controlled by our industrial competitors; thirdly, for industrial and domestic purposes the obtaining of an adequate supply of a more smokeless type of fuel, the use of which would effect to the nation considerable economies in other directions."

At the World Power Conference at Wembley, Prof. Gibson expressed a hope that a large extension of water-power plant in the United Kingdom could be obtained economically. The further development of water power for large stations will doubtless depend on the success of the Severn experiment, but it may be pointed out that the Chester Corporation have for some years obtained power for electric tramways from the River Dee, and that small hydro-electric plant is stated to be very economical in comparison with larger installations. In countries such as the United States, Canada, Scandinavia, etc., the developments may be enormous.

THE SMOKE PROBLEM.

Another of the important questions urgently calling for solution is the diminution and eventual abolition of the smoke nuisance. Sufficient figures have been quoted to show the wastefulness of our present methods of consuming coal and that it would be economical to alter them, but what cannot so readily be shown in figures is the enormous damage to life and health caused

* *Journal I.E.E.*, 1922, vol. 60, p. 377.
† *Electrical Review*, 1924, vol. 95, p. 239.

by the conditions under which we live. All our great cities are under an unnecessary pall of smoke which robs us of many hours of sunshine per year and damages not only the health but the temperament of people. It has been shown over and over again that smoky districts invariably have a high infantile death-rate, and it is not a matter of coincidence but of cause and effect that the most discontented people and those most ready to fly to violent remedies are the inhabitants of smoke-laden cities. In 1923 the diseases classed as "rheumatic" (which are notably affected by the absence of sunlight) cost the approved societies 2 million pounds in sickness benefit, and the nation 3 million working days of insured persons alone. In Leeds thousands of pounds a year are spent on the additional washing of men's collars owing to unnecessary smoke and dirt. The smoke nuisance is tolerated largely because we have grown up with it, and also because of the strongly ingrained impression that "dirt means wealth." It is high time that people realized that the wealth can be produced without the accompaniment of so much dirt. If the political parties can be convinced that the question of smoke abatement is one on which votes can be obtained, a speedy improvement will be seen. The time has come for a strong lead to be given by the various Institutions, and the Government should give a time limit to all factories using raw coal. Manufacturers would then take care that, in making any alteration or extension, electrical driving would be provided for in anticipation of the compulsory change.

There is also the question of domestic coal fires. Every effort should be made to spread the use of electrical appliances for domestic use, and as showing the magnitude of the task in this country it may be pointed out that in the United States of America there are more than 11 million homes wired for electrical service. Municipal corporations should become alive to the fact that a policy of taking profits from electricity, gas, water and tramway undertakings, in order to reduce and camouflage rates, is a great mistake. After making provision for interest, repayment of capital, and depreciation, the balance should be devoted to the spread of the use of electrical, gas and tramway undertakings. To the average citizen this would be a positive gain financially, while from the point of view of health and cheerfulness the gain would be much greater still. It is satisfactory to learn that the Glasgow Corporation have decided to install Maclaurin producers for the manufacture of smokeless fuel and the provision of gas at the Dalmarnock generating station. Extensive experiments with such plant have shown that a satisfactory smokeless fuel can be produced and sold at a price equivalent to that of coal when regard is paid to its calorific value, and that the gas produced can be used for firing steam boilers. Many of the large modern buildings in London are heated by steam from boilers fed by oil fuel, and this practice seems to be making considerable progress. At Nottingham a scheme has been adopted for setting up plant at pit-heads which are quite near to the city, where the coal will be treated by a low-temperature carbonization process, producing a supply of gas for the city mains and leaving behind a residue of oil and smokeless fuel. It is claimed that this scheme will make Nottingham the first smokeless city in the country.

Telephony.

It seems almost incredible that the first telephone exchange was established so late as 1878, while to-day there are well over 20 million telephone exchange stations in various countries, nearly $1\frac{1}{4}$ millions being in Great Britain. The first multiple exchange was established 10 years later, and by means of these multiple boards one operator can have access to 10 000 lines. It is physically impossible for one operator to obtain access to a greater number. With the development of the automatic system, however, this limitation disappeared. The first automatic exchange in this country was opened at Epsom in May 1912, and several others were completed in 1915 and 1916. The first large city to be provided with an automatic exchange was our own city of Leeds, where, in spite of serious difficulties owing to the war, a 5-figure exchange constructed by the Automatic Telephone Manufacturing Co. was opened in May 1918. This was the largest automatic exchange in Europe, and the largest in the world to be transferred from the manual to the automatic system. It is still the only 5-figure exchange in Great Britain, but a similar one is being constructed in Sheffield, other automatic exchanges are being provided in various towns, and the conversion of the London system to automatic working has been commenced. A 4-figure exchange at Grimsby constructed by Messrs. Siemens was opened in September 1918, and proved equally satisfactory. Another 4-figure exchange has just been opened at York, and the conversion of the Leeds suburban exchanges to automatic working is proceeding steadily. A 4-figure exchange at Harrogate has been commenced, one at Halifax will be started as soon as the building is ready, and others will follow at Wakefield, Keighley and other places within the area of the North Midland Centre. The Hull Corporation have also opened two automatic suburban exchanges. We are glad to know that the system in Leeds has proved the advantages of automatic telephone working, and that the Post Office authorities are now definitely committed to the establishment of automatic working as the standard method for large exchanges.

Another important development in telephony has been in the distance over which speech can satisfactorily be transmitted. In Graham Bell's first business circular it was stated that telephones could be furnished for the transmission of speech through instruments not more than 20 miles apart. With the improvement of lines and apparatus the distance was largely increased, but was still limited. Continued attempts were made to devise a telephonic relay to repeat telephone currents in the same way as the well-known telegraphic relay, but all these proved unsatisfactory. With the invention of the thermionic valve or repeater, however, the difficulty disappeared, and there is now practically no limit to the distances over which speech can be transmitted. Speech is already carried from East to West of the American continent, and there is no technical

reason why it should not be carried equally well between the extremes of North and South America.

Improvements in the condition of the lines used for telephone working have been remarkable. For many years it was necessary to use aerial wires, owing to the limited distance possible with gutta-percha-covered or rubber-covered conductors. Air-space cables increased the distance considerably, and the invention of the loading coil straightway enabled the distance to be increased about threefold. In 1913 the first balanced cable for both telegraph and telephone wires in this country was laid between Leeds and Hull, and proved so successful that the laying of such cables for long-distance telephony became the standard practice. This balancing enables thermionic repeaters to be used, and telephonic communication by means of balanced cables, loading coils and thermionic repeaters can be carried on from one end of the country to the other.

International Telephony.

It will be remembered that Mr. Gill during his presidency of the Institution devoted great attention to the development of international telephony, and the development of this phase of telephony will undoubtedly occupy a prominent position in future. Here, again, the invention of the thermionic valve opened up a new era. By its means the British military authorities were enabled to have telephonic communication between London and the Expeditionary Force Headquarters in France. The Germans with the great advantage of land frontier had circuits from Berlin to the Army Headquarters in Northern France and Russia, and also right across Austria and the Balkans to Constantinople. Owing to its geographical position, as well as for other reasons, Germany is bound to occupy a large place in any scheme of European intercommunication. At the international conference held in Paris last year, at which Belgium, England, France, Italy, Spain and Switzerland were represented, much work was done in getting unanimous approval to many important technical proposals which were officially confirmed by the Governments of those countries, and further progress was made at a record conference in Paris in April last when no fewer than 21 European countries were represented. It is much to be hoped that Mr. Gill's plan of an international board for constructing, maintaining and operating long-distance circuits will be adopted. The influence of such an association and of international telephony would extend far beyond the boundaries of telephone working, and be of great service in creating and maintaining good feeling between the peoples of different countries, thus removing national misunderstanding, inspiring confidence and removing friction.

The Vocation of the Engineer.

If the electrical engineer has so much influence over the lives of fellow citizens and the conditions under which they live and work, it follows that whether employed by the State, a municipality or a limited company, he is in the best and most complete sense of the term a public servant, and he should realize the obligations which this places upon him. The education and training of the engineer are of great importance and have been dealt with in various addresses to the Institution. The pay of the engineer is also of importance, and the Institution should, without undue interference in wages questions, use its influence to raise the general standard of remuneration of engineering officers and men. In this connection reference is gratefully made to the letter sent by the presidents of the professional and technical institutions to the Prime Minister in February last, in which the greater recognition of scientific and technical men in the Government service was urged. It is wrong, for instance, that engineering workmen of long experience and training, and of great skill, should be receiving less wages than unskilled labourers in some occupations.

Of greater importance is the character of the engineer and the spirit which animates him. Realizing that the public depends upon him to so great an extent, the engineer will look upon his work not merely as an occupation by which he can earn a certain amount of money, but as a vocation. The public is entitled to the best service he can give, and a high ethical conception must be put on his duties.

There is one way, in particular, in which the electrical engineer can be of very great service in an important direction. Writers and speakers generally refer to capital and labour as if these were the only two classes affected in industrial matters, whereas the great bulk of the members of the Institution do not come within either of these categories, but are supervisors, etc. The ownership of factories in the North of England has changed in such a way as to alter largely the character of local life: whereas formerly the great productive concerns were owned and conducted by strong, shrewd men who had climbed out of lower ranks, their descendants have largely sold out to company promoters. Many men who still continue to be directors have mostly gone to reside at a distance, and their interest in the place of their origin, and in the community from whom they have derived their ample means, is ended, except for the limited duties of the board-room. With the decrease of private ownership which goes on at an increasing rate year by year, the old relations between the employer and his workmen are practically dead, with the result that there is a large amount of misunderstanding, distrust and fear between them. The engineer, whatever his supervising grade may be, can do a great deal towards filling the gap. He can represent the requirements of the employers to the men in a reasonable light, instead of simply issuing orders, and can receive suggestions or, if necessary, remonstrances, from the workmen, and represent them to the employers or directors. Many of the most serious industrial troubles of recent years have undoubtedly been due to misunderstanding and suspicion, and the engineer who shows himself worthy of trust by both parties, and loyal both to those above him and those below him, can exercise a very valuable influence in minimizing trouble. Engineers stand between capital and labour, and also between the public and its safety, and by their education, training, and sympathy with all classes seem specially competent to work out a solution of the industrial problem.

The engineer must look upon himself as a trustee and cultivate a high sense of the importance of his duty—which is not a question of self-importance—to his superiors, his subordinates, and the public. Employees must not be treated as machines or "hands" but as brother men engaged in improving the conditions of life and furthering the progress of mankind. There must be a spirit of real comradeship, which will have a high spiritual value and help to inspire the spirit of service in others. As has been well said, "The greatest service a man can do is to carry out his daily work in a spirit of service to God and man."

SCOTTISH CENTRE: CHAIRMAN'S ADDRESS

By ALEXANDER LINDSAY, Member.

(ABSTRACT *of Address delivered at* GLASGOW, 11*th November*, 1924.)

To-night, after some general remarks, I propose to refer more particularly to a matter of topical interest—The Cultivation of, and Distribution for, the Domestic Load. In fact, to give it a slogan, let us have "Electricity for the Million."

Whenever we have a few quiet moments it is interesting to look back and record progress. In 1924, it is not only interesting but instructive to look back and note the growth of Electrical Science, Electrical Industry and Electrical Institutions.

Taking the last-mentioned subject first, it is 53 years ago since the Society of Telegraph Engineers was formed with 66 members. In 1900, when my association with the Institution began, the total membership was 3 661 and Scotland accounted for 158. To-day the membership of the Institution is 11 315, of which the Scottish Centre accounts for 652. These figures are a very striking commentary on the growth of the parent Institution during a single generation. Not only so, but the original name of "Telegraph Engineers" indicated the only real commercial use of electricity at that date. How shall we compare it with our present title of "Electrical Engineers," and with the fact that the latest issue of a Trades Directory contains no fewer than 975 distinct trade headings, from which we may gather that there are just so many distinct or partially distinctive ramifications in the industry as at present constituted?

The importance to the community at large of the electrical industry—and of this Institution in particular—has been recognized by the highest authority in the land. We are now incorporated by Royal Charter and thus enabled to use the designation of "Chartered Electrical Engineer." This is a privilege of which we may well be proud, both as individual members and as an Institution which is representative of the scientific and technical development of the industry. With the privilege comes the added responsibility to maintain the Institution always in the forefront of progress and so make its future history worthy of its past record and of the best traditions of our race.

The development of the electrical industry, looked at from the financial aspect, has been phenomenal during the years that the Institution has been in existence. It is always difficult to ascertain exactly all the capital invested in any industry at any given time, but it is fairly safe to assume that it is proportionate to the amount invested in public companies. If we compare the figures for 1922–3 with those of 1897 we find that the capital invested in the latter year was only one-tenth of that in the former, the actual amounts in round figures being:—

	Total invested capital
1897	£68 000 000
1922–3	£650 000 000

These figures include supply, manufacturing and distributing concerns, and also include the loans authorized to municipal electric supply undertakings. In addition to this, there is the capital sunk in private businesses, which must amount to a very large sum in the aggregate.

No figures seem to be available of the number employed in the electrical industry. It is computed—though I cannot vouch for its accuracy—that the number of workers directly engaged in electrical manufacture and distribution is somewhere approaching 250 000. This I can believe, as one manufacturing company alone numbers its employees in tens of thousands. Truly this is an industry in which we ought all to feel a glow of pride, more especially as this development has taken place within our own lifetime and before our own eyes.

The growth of electrical science has been even more striking and, in many ways, has a distinct suggestion of romance. As I write I have before me a thin, tattered, old volume entitled, "Lectures on Electricity, by James Ferguson, F.R.S., a new edition, corrected, with an Appendix adapting the work to the present state of science," by C. F. Partington, and it is dated 1825. It was bought for a few coppers from an old book-barrow in a Glasgow street, but its value to-day,

is not measured by its tattered cover, its faded pages, or its actual cost. It is a milestone on the march of progress, and its line drawings and quaint phraseology are at once incentive to us towards further endeavour, and a warning not to decry or belittle the day of small things. This little volume is devoted exclusively to descriptions of apparatus for producing static electricity and to experiments which could be performed with the globe, cylinder and plate machines. We learn, for instance, that 30 square feet of coated surface distributed over a number of "Leyden phials" will "fuse the greater part of two feet of wire one-fiftieth of an inch in diameter." It is a very far cry from those small condensers to the large industrial condensers of to-day, for power factor improvement, which can deal with thousands of kilowatts.

We need not go back 100 years, however, to discern the huge advances which we have made in scientific knowledge. The professor whose junior assistant I was at an early stage of my electrical career airily dismissed alternating currents from his lectures by the casual remark that there were one or two central stations giving such a supply, but it was only a fad which would soon die a natural death! He has long since crossed the great divide, but alternating-current supply is not yet dead; it is daily running more and more of the world's business and pleasures.

The growth of scientific knowledge at once renders it necessary to provide greater facilities for study, and the way in which our technical colleges have expanded is ample evidence of the changes that have taken place during the past 30 years. Many of you can remember, as I do, when the technical institution of this city had to be housed in three different buildings, all inadequate. We had the College of Science and Art, 38, Bath-street, and the Andersonian College, in George-street, and the overflow classes from both buildings were held in some of the rooms in Allan Glen's School. Some of us had to be in two places on the same evening. The class-rooms were cramped and badly lighted, the laboratory accommodation was extremely limited, and the apparatus was excessively crude compared with present-day standards. In spite of, or perhaps because of these disadvantages, there was a keen body of students who put heart and soul into their work and studies. Many names which are now well known and looked up to in their respective spheres were inscribed on the roll of students in those days. Times have changed and the magnificent building which now houses the Royal Technical College covers the site of the old Andersonian and many adjacent sites as well. Its laboratories are fully equipped, not only with the finest measuring instruments, but with full-grown machinery and apparatus very unlike the toy gear we had to work with in our student days.

I sincerely hope that the youth of our city and neighbourhood appreciate the advantages that they now enjoy, and that the result may be to incite them to keener study and a greater devotion to the cultivation of scientific research.

When Glasgow Corporation took over from Muir, Mavor and Coulson the electric power station in John-street, and so became electricity undertakers for the city, the largest single unit in use was one of 80 h.p., equivalent to 60 kW. That was in 1892; to-day the largest single unit in the Dalmarnock power station is of 25 000 h.p., equivalent to 18 750 kW—another indication of the march of progress.

The growth of the Clyde Valley Power Company has been just as striking. In the opening year, 1905–6, the largest unit was 2 000 kW; now this has given place to units of 21 000 kW. The total capacity of the plant in 1905–6 was only 4 000 kW; to-day it is 87 500 kW, with a further 20 000 kW of steam plant and 15 000 kW of water-power plant on order.

The total capacity of the Glasgow Corporation plant in 1892 was 270 kW, whilst now 150 850 kW is available. Just think of it for a moment—the original capacity multiplied 560 times in the space of 32 years. What will be the increase in the next 20 or 30 years? From the accompanying table it will be seen that the plant capacity has been trebled in the last 10 years, while the units generated have increased about 120 per cent.

Growth of Glasgow Corporation Electric Supply Undertaking.

Year	Net capital expenditure, less depreciation	Gross revenue	Capacity of plant installed	Units generated	Coal per unit generated
	£	£	kW		lb.
1893	96 697	7 784	360	408 529	20·23
1904	1 119 048	158 190	13 950	17 770 488	5·23
1914	2 456 782	378 315	54 787	92 286 953	3·41
1924	7 068 472	1 153 194	150 850	205 874 443	1·89

This table is interesting in another respect. The last column gives the number of pounds of coal consumed per unit generated. In 1893 it required 20·23 lb. to produce a unit of electricity at the switchboard. To-day this figure has been reduced to 1·89 lb., less than one-tenth of the amount used 30 years ago.

We seem now to be approaching the limit of reduction in fuel consumption, as an increase in the number of units generated gives us only a fractional advantage, and I fear, therefore, that we can look for cheaper electricity only when we have discovered some more revolutionary method of producing it. This brings me to a matter of immediate and material interest to us all: How to increase and develop the domestic load?

I remember quite well a period, not so long ago, when the Electricity Department discouraged the use of electric heating and cooking appliances in private

houses. That was a passing phase due to overloaded mains and out-of-date distribution. The provision of high-tension feeder cables and district substations paved the way for a campaign to increase the domestic load. For some years now a good deal of encouragement has been given to the use of heating and cooking appliances, and yet we have only touched the fringe of the possible business to be done. Not only is there a heating and cooking load to be worked up, but there is an even greater lighting load absolutely untouched, awaiting development. It is calculated that there are more than 8 million houses in Britain without electric light, equivalent to an annual load valued at £49 000 000, and each of these houses when once supplied with current is a potential user of heating and cooking gear as well as light.

I think that it is wise, therefore, to consider why the results so far obtained have been so meagre, compared with the energy expended in advertising, canvassing and demonstrating. There would seem to be several reasons for this state of affairs:—

(1) The installation cost has scared off a great many likely users.

(2) The first cost of cooking appliances is high, much higher than that of corresponding gas-heated devices.

(3) The cost of electrical energy is still in many cases too high.

(4) The method of charging for energy supplied is often too complex for the comprehension of the average consumer.

As there is no intention in this address to go deeply into detail I shall content myself with a few general observations on these points.

(1) *Installation costs.*—In a city such as ours, where the great majority of the possible users are resident only in rented premises, the question of the cost of an installation assumes an importance altogether out of proportion to its intrinsic importance. Whenever electric wiring is installed in a house or shop or office, it at once becomes automatically part of the building and, as such, passes out of the ownership of the occupier who has the use of it only during his tenancy. Consequently, costs which may be quite reasonable in themselves assume an entirely different aspect when looked at from the point of view of a tenant with uncertain tenancy. The introduction of electric lighting into any premises enhances their value, and it seems unreasonable that the outgoing tenant should not be recompensed by the proprietor for such an obvious improvement. If the tenant farmer finds it necessary to build a dyke round his piggery he can claim against his landlord for this improvement, while for a similar case the city dweller may not—either an injustice to the latter or a gratuitous pampering of the former.

The scheme recently introduced by Glasgow Corporation, whereby the proprietors and tenants (with the backing of the Electricity Department) share in the cost of installation, appears to be a step in the right direction. Here, the proprietor pays for the main cabling, whilst the tenant pays by instalments for the wiring of his own house. It is manifestly unfair to ask the tenant on the third floor of a tenement to pay for mains from the street-level; that is the proprietor's duty, and his alone. Personally I am of opinion that he should also pay at least a proportion of the cost of the internal wiring. He gets that extra value added to his property and I can see no reason why a property owner should receive presents of this nature. The Glasgow scheme has now been in operation for three months and the results to date have been sufficient to warrant confidence in its success.

(2) *Cost of apparatus.*—From the very nature of electrical appliances, compared with gas cookers and heaters, there must be a great difference in first cost, and it is our duty frankly to acknowledge such a basic fact. Our contention should be that the convenience, comfort, cleanliness, economy and safety of the electrical apparatus so far exceed those of the rival gear that the extra expenditure is fully warranted and will be repaid with interest during the useful life of the appliances. I am pleased to notice that the cost of good-quality gear is steadily decreasing. Increased production due to increased demand, coupled with standardization and simplification of design, should lead to further reductions, and I hope that we may soon see an electric cooker placed on the market at a price within reach of the proverbial "million."

Our Electricity Department within recent years organized a very popular hire system. It is possible to have various opinions on this method of creating increased demand for energy. If the cost of upkeep of the apparatus, added to the interest on invested capital and a proper amount for depreciation, can all be covered by the annual hire payment, then everything is all right. On the other hand, if such is not the case and the hiring results in a loss which is made up by the price charged for the current, then this method is wrong. There is no reason whatever why one person should be given a too cheap electric cooker service while every other user of current has to make up the loss involved in doing so.

The hiring scheme in Glasgow has been a great success and has exceeded all expectations. There are now approximately 1 100 electric cookers and 3 500 radiators let out on hire to consumers on the system.

(3) *The cost of energy.*—This is a very large subject and a most vexatious one to deal with, for it at once introduces complicated factors in connection with not only the generation but also the distribution and use of electrical energy.

The increase in the size of generating units has resulted in a decrease in the generating costs, and the figures in the table already referred to, showing the number of pounds of coal per unit generated in the Glasgow stations, is instructive, as showing the economies effected during the last few years. In this connection it is of interest to note that the Report of the Electricity Commissioners places the Glasgow stations at the head of their list for thermal efficiency, and the Clyde Valley figures are not far behind.

High-tension distribution to local substations from which there radiates a compact system of distributors is reducing the losses in that part of the system. It would appear, however, that the cost of distribution

is still too high, being much in excess of the cost of generation, and supply engineers will have to concentrate their efforts in effecting reductions in this direction.

No supply undertaking is, however, capable of controlling the manner in which the energy is used by the consumer. This is where the contractor can do a lot of useful work. By planning an educational campaign for the benefit of his clients, by instructing them as to the most economical lamps and apparatus to use and how to get the best results at the least expenditure, their bills will be reduced, with the ultimate result that the same people who now grumble at their electricity bills will install more consuming devices, because they will realize that they are getting efficient apparatus and good value for their money.

In this work the contractor might get a good deal of assistance from the British Electrical Development Association, which issues literature intended primarily for the consumer's education. The fact that we now have such an organization is a further sign of progress. To make this body of greater service to the industry as a whole, it is obvious that it needs the whole-hearted support of the supply, manufacturing and contracting interests. A very fine exhibit at Wembley Exhibition arranged and controlled by the Association must have brought home to millions the convenience, utility and comfort of electric light and power.

The cost of energy to the consumer is not merely the rate per unit charged by the supply undertaking, but is also the cost to him of inefficient apparatus and faulty use. It would pay both the suppliers and the contractors to reduce this cost as far as possible, for a satisfied customer is the very best advertisement which it is possible to have.

(4) *System of charging.*—The varied and, in many cases, complicated systems in use for charging for the supply of electrical energy have certainly not done anything to popularize the use of electricity, and I am very pleased to see that there is now a decided tendency to leave mathematical methods severely alone and give a simple straightforward tariff.

For domestic supply, while the maximum-demand tariff is still used by both the large supply authorities in our area, they are now giving an alternative rental method which involves a flat rate for all units recorded on the meter. This rental system consists of two parts: (1) a fixed annual charge and (2) a flat rate per unit as recorded on the meter. In one instance, for example, the fixed annual charge is based on the size of the house, being 20s. per room; and in another the fixed charge is equal to approximately one-eighth of the house rent. The flat rates per unit vary from $\frac{3}{4}$d. to $\frac{1}{2}$d. per unit recorded on the meter.

A comparison of two typical residential areas shows that where the maximum-demand tariff is in operation the average price per unit is 3·1d. and the average income per consumer is £6 1s. 6d., whilst where the rental tariff is in use the average rate per unit is only 1·39d., but the income per consumer is on the average about £14.

Many consumers who use electricity for cooking and heating throughout get their supply for much less than this figure, the rate per unit in some cases falling as low as 0·915d. Figures such as these would suggest that a simple understandable method of charging will assist in raising the domestic demand to a much higher level than the station engineer has yet conceived. This new era will not arrive, however, unless we work for it.

As a contractor, I would address a few words especially to the contractor members of the Institution. The association between the contractors and the Institution should be closer than it is at present. The Institution is democratic, and as such welcomes the contractor as a member, and he should take his place and make his presence and interest felt. For many reasons the Institution is well worthy of all the support the contractors can give it. To instance two or three only: There is the National Scheme of Registration, and the issue of Wiring Regulations for the Electrical Equipment of Ships and also Buildings.

For years a Committee of the Institution studied and discussed the registration question, and finally evolved the scheme now in force, a scheme which is attracting the contractor in increasing numbers and which is undoubtedly raising his status.

The Institution Wiring Rules issued many years ago have now been re-drafted and their scope widened, and they are now termed Regulations for the Electrical Equipment of Buildings. The present issue is the Eighth, dated June 1924. This is good work for the community and for the contractor. Some are inclined to suggest that we have too many regulations and too many laws, but just as the honest man can walk without fear of the law so the honest contractor has no quarrel with regulations designed for the good of the industry. I think that, for these reasons alone, the contractor should support the Institution to the utmost.

Now to drive home a moral. We all look forward to the time when electric cookers, radiators, vacuum cleaners and so on will be as plentiful and commonplace as autumn leaves in the forest. What are we doing to help? How many in this room have their meals cooked electrically at home? How many radiators have you? Is your electric lighting carried out on modern scientific lines? If we do not set the example ourselves, how can we expect others to do what we merely advise? It is, therefore, most essential that we should first set the example, so that others may follow.

EAST MIDLAND SUB-CENTRE: CHAIRMAN'S ADDRESS

By T. R. SMITH, Member.

"THE NEW LEICESTER CENTRAL GENERATING STATION."

(ADDRESS *delivered at* LOUGHBOROUGH, *7th October*, 1924.)

It has been a matter of some concern to me to select a suitable subject for my address, but I feel that perhaps I cannot do better than give some particulars of the new Leicester central generating station, the design and construction of which has been my principal task during the past three years.

The station is still in course of construction, but I propose that my remarks shall fall into three distinct sections, as follows:—

(1) A general description of the work at present in hand, or completed.

(2) Particulars of the general performance of that portion of the plant which is at present in operation.

(3) Some discussion of the lines on which the future development of the station may take place.

(1) GENERAL DESCRIPTION OF WORK IN HAND, OR COMPLETED.

The Leicester central generating station was designed for an ultimate plant capacity of 65 000 kW.

Site.—This is adjacent to the River Soar, the subsoil consisting of gravel and marl with a layer of shale at a depth of 9 ft. capable of carrying the foundations of plant and buildings.

The river widens out into two large basins opposite the site, separated by a weir 500 ft. in length. In time of dry weather circulating water is drawn from the lower basin and discharged above the weir, but when there is a large quantity of water coming down the river the water is returned to the lower basin.

The London Midland and Scottish Railway runs along the southern boundary of the site and coal can therefore be delivered by either rail or barge.

Buildings.—The portions at present erected are No. 1 boiler house, the turbine room and annex to a point between Nos. 2 and 3 turbines and a portion of the e.h.t. switch-house. The whole of the buildings, with the exception of the e.h.t. switch-house, are of steel-framed construction, the concrete foundations for the stanchions extending down to the shale.

The turbine house is 159 ft. long and 42 ft. in span between the crane rails, the basement floor being at the site level and the turbine floor and the eaves of the turbine room being respectively 20 ft. and 46 ft. above the basement floor. The annex to the turbine room is 19·5 ft. wide and has four floors, viz. the workshop floor, the low-tension control-room floor, the high-tension control-room floor, and the tank-room floor.

The circulating-pump chambers adjoin the turbine room annex; they are 15·25 ft. below the basement level and the pumps are totally immersed at all times.

The boiler house is 152·5 ft. long by 87·75 ft. wide, the basement being at the same level as that of the turbine room. The basement contains the forced-draught fans and duct, the stoker motors with reduction and driving gear, and is so arranged that special ash wagons of 4 ft. 8½ in. gauge can be run in directly beneath the boiler ash hoppers.

The firing floor is 12 ft. above the basement and carries the induced-draught fans in addition to the boilers. The coal supply to the boilers is taken from steel bunkers, the total bunker capacity being 1 000 tons.

The high-tension switch-house is 133·5 ft. long by 24 ft. wide. The ground floor accommodates concrete cubicles which house the oil switches, the feeder isolators, the instrument and protective transformers and the current-limiting reactances. The first floor, which is 12·5 ft. above the ground, contains the busbar chambers with busbar isolators.

A cable tunnel 7 ft. deep by 8·5 ft. wide runs the entire length of the switch-house and is continued into the main turbine room.

Coal-handling plant.—The bulk of the coal used is delivered by rail into the sidings on the bank at the southern side of the site. Trucks are weighed and drawn by locomotive or capstan into the tippler on the embankment. The tippler, which has automatic clamping gear, discharges the coal on to the long conveyer. The coal is then either moved to the overhead bunkers by means of cross-conveyer and skip hoist or placed on the storage heaps by means of the small movable distributing conveyer, which can be moved to any position throughout the length of the long conveyer.

The conveyers consist of rubber belts running on ball-bearing idlers, are driven by back-geared three-phase motors at a speed of 360 ft. per minute and are capable of handling 120 tons of coal per hour. The skip hoist has a similar capacity to the conveyers and is entirely automatic. A 3-ton grab on an electric level luffing travelling crane is used for reclaiming coal from the storage heap. The reclaimed coal is placed into a movable hopper which feeds it on to the long conveyer, from whence it passes up to the bunkers via the cross-conveyer and skip hoist.

Ash plant.—The ashes are discharged over the ends of the chain-grate stokers into steel-framed ash hoppers, where they are quenched by water sprinklers fixed in the upper portion of the hoppers. The hoppers discharge by means of sliding valves into special ash wagons in the basement.

Boilers.—The boiler house contains eight steel-cased boilers, four Babcock boilers and four Spearing boilers.

The Babcock boilers are of the well-known cross-drum, marine type, with integral superheaters, and "tritube" superposed cast-iron economizers. The heating surfaces of the boiler, superheater and economizer are respectively 6 948 sq. ft., 2 368 sq. ft. and 4 435 sq. ft. Each Babcock boiler is equipped with three Babcock chain-grate stokers 16 ft. long by 6 ft. 6 in. wide, giving a total grate area of 312 sq. ft. per boiler. Each stoker chain is driven by a worm, four-speed gear-box and chain from a shaft running the entire length of the boiler-house basement. The shaft is divided by dog clutches into four sections which can be coupled together at will, and each section of shafting is coupled by means of a chain and worm reduction gear to a 6-h.p. motor running at 950 r.p.m. Six stokers may be driven by any one motor. The forced-draught fans, three in number, are situated in the basement and discharge into a common duct running the length of the boiler house. Three 40-h.p. motors running at 360 r.p.m. are direct-coupled to the three forced-draught fans, and any two fans are capable of supplying the needs of all four boilers. An induced-draught fan driven by a 46-h.p. motor at 410 r.p.m. is provided for each boiler on the firing floor level, and is capable of dealing with the gases from one boiler only. The Babcock boiler plant is designed for a duty of 45 000 lb. of steam per hour per boiler, at 275 lb. per sq. in. (gauge) and 700° F. total temperature, with feed at 180° F. and coal of 8 000 B.Th.U. (lower net calorific value as fired). The coal most generally fired gives on test the following results:—

Lower net cal. value (212° F. exit temp.)	=	9 330 B.Th.U./lb.
Total moisture, per cent ..	=	13·7
Volatile (as fired), per cent	=	29·0
Ash (as fired), per cent ..	=	15·7

and with this fuel the above duty is easily obtained.

The Spearing boilers are at present in course of erection and are of the double-drum type with special downcommer pipes. Integral superheaters and superposed "tritube" cast-iron economizers are embodied. The heating surfaces of boiler, superheater and economizer are respectively 7 590 sq. ft., 2 300 sq. ft. and 5 200 sq. ft. These boilers are rated similarly to the Babcock boilers and the general arrangement of their auxiliaries is somewhat on the lines adopted for the Babcock boilers, with the exception of the stokers and forced-draught fans. The stokers are of the Illinois type, and one stoker 16 ft. long by 18·5 ft. wide is provided for each boiler. These stokers are driven by a worm gear-box and chain from a shaft in the basement, as in the case of the stokers previously described. A forced-draught fan driven by a 32-h.p. motor at 410 r.p.m. delivers air into two wind-boxes one on either side of the stoker, from whence the air passes through dampered openings into eight compartments running transversely beneath the stoker chain. This arrangement enables the quantity of air passing through the grate over any compartment to be adjusted according to the requirements of the fire bed at that point, and results in a better CO_2 figure than can be obtained with the non-compartmented type of stoker.

Steam ranges.—Each line of four boilers feeds into a separate receiver, the two receivers being interconnected by a 12-in. pipe. The steam range connecting with the Spearing boilers has been carried overhead in order to secure the maximum flexibility and thereby to reduce temperature stresses to a minimum. It is hoped that this will possess marked advantages over the earlier range which is situated in the basement.

Feed-ranges.—These are constructed of cast-iron pipe with steel bends. The arrangement enables either set of boilers to be supplied from either the steam or electric feed pumps. A master Venturi meter measures the total feed supplied to either of the two main feed-ranges, and Venturi meters are also placed between individual boilers and the range. The feed to all the boilers is controlled by automatic regulators. The whole of the make-up feed water is taken from an evaporator, and the arrangement of the feed system has proved most satisfactory.

Turbine plant.—There are two main turbo-alternators and one small turbo-alternator for house-service purposes. No. 1 turbo-alternator has a maximum continuous output of 10 000 kW at 1 500 r.p.m., with an overload capacity of 25 per cent for two hours.

The terminal conditions of this machine are as follows:

Voltage	6 600
No. of phases	3
Frequency	50 periods per second
Steam pressure	250 lb. per sq. in. (gauge)
Steam temperature ..	700° F.
Vacuum	28·7 in. (bar. 30 in.)
Circulating water inlet temp., 65° F.	
Circulating water outlet temp., 78° F.	

With these terminal conditions the machine consumes 10·6 lb. of steam per kWh at full load, exclusive of the steam consumed by the ejectors. The turbine is of the impulse type having 10 pressure stages and two velocity stages in the first pressure stage. The nozzles of the first pressure stage are divided into three groups, each group being controlled by an automatic valve, the nozzle area being varied to suit the load conditions. A surface heater takes steam from a point immediately in front of the sixth stage of the turbine, heating the main condensate as described later.

The alternator is of the usual type with a closed air circuit and air cooler. The rotor is a solid steel forging carrying fans at either end. The exciter is carried on an extension of the main bedplate and is driven from the end of the alternator shaft by means of a pin coupling.

The condenser, which is supported on springs, is bolted direct to the turbine exhaust flange and has a total cooling surface of 17 750 sq. ft. Duplicate plant is provided for extracting the air, either by steam-jet ejectors or a rotary kinetic air pump. The pumps for extracting the condensate are also in duplicate.

No. 2 turbo-alternator has a maximum continuous rating of 12 500 kW at 3 000 r.p.m., with no overload guarantees. The terminal conditions under which this machine operates are exactly the same as those for

No. 1 turbo-alternator, and under these conditions the full-load steam consumption is 10·72 lb. per kWh, and at a load of 10 000 kW the consumption is 10·37 lb. per kWh.

This turbine is of the impulse type with 7 pressure stages, a hand-operated valve being arranged to by-pass the first wheel on overload. The alternator for this machine is of the two-pole type with the exciter armature carried on an extension of the shaft over-hung from the outboard bearing.

In design and construction this machine is very similar to No. 1 alternator. The condenser has a total cooling surface of 17 800 sq. ft. and is supported and connected to the turbine exhaust in a similar manner to No. 1 condenser.

The air-extraction plant and the condensate-extraction pumps are both in duplicate, the air extraction being carried out entirely by steam ejectors.

Condensate and feed heating systems.—The condensate from both main generating sets unites into a common stream after it has passed through the Venturi tubes, flowing through the surface heater of the house-service set and the bleeder heater of No. 1 main set direct to the boiler feed pumps.

The surface heater utilizing the exhaust of the house-service set and the heater utilizing bled steam from No. 1 main set can be by-passed. The condensed steam from the house-service set is extracted by means of a small pump which feeds it into a drip tank. The drip tank also serves as a collecting tank for all clean-water drains in the station. The contents of the drip tank are returned to the main condensate stream by means of a small pump. No hotwells are provided, any inequalities in the rates of flow through the feed pumps and the extraction pumps being balanced by a surge tank in the annex. The surge tank also gives storage capacity and receives any make-up that is necessary from the evaporated-water storage tank, which is also in the annex. It is to be noted that complete control of the feed temperature is obtained by varying the load on the house-service set, or by varying the amount of steam bled from No. 1 main turbine.

Circulating water system.—Water may be taken in at two points below the weir and discharged above the weir, or in times of flood it may be both taken in and discharged below the weir. Two motor-driven circulating pumps in chambers adjacent to the turbine room annex supply water to each main condenser. They are totally immersed at all seasons and each pump is capable of supplying half the amount of water required by the condenser when on full duty.

Drive of auxiliaries.—With the exception of the feed pumps, all the auxiliaries are electrically driven from a three-phase, 50-period supply at 415 volts. Energy for driving the auxiliaries is obtained either from the house-service set of 500 kW capacity or from two 1 000-kVA transformers, stepping down from 6 600 volts to 415 volts.

The house-service set is usually in parallel with the auxiliary transformers and operates at a vacuum varying from 10 to 23 in., according to the load on the main sets, but in cases of emergency the house-service set is used exhausting direct to atmosphere.

Feed pumps.—There are four boiler feed-pumps, each pump being capable of delivering 25 000 gallons of water per hour against a pressure of 320 lb. per sq. in. The temperature at the feed-pump suctions is normally 180° F. and there is a pressure head of 23 ft. on the suction side. Two of the pumps are steam-turbine-driven and two are driven by 135-h.p. electric motors. The turbines of the steam pumps are arranged to exhaust into the surface heater of the house-service set.

Main e.h.t. switchgear.—The station will eventually have four main sections of e.h.t. busbars with a reserve busbar and a set of reactance tie-bars. At present there are two main sections of busbars, with reserve bars and reactance tie-bars. It is possible to connect the main busbar sections directly together by means of a section switch, or to connect them together through reactances and the tie-bars. It is also possible to connect either of the main busbar sections in a similar manner to the reserve busbars. By suitable arrangement of the isolating switches it is possible to connect a generator or feeder to either the main busbar section or the reserve busbars. Each of the main oil switches has a rupturing capacity of 500 000 kVA, and the reactances are so proportioned that the worst fault will give a short-circuit current within the rupturing capacity of the oil switches.

(2) General Performance.

The performance of the station under normal conditions for the period 8th September to 22nd September, 1924, is given below.

Period under observation ..	336 hours
Steam pressure	251 lb. per sq. in. (gauge)
Steam temperature ..	692° F.
Vacuum (bar. 30 in.) ..	28·4 in.
Temperature of feed water	168° F.
Total heat of steam from feed temperature ..	1 223 B.Th.U./lb.
Coal.	
Calorific value of dried sample	11 304 B.Th.U./lb.
Lower net calorific value (212° F. exit temperature)	9 300 B.Th.U./lb.
Moisture	13·26 per cent
Volatile (as fired)	29·07 per cent
Ash (as fired)	15·56 per cent
Evaporation.	
Weight of coal consumed ..	1 608·4 tons
Weight of water evaporated	21 679 800 lb.
Weight of ash made ..	246·3 tons
Weight of water evaporated per lb. of coal	6·02 lb.
Boiler efficiency based on lower net calorific value..	79·2 per cent
Boiler efficiency based on coal of 9 850 B.Th.U./lb.	74·7 per cent
Station output.	
Units generated	1 551 300
Units sent out	1 475 020

Units used on works ..	76 280
Maximum generator load ..	10 800 kW
Weight of coal per unit generated	2·32 lb.
Weight of coal per unit sent out	2·44 lb.
Overall station efficiency based on units sent out and lower net calorific value	15·0 per cent
Overall station efficiency based on units sent out and coal of 9 850 B.Th.U.	14·2 per cent

The plant in service during the period under observation consisted of No. 1 turbo-generator (normal rating 10 000 kW), and three Babcock boilers each rated normally at 45 000 lb. evaporation per hour from feed at 180° F. to steam at 275 lb. per sq. in. (gauge) and 700° F. total temperature.

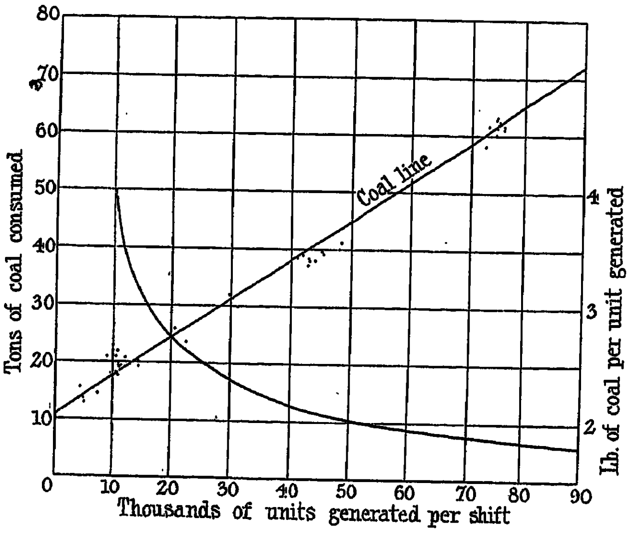

FIG. 1.—Coal line.

$C = 24\,600 + 1\cdot515\,K_g$

where C = coal consumption in lb. per 8-hour shift (10 000 B.Th.U. lower net calorific value; exit temperature, 212° F.);
K_g = units generated per 8-hour shift.

The plant had been in commercial service for a period of 22 months when the readings were taken, and during the period under observation it was operated under normal station conditions. It should be noted that no special boiler-cleaning had taken place before the test.

Special note should be taken of the coal used. This is a fine slack of inferior quality, the moisture, volatile and ash contents being high, while the carbon content is particularly low.

In order to facilitate comparisons between the performance of this station and others working under different conditions of load factor the results have been plotted in the form of Parsons lines based on coal at 10 000 B.Th.U. per lb. lower net calorific value (212° F. exit temperature). Fig. 1 shows the coal line per shift, and Fig. 2 the steam line per shift, while Fig. 3 shows the evaporation line.

Coal line.—Fig. 1 connects the coal used during any 8-hour shift with the units generated. The equation of this curve is $C = 24\,600 + 1\cdot515\,K_g$, and therefore

$$E = \frac{24\,600}{K_g} + 1\cdot515$$

where C = weight of coal in lb. per 8-hour shift,
K_g = units generated per 8-hour shift, and
E = coal consumption per unit generated (average).

From these equations, or from the curve, it is possible to predict the coal consumption per shift for any electrical output, and it will be noticed that the constant

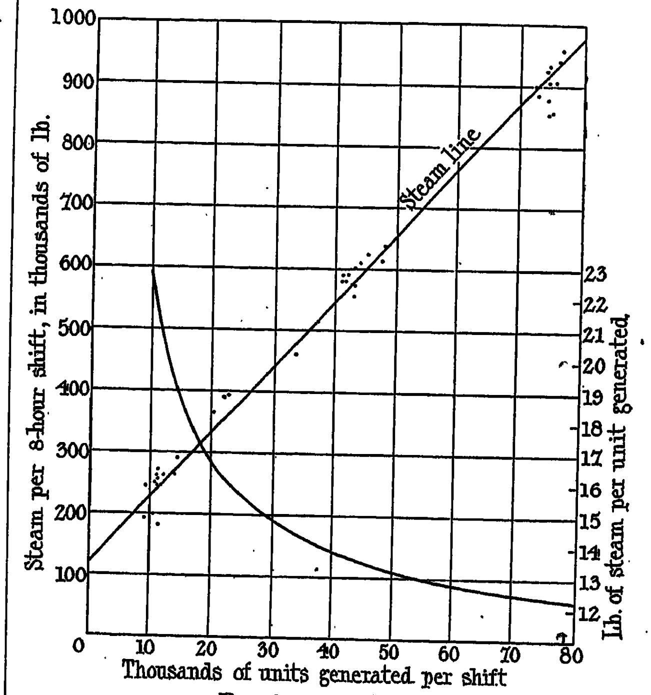

FIG. 2.—Steam line.

$S = 120\,000 + 10\cdot75\,K_g$

where S = lb. of steam per shift;
K_g = units generated per shift.

24 600 represents the weight of coal in lb. required to keep the station running at no load. It is seen that 1·515 lb. of coal per unit generated corresponds to the limiting thermal efficiency of the station, which would theoretically be 22·5 per cent. The actual overall thermal efficiency on full load is 18·75 per cent.

Steam line.—Fig. 2 shows the steam consumption during any 8-hour shift, plotted against the units generated. The equation of this curve is $S = 120\,000 + 10\cdot75\,K_g$

from which $$U = \frac{120\,000}{K_g} + 10\cdot75$$

where S = total steam consumption in lb. per shift,
U = steam consumption in lb. per unit generated, and
K_g = number of units generated.

The quantity S includes the steam used by the boiler feed-pumps, two battery storage locomotives used in connection with the coal and ash plant, and steam used for heating offices, mess rooms, etc. The constant of 120 000 lb. represents the amount of steam which must be generated during every 8-hour shift in order to keep the station running on no load. The figure of 10·75 lb. is the limiting steam consumption of the station. This would be reached when the output had reached such magnitude as to render the no-load losses insignificant. This is equivalent to a limiting thermodynamic efficiency of 72·4 per cent.

Evaporation line (Fig. 3).—From the foregoing equations it follows that:—

$$C = 7\,730 + 0{\cdot}141\,S \qquad S = 7{\cdot}1\,C - 54\,800 \qquad E = 7{\cdot}1 - \frac{54\,800}{C}$$

where E = evaporation in lb. of steam per lb. of coal,
S = steam generated per 8-hour shift, and
C = coal consumed per 8-hour shift.

The constant 7 730 is the weight of coal in pounds required to maintain the boilers at full pressure when

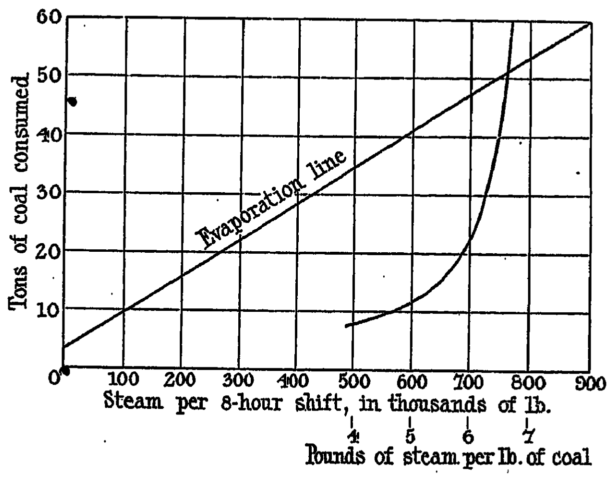

FIG. 3.—Evaporation line.
$C = 7\,700 - 0{\cdot}141\,S$
where C = lb. of coal per shift (10 000 B.Th.U. lower net calorific value);
S = steam per shift.

the station is at no load—in other words the banking loss—and by subtracting this quantity from 24 600 the constant no-load heat loss of the turbine room is obtained. It is therefore seen that the boiler-house no-load heat loss is equivalent to 3·45 tons of coal per shift and the turbine-room no-load heat loss to 7·55 tons of coal per 8-hour shift.

The limiting boiler-house efficiency corresponds to 7·1 lb. of steam per lb. of coal, or 86·9 per cent. It is felt that this performance is fairly creditable having regard to the low-grade fuel used. During the period under review the lower net calorific value varied between limits of 8 750 B.Th.U. and 9 820 B.Th.U., the ash (as fired) between 13 per cent and 21·3 per cent and the moisture between 11·4 per cent and 14·9 per cent.

Considerable trouble was experienced when the station was first put into commission, due to lack of uniformity of the fire bed, the nuts and peas tending to separate from the fine coal. After much experiment with baffles in the coal chutes from the bunkers this trouble was practically eliminated. Our next trouble was a tendency of the fire to burn thin down one side of each grate, greatly upsetting our CO_2 figures. This has recently been remedied by a special arrangement of baffling in the ash pits; this produced an immediate improvement of 1½ per cent in the CO_2 figures. We are at present experimenting with varying designs of arch and I have every hope that we shall be able to show an improvement on our present boiler-house efficiency in the course of a few months.

When non-compartmented stokers are used to burn a coal of high moisture and ash content, great difficulty is experienced in burning out the ash with a reasonable amount of excess air. This is our great difficulty with the present Babcock stokers and we find it necessary to take ash samples for each shift with as much care as we expend on coal sampling, keeping careful watch on the percentage of unburnt carbon in the ash.

The boilers nearing completion are equipped with compartmented stokers and it is hoped that we shall have much less trouble in dealing with low-grade fuel on them.

(3) FUTURE DEVELOPMENT.

In order to bring the station up to its ultimate capacity there still remain three 15 000-kW generating units and another boiler house of equal capacity to the existing house to be installed, together with switchgear and auxiliaries. The switchgear is bound to follow the scheme which has been prepared, of which the present gear forms a part. It can also be predicted with certainty that all the auxiliaries will be electrically driven, thus leaving greater possibilities in regard to bleeding the main units for feed-heating purposes. The main 15 000-kW turbo-generators will operate at 3 000 r.p.m. and, though there would be an increase in the available heat-drop and therefore in the limiting station thermal efficiency due to an increase in boiler pressure, I am inclined to think that it will be necessary to retain our present pressure in the interests of flexibility. I also feel that the present steam temperature of 700° F. cannot be exceeded without involving serious maintenance costs.

We shall do as much bleeding from the main sets as possible, but the amount of bleeding will depend very much on the policy adopted in the boiler house. The boiler house presents an absorbing problem. The rate of advance in the design of steam-raising plant is greater now than at any previous period and we have to consider the claims of low-temperature carbonization with by-product recovery of pulverized fuel, and mechanical stokers. Our particular circumstances will, I think, enable us to dismiss the former and turn our attention to the rival claims of pulverized fuel and stokers. The problem is simply which of these two systems will economically give us the higher percentage of CO_2, the lower flue-gas temperature and the lower ash pit loss, with a given feed temperature. From past experience,

I am inclined to think that my next boiler specification will not call for an efficiency guarantee. I shall ask for a guarantee as to CO_2, flue-gas temperature and unburnt carbon in the ash, with fuel of a given ultimate analysis and feed at a stated temperature. These figures govern the chief losses and are easily obtainable.

With the present pressure the temperature of the gases leaving the boilers is more or less fixed at, approximately, 550° F. for both pulverized-fuel and stoker plant, and in both cases some method of securing a reduction of this temperature has to be devised. At present, the usual practice in this country is to provide extra cooling surface in the form of economizers through which the feed water is pumped. With economizers it is economically possible to get the gases down to 375° F., thereby reducing the chimney loss to approximately 14·2 per cent with the feed temperature about 160° F. If the temperature of the feed is increased the efficiency of the economizer is reduced, and it will be seen that the use of economizers places a limit on the amount of bleeding that can be done from the main turbine.

There are two great streams of waste heat from a power station, viz. the heat wasted up the chimney and the heat wasted in the circulating water, and we can only hope for any considerable improvement in efficiency by absorbing heat from these two streams. The only way of recovering heat from the circulating-water stream is by bleeding the main turbine as much as possible. This therefore causes us to look for means other than the economizer for reducing the temperature of the gases after they leave the boiler, and it at once becomes apparent that an efficient system of extracting the heat from the flue gases and imparting it to the air entering the furnace is extremely desirable. There are various practical difficulties in the design of air heaters, but it is possible theoretically to design a heater which would reduce the flue gas temperature to 375° F., thereby obtaining a boiler efficiency equal to that obtained with economizers.

Turning now to the effects of bleeding the main turbine, and assuming the turbine to be bled at one point only, the thermodynamic efficiency being 75 per cent, it can be shown that the heat-conversion coefficients of the plant with feed heated to 160° F. and 330° F. are 0·351 and 0·3705 respectively. The plant with feed heated to 330° F. would therefore consume approximately $5\frac{1}{2}$ per cent less coal than the plant with feed at 160° F., provided always that the flue-gas temperature attained with the air heaters was as low as that attained with economizers. It can therefore be taken for granted that if air heaters are a practical proposition when the next boiler extension takes place, we shall certainly install them with extensive bleeding of the main turbines. The bleeder heaters will of course be on the pressure side of the feed pumps. The use of an air heater will of course render the links of chain-grate stokers more liable to burn out, but this is one of the difficulties which have to be overcome.

Owing to the better mixing of the air with the fuel it has been shown to be possible in pulverized-fuel plants to work with very small amounts of excess air, thereby increasing the furnace temperature and reducing the stack loss. Pulverized-fuel plants have of late been able to show a higher efficiency both on this account and because of their well-designed combustion chambers. They also have the advantage of great flexibility, being easy to control, quick steaming, and having no banking loss. If the capital cost of the pulverized-fuel plant can be sufficiently low it will undoubtedly oust the mechanical stoker, but I feel that this is by no means certain.

I think that there is room for very considerable improvement in the design of stoker plant, with corresponding increase in efficiency. Non-compartmented chain grates will of course disappear, and I think that much improved combustion chambers will be evolved. Trouble with the brickwork has caused designers of pulverized-fuel plant to adopt large combustion chambers. Such chambers have made complete combustion of the gases possible before the tubes are reached. The advantage of adequate combustion space is now being appreciated by designers of stoker plant, and I feel sure that a considerable increase in efficiency will result. In the case of very large units the difficulty of providing a stoker with sufficient grate area gives the pulverized-fuel plant a very decided advantage. At present I am keeping an open mind between pulverized-fuel firing and stoker firing in regard to our future extensions.

I have endeavoured to give some outline of what I conceive to be the main possibilities in regard to our future extensions. There is, of course, a mass of practical details to be considered, but I feel that this is not the place to discuss them.

IRON LOSSES IN D.C. MACHINES.*

By EDWARD HUGHES, B.Sc. (Eng.), Associate Member.

(*Paper first received* 11*th March, and in final form* 22*nd April*, 1924.)

SUMMARY.

In Section 1 the iron loss in six d.c. machines with undistorted flux has been analysed to determine :—

(a) The effect of high flux-density upon the hysteresis loss.
(b) The hysteresis and eddy-current exponents over a wide range of flux density.
(c) The ranges of frequency and of flux density over which the total iron loss can be represented by an expression of the form $k_1 f^x B^y$.
(d) The values of k_1, x and y for 0·018 in. lohys laminations.
(e) The agreement between values of iron loss calculated from $k_1 f^{1 \cdot 5} B^2$ with the measured values over wide ranges of frequency and of flux density.

In Section 2 the increase of iron loss with load is examined. The iron loss due to the commutating-pole flux is considered, and a method of calculating the iron loss for any degree of distortion of the main flux is suggested. The values calculated by this method are compared with those measured on a dynamo in which different degrees of distortion were obtained by means of a compensating winding.

SECTION 1. IRON LOSSES WITH UNDISTORTED MAGNETIC FIELD.

A large amount of experimental work has been done on the measurement of rotational hysteresis loss. Practically all investigators except Hermann † have found this loss to be a maximum at a flux density of about 16 000 lines per cm². Hermann employed ring-shaped stampings wound with coils carrying polyphase currents, so that the hysteresis loss measured was due to a mixture of alternating and rotating fluxes. This may account for his failure to detect any difference between rotating and alternating hysteresis losses.

In spite of the fact that all the tests on rotational hysteresis appear to have been carried out on discs resembling a smooth core, many writers have applied the results thus obtained to the calculation of the iron loss in the teeth of armatures, maintaining that at high flux densities the tooth loss does not increase as rapidly as at lower densities, owing to the decrease in the hysteresis loss.

It has been pointed out by Thornton ‡ that as a tooth moves from under a pole shoe "the lines of force become oblique, and midway between the poles horizontal, though the density never drops to zero. There is, therefore, a rotating magnetization in the teeth which is at the same time fluctuating between limits" of 18 000 and 4 000 lines per cm², these values being deduced from his photographs of stream lines. A rough estimation for machine A, the particulars of which are given in Appendix 1, shows that for a flux density of 15 000 in a tooth tip directly under a pole, the tip density due to transverse flux when midway between the poles is reduced to at least 2 500, whilst that at the root of the tooth is reduced to a far greater extent. It therefore follows that the flux in the teeth approaches much more closely to an alternating than to a rotating field; and it was partly for the purpose of checking this conclusion that the experiments dealt with in this paper were undertaken.

The core loss is influenced by so many factors * that it appears almost hopeless to take all of them into account; and judging by the variations in the core loss of even similar machines it seems that the value obtained from a simple expression based upon test-results is almost as reliable as that calculated by the most elaborate formula.

Macfarlane and Burge † give the iron loss in an armature core built of 0·018 in. laminations as

$$W = 7 \cdot 6 \times 10^{-6} f^{1 \cdot 3} (V_a B_a^2 + V_t B_t^2) \text{ watts}$$

where B_a = flux density in armature core in kilolines/cm²,
B_t = average flux density in teeth in kilolines/cm²,
V_a = volume of iron in core in cm³,
V_t = volume of iron in teeth in cm³,
and f = frequency.

A similar result is given by Schukkerman, ‡ namely

$$W = k f^{1 \cdot 3} B^2 V \times 10^{-6} \text{ watts}$$

where k = 7 to 9,
B = mean flux density,
and V = volume of core and teeth in cm³.

Schukkerman found that the index of f increased to 1·45–1·5 at high flux densities, due to the greater ratio of eddy loss to hysteresis loss.

The constants just given apply to ordinary soft-iron laminations. Since most armature cores for d.c. machines are now made with lohys, it seemed desirable to determine whether the above indices apply to this quality of alloyed iron, and also to determine the value of k.

The author was fortunate in having at his disposal

two motor-generator sets fitted with ball bearings, together with a reliable moving-coil ammeter possessing an exceptionally large inertia. It was therefore possible to obtain very accurate and consistent results. The two sets were by the same maker, and one of the machines was fitted with a compensating winding.

Two machines fitted with plain bearings and by different makers were also tested, so as to compare the iron losses with those of the other four machines; but the same accuracy was not possible in these tests.

The losses were in all cases measured by noting the input to a motor directly coupled to the machine under test. The brushes on the latter were lifted to avoid any circulating currents, and a correction was made for

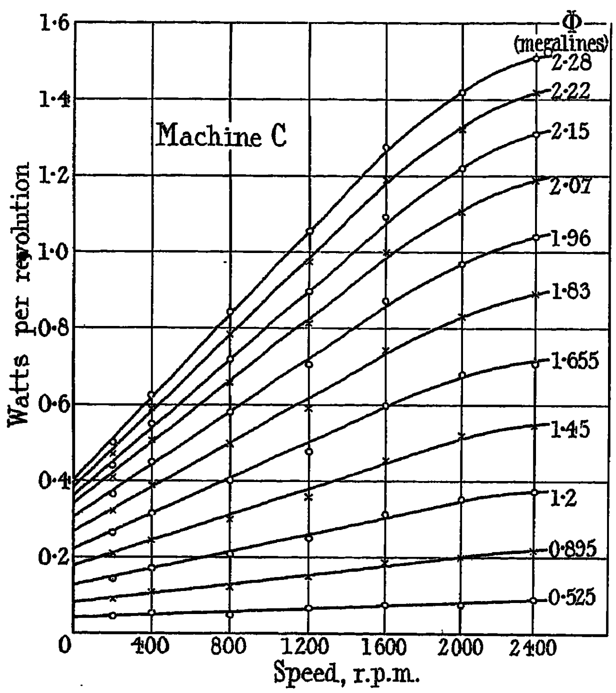

FIG. 1.

the slightly increased copper loss in the motor with increased excitation on the driven machine.

The core dimensions and other particulars of the machines are given in Appendix 1.

The core losses at the various speeds were plotted against flux per pole entering the armature; and from these curves the core loss per revolution was calculated at different fluxes, the curves for machines C and D plotted in Figs. 1 and 2 being typical of the results obtained.

It is of interest to note how W/n deviates from the straight line for speeds of about 1 500 r.p.m. (50 periods per sec.) upwards. This tapering-off of the iron loss was not due to any increase of the armature temperature, since each set of readings took only a few minutes, and several of the tests on these machines were checked by being immediately repeated. The effect in question must therefore be due to the reactance of the eddy-current circuits becoming comparable with their resistance.

From these curves the hysteresis and eddy losses at 1 000 r.p.m. were calculated, the results for machines C and D being plotted in Figs. 3 and 4. It will be noticed that the hysteresis losses for the two machines are approximately the same, but the eddy loss in D is much greater than that in C. This difference is probably due partly if not entirely to the presence of slots in the pole shoes of D, especially as machines A to D are by the same makers and the constants for the iron losses in machines A, B and C are in close agreement (see Table 3). Eddy currents induced in the armature conductors could not be responsible for the

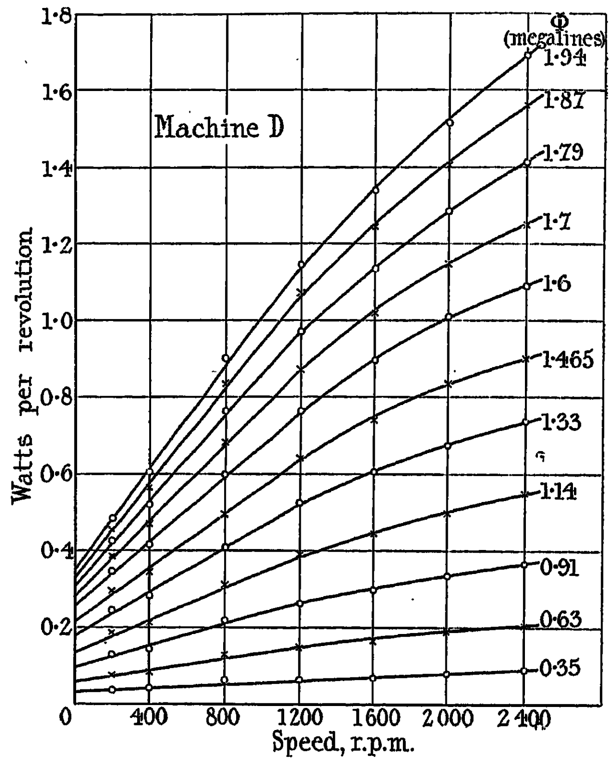

FIG. 2.

increased losses in D; thus, taking the eddy-current loss per cm³ of armature conductor as

$$w = \frac{\pi^2}{6} \cdot \frac{1}{\rho} t_c^2 f^2 B^2_{max.} \times 10^{-16} \text{ watts *}$$

we have for the present case

$$t_c = 0 \cdot 25 \text{ cm}$$

$$f = \frac{1\,000 \times 2}{60} = 33 \cdot 3$$

$B_{max.} = 400$, say, for a flux density of 20 000 in teeth

therefore $w = 0 \cdot 91 \times 10^{-3}$ watts/cm³.

But volume of embedded copper = 643 cm³,

∴ total eddy-current loss in conductors = 0·6 watt.

The curves in Figs. 5, 6 and 7 have been plotted from the logarithms of the flux and of the hysteresis and

* MILES WALKER: "Dynamo-Electric Machinery," p. 144.

eddy-current losses for the six machines. It will be noticed that the slope of most of the curves decreases with decrease of flux density. In each case, however,

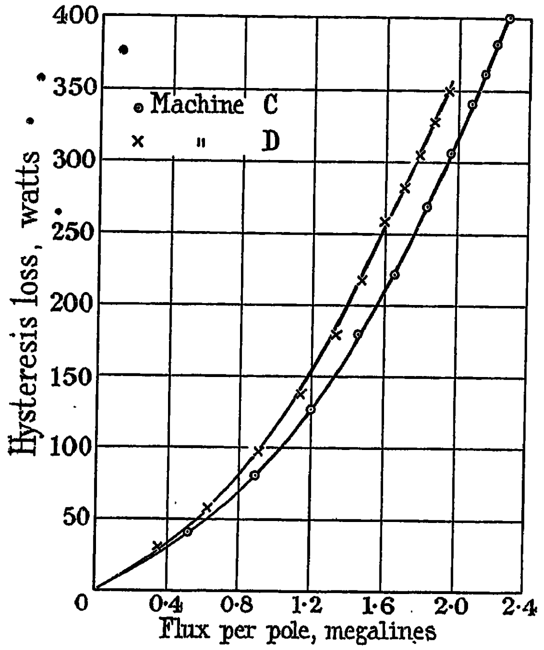

FIG. 3.

a straight line may be drawn through points covering a large range of flux density—including the flux densities usually employed in d.c. machines. To facilitate the

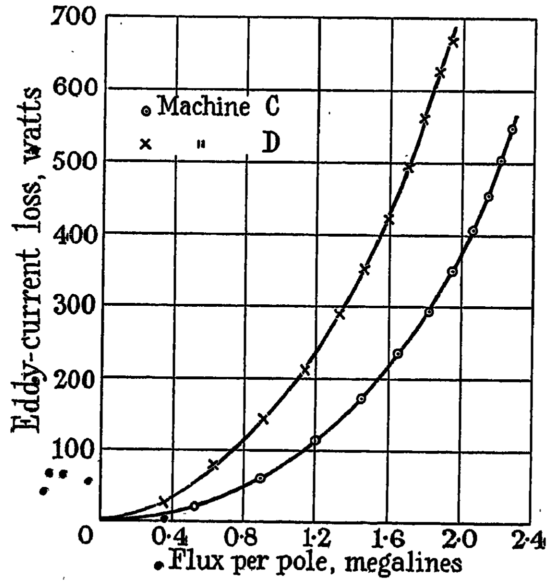

FIG. 4.

comparison of the indices, Table 1 has been compiled from the above curves.

From Table 1 it is seen that the indices for the hysteresis and eddy-current losses vary considerably for different flux densities and for different machines. This illustrates the difficulty of predetermining the iron losses and especially of calculating the losses for the teeth and the core separately.

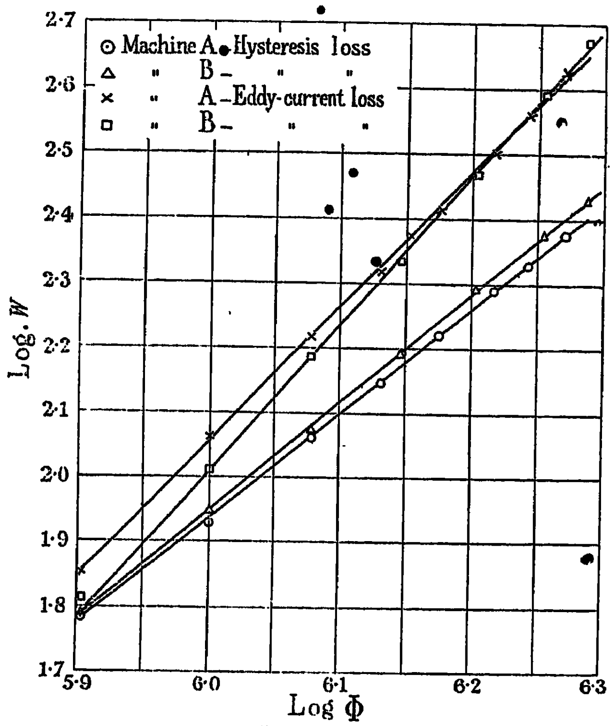

FIG. 5.

It will also be noticed from Figs. 5, 6 and 7 that there is no indication whatever of the hysteresis loss decreasing at high flux densities. Only in the case of machine F —constructed of soft-iron laminations—does the index

son,* working with a sinusoidal flux wave, found that up to a flux density of 19 500 lines/cm^2 the hysteresis loss in stalloy varied as $B_{max.}^{1\cdot 58}$; but that for higher flux densities the index appeared to increase rapidly.

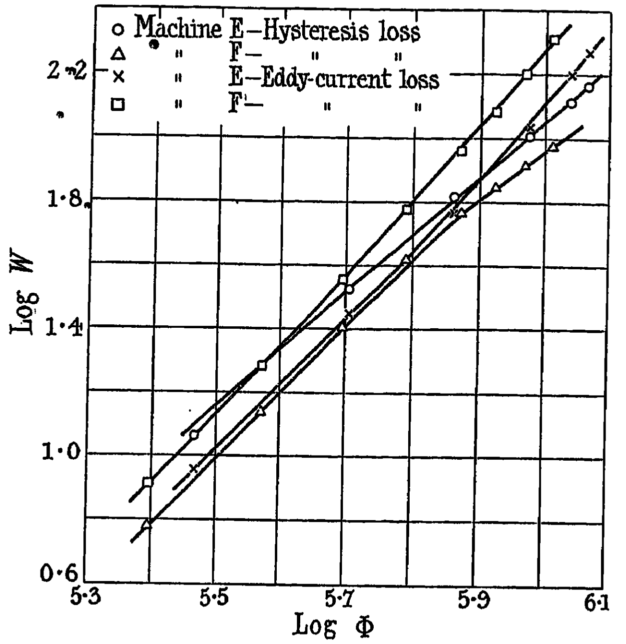

FIG. 7.

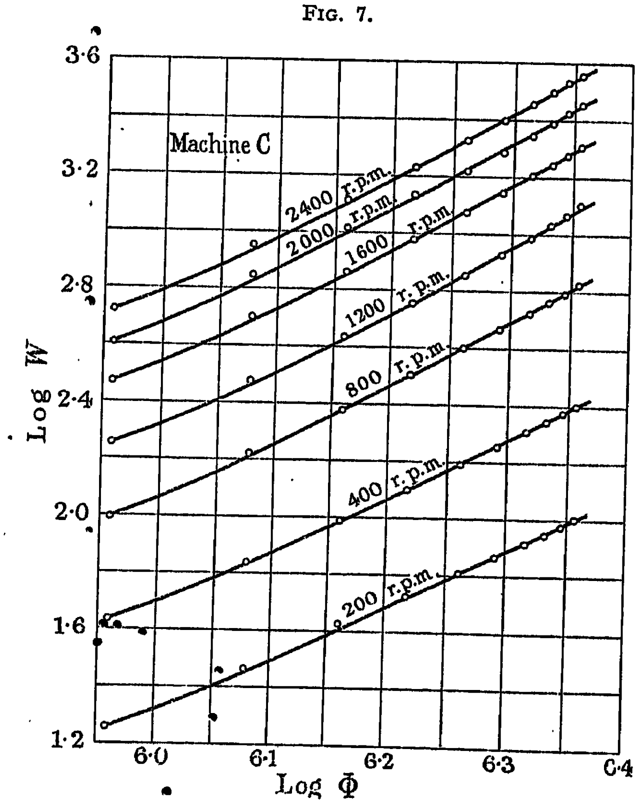

FIG. 8.

* "The Magnetization of Iron at High Flux Density with Alternating Currents," *Journal I.E.E.*, 1915, vol. 53, p. 253.

Also, Lloyd * cites results obtained on a modified Epstein tester, where the hysteresis exponent for the majority of the specimens increased from about 1·6 for a flux density of 5 000 to about 2 for 10 000 lines/cm^2.

In view of the wide variations in the exponents of the hysteresis and eddy-current losses, it was decided to determine the ranges of speed and of flux over which the *total* core loss could be expressed with sufficient accuracy by a simple expression of the form

$$W = an^x\Phi^y$$

where $\qquad n =$ speed in r.p.m.

Curves were drawn of log W against log Φ and also of log W against log n for the various machines at different speeds and at different fluxes respectively. Figs. 8 to 11 for machines C and D are typical of the results obtained; and it will be noticed that the relationships are linear over a large range of flux density and over a surprisingly large range of speed. For purposes of comparison, the results derived from the curves for the six machines are given in Table 2.

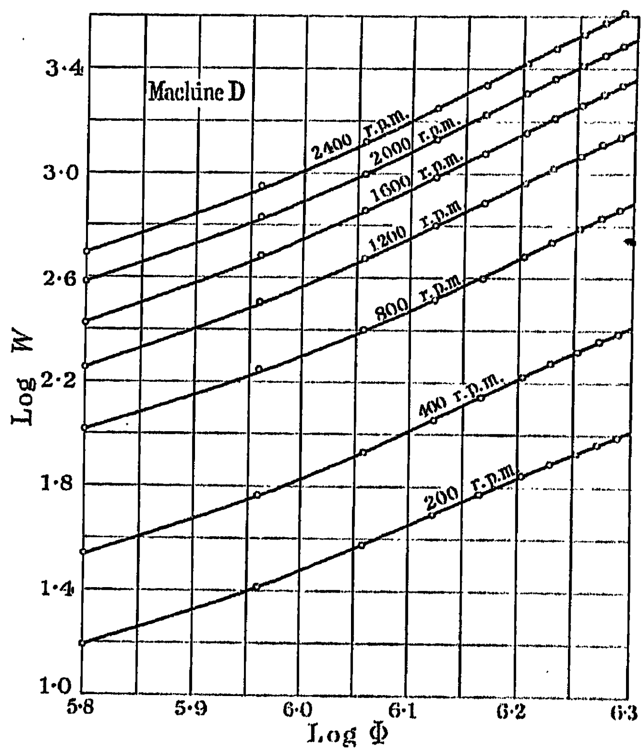

FIG. 9.

The average values of x and y in Table 2 are 1·50 and 2·06 respectively, so that the total iron loss is fairly closely represented by

$$W = an^{1\cdot 5}\Phi^2$$

It will be noticed that the index of the flux is the same as that given by Macfarlane and Burge and by Schukkerman (see page 35), but that the index of the speed or frequency is 1·5 instead of 1·3.

* "Magnetic Testing of Iron," *Electrician*, 1909, vol. 64, p. 319.

A comparison of Tables 1 and 2 and a reference to Figs. 1 and 2 are sufficient to indicate that more consistent values of the exponents for the iron loss are obtained from the total iron loss than from the hysteresis and eddy-current losses considered separately; and that, in general, the values of iron loss calculated from the simple expression $an^{1.5}\Phi^2$ are quite as reliable as those based upon an expression of the form

$$(bn\Phi^{1.7} + cn^2\Phi^2)$$

where b and c are constants for the hysteresis and eddy-current losses respectively.

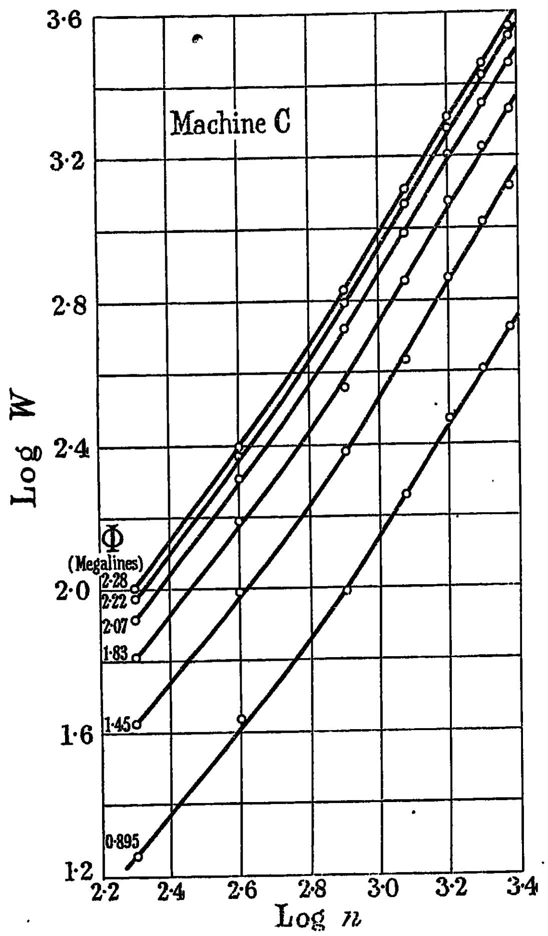

Fig. 10.

Core loss in terms of volume.—Assuming the symbols given on page 35 and making use of the indices just derived, we have:—

$$\text{Total core loss} = W = kf^{1.5}(V_aB_a^2 + V_tB_t^2)$$

If A_a = area of armature core per pole,

and A_t = average area of teeth carrying flux per pole,

then $B_t = \dfrac{A_a}{A_t}B_a$

$$\therefore \quad W = kf^{1.5}B_a^2\{V_a + (A_a/A_t)^2V_t\}$$

$$= k_1f^{1.5}B_a^2 \text{ for a given machine.}$$

The best values of k_1 and of k have been determined for the different machines and are given in Table 3.

The values of k derived for machines A, B, C and E agree very closely with one another, whilst the values for machines D and F are considerably higher. The increased eddy-current loss in D has already been referred to on page 36, and is probably due to the flux pulsation and oscillation caused by the slots containing the compensating winding. The larger coefficient

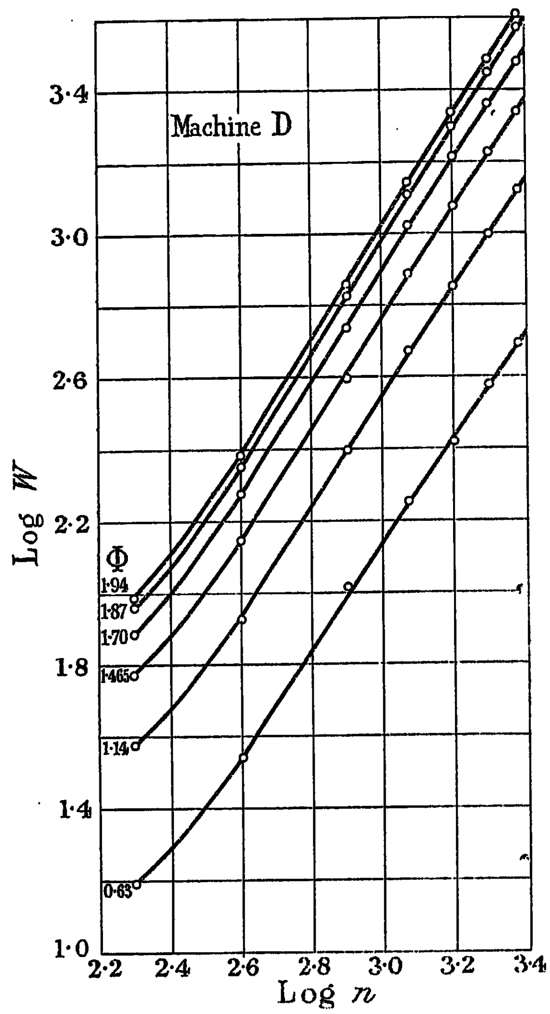

Fig. 11.

for machine F, on the other hand, is mainly due to the laminations being of charcoal iron.

In order to illustrate how closely the core losses calculated from the coefficients given in Table 3 agree with the measured losses, Table 4 has been compiled. For convenience of comparison the ratio of the two values has also been included; and it will be noticed that in the majority of cases the calculated value is within 5 per cent of the measured value over a wide range of frequency and flux density.

Section 2. Influence of Cross Flux and of Commutating-Pole Flux upon Iron Loss in D.C. Machines.

The first section of this paper dealt with undistorted flux, the iron loss being in all cases measured on no

load. When a machine is on load, however, it is well known that the field distortion due to armature reaction increases the iron loss, but it is generally difficult to determine the magnitude of this increase. The weaker the main field in comparison with the cross field, the greater the flux distortion and consequently the greater the increase in the iron loss. There are many cases, such as variable-speed motors, where the predetermination of the iron loss on load is of particular importance, since the maximum load in such machines usually occurs at the highest speed. At the same time, it is necessary to realize that the iron loss depends upon so many factors of construction as well as of material that a very elaborate method of calculating the iron loss is practically useless.

General expressions for eddy-current losses in dynamo teeth and in the pole faces have been derived mathematically by Press * and by Carter †; but these expressions are based upon various assumptions relating to flux distribution, etc., contain unknown constants and are so cumbersome that they are hardly likely to be adopted by the average designer. It is doubtful

whether the results deduced from such expressions, which account for only a portion of the total loss, will be nearer the actual value than those based upon much simpler expressions. In the paper already referred to on page 35, Lamme states that "while the no-load losses are difficult to predetermine, the full-load losses are still much more difficult to calculate," and he then goes on to give a rough qualitative analysis of the problem.

It was with the purpose of discovering whether the incremental iron losses could be calculated easily and fairly accurately over a wide range of speed, load and excitation that the tests described below were carried out. Machine D referred to in Section 1 of this paper was fitted with a compensating winding. By passing a current through the latter and by separately exciting the field winding it was possible to measure the iron losses at different excitations and with different degrees of distortion. The input power was measured as already described on page 36. No current was passed through the C.P.* winding, partly to simplify the test, but mainly because the flux density under the commutating poles due to the current in the compensating winding happened to be approximately what might be expected in a normal machine. The brushes were lifted off the commutator to eliminate any currents circulating round the armature winding. Fig. 12 shows the results obtained at 2 000 r.p.m., these curves being typical of those obtained at the other speeds; and the losses at different speeds, etc., are given in Table 5.

The iron losses in the machine under test may be resolved into :—

(*a*) Iron loss in teeth under commutating poles.
(*b*) Iron loss in teeth under main poles.
(*c*) Iron loss in armature core.

(*a*) *Iron loss in teeth under commutating poles.*—It is curious that this loss is never referred to as being partly responsible for the incremental loss. This is probably due to the impression that owing to the comparatively low flux density and the short duration of the period of magnetization the iron loss is negligibly small. This, however, is far from being the case. For instance, the hysteresis loss per period depends upon the maximum flux density and is independent † of frequencies obtaining in a d.c. machine. The period of magnetization is slightly unsymmetrical, but the effect is too small to be detected (see page 50). It therefore matters not whether a tooth be passing a commutating pole or a main pole; the hysteresis loss per cm³ per period is exactly the same for a given maximum flux density. From this point of view the integration method suggested by Thornton ‡ for calculating the heating effect of hysteresis loss in an armature is not correct.

Let us next consider the eddy-current loss. This loss may be regarded as being due to two distinct causes; first, the teeth in moving through the flux generate an E.M.F. in just the same way as do the

* Commutating pole.

armature conductors. The path of the eddy currents due to these "speed" E.M.F.'s is mainly radial, but it seems impossible to calculate the resistance of this path with any degree of accuracy. The main features of these eddies, however, is that they are directly proportional to the flux density and that their duration is practically proportional to the width of the C.P. shoe. Consequently the loss due to these eddies should be comparatively small.

The second cause of eddy-current loss is the transformer action that occurs in each tooth as it moves into and out of a magnetic field, eddy currents being induced transversely in the tooth of each lamination. So long as a tooth is moving in a field of uniform strength, the loss due to this cause is zero. Consequently, the width of the pole arc has no effect, and the loss for a given flux density is just as large when a tooth passes into and out of the C.P. field as when it passes into and out of the main-pole field.

Circumstances prevented the author from carrying out any further tests on machine D, so that it was not possible to check the iron loss due to the C.P. flux alone for that machine. Tests were therefore carried out on another machine G of about the same size, and in order to avoid confusion at this point the results are given in Appendix 2. The conclusions from these tests, however, may be briefly stated thus:—

(i) The polarity of the commutating poles relatively to that of the main poles has no measurable effect upon the loss due to C.P. flux.

(ii) The increase in the iron loss due to a given current in the C.P. winding is practically independent of the flux in the main poles.

(iii) The loss due to the C.P. flux calculated from the expression $kf^{1.5}B^2V_t$ with the value of k derived from the loss due to the main-pole flux alone, agrees fairly closely with the actual loss over a wide range of C.P. flux.

These results enable us to proceed with the calculation of the loss in the teeth under the commutating poles, the figures for machine D being:—

Length of C.P. gap = $0\cdot254$ cm
Tooth pitch at tip = $2\cdot8$ cm
Width of slot = $1\cdot15$ cm

Carter's correction coefficient = $0\cdot485$ for present case.

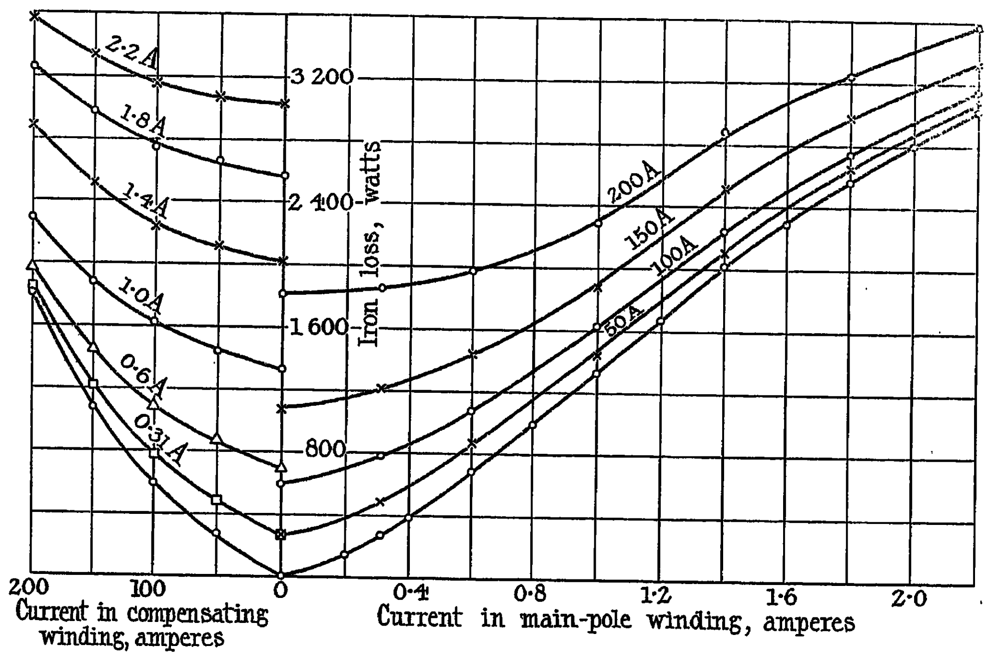

FIG. 12.

∴ Effective length of C.P. gap

$$= 0\cdot254 \times \frac{2\cdot8}{2\cdot8 - 0\cdot485 \times 1\cdot15}$$
$$= 0\cdot317 \text{ cm.}$$

With 200 amperes in the compensating winding the ampere-turns per pole acting on the C.P. magnetic circuit is

$$200 \times 6 = 1\,200$$

If the reluctance of the iron portion of the magnetic circuit be neglected in comparison with that of the air-gap, then the average flux density in C.P. air-gap

$$= \frac{1\,200}{0\cdot8 \times 0\cdot317}$$
$$= 4\cdot74 \text{ kilolines/cm}^2.$$

Size of C.P. shoe = $11 \cdot 44 \times 3 \cdot 175$ cm.
Flux per tooth pitch per cm axial length of core

$$= 4 \cdot 74 \times 2 \cdot 8$$
$$= 6 \cdot 91 \text{ kilolines.}$$

Average wide of tooth = $1 \cdot 41$ cm.

$$\therefore \text{Average flux density in tooth} = \frac{6 \cdot 91}{1 \cdot 41 \times 0 \cdot 9}$$
$$= 5 \cdot 45 \text{ kilolines/cm}^2.$$

The armature core had two vent ducts under the C.P. shoe, so that the effective length of core carrying flux under the commutating poles may be taken to be approximately the same as that of the C.P. shoe.

Hence volume of teeth subjected to the C.P. flux is

$$1 \cdot 41 \times 2 \cdot 86 \times 11 \cdot 44 \times 0 \cdot 9 \times 37 = 1\,530 \text{ cm}^3.$$

In Section 1 it was found that the iron loss of this machine is given by

$$W = 4 \cdot 2 \times 10^{-6} f^{1 \cdot 5} B^2 V$$

Hence, at 2 000 r.p.m. and with 200 amperes in the compensating winding, iron loss in teeth under C.P.

$$= 4 \cdot 2 \times 10^{-6} \times \left(\frac{2\,000 \times 2}{60}\right)^{1 \cdot 5} \times (5 \cdot 45)^2 \times 1\,530$$
$$= 383 \text{ watts.}$$

The effect upon the C.P. flux of its superposition upon the main-pole flux in certain portions of the yoke was estimated, but the reduction was found to be comparatively small; and any effect upon the loss is negligible, as shown experimentally in Appendix 2.

If the C.P. flux be assumed proportional to the current in the compensating winding, then iron loss in teeth under C.P. is 215 watts with 150 amperes, 96 watts with 100 amperes and 24 watts with 50 amperes.

(*b*) *Iron loss in teeth under main poles.*—The remarks concerning hysteresis and eddy-current losses made in connection with the C.P. flux apply equally well here. The problem is further complicated, however, by the fact that the flux density varies over the pole face and may even become reversed, as indicated in Fig. 14, when the main field is weak relatively to the cross field.

If the magnetization curve be as represented in Fig. 15, then for an excitation OA with undistorted field, the flux density is uniform and proportional to AH.

Let I = total current through armature,
q = number of parallel circuits through armature,
C = total number of armature conductors,
p = pairs of poles,
and ψ = pole arc/pole pitch.

Then cross ampere-turns per pole acting at pole-tips

$$= \frac{I}{q} \cdot \frac{C}{2} \cdot \frac{\psi}{2p}$$

If AC and AB be made to represent these cross ampere-turns per pole, the distribution of the flux over the pole arc is given fairly closely by the curve JHG. Further refinements in determining this distribution are hardly justifiable in the present problem. The flux per pole is therefore given by BN, the average height of JHG; and the maximum density at the mean section of the teeth is given by

$$B_1 = \frac{\text{flux CG}}{\text{average area of teeth carrying flux per pole}}$$
$$= \frac{\text{flux CG}}{109 \cdot 25} \text{ for the present case.}$$

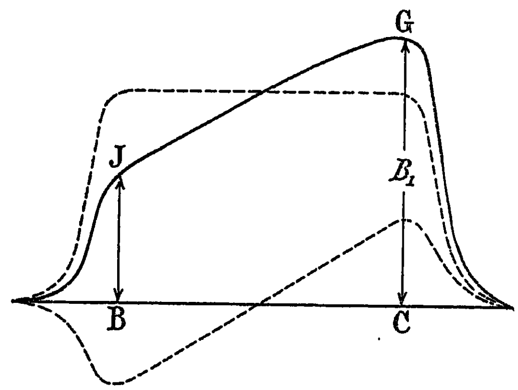

FIG. 13.

With a comparatively weak excitation, such as OD, the flux distribution is represented by Fig. 14, the resultant flux per pole being given by the average height FP of the curve MLK. The flux density at

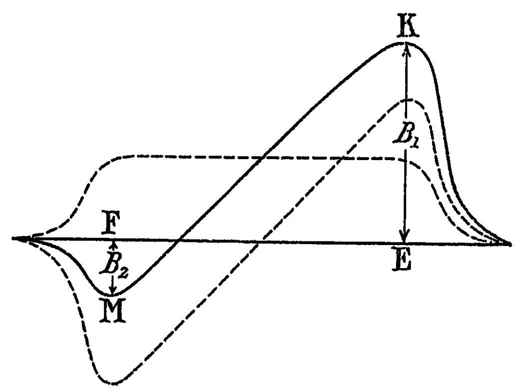

FIG. 14.

the mean section of the teeth under one pole-tip is given by $B_1 = \dfrac{\text{flux EK}}{109 \cdot 25}$, whilst that under the other pole-tip is given by $B_2 = \dfrac{\text{flux FM}}{109 \cdot 25}$.

The hysteresis loss in the teeth with a flux distribution as in Fig. 13 depends only upon the flux density corresponding to CG; but with a flux distribution like that of Fig. 14 the hysteresis loss is made up of two distinct components, namely that due to magnetization EK and that due to magnetization FM.

The effect of distortion upon the eddy-current loss may be considered in a general way thus :—

Suppose the distribution of undistorted flux round the periphery of the armature to be represented by

$$B_\theta = B_1 \sin\theta \pm B_3 \sin 3\theta \pm B_5 \sin 5\theta \pm \quad . \quad . \quad .$$

where B_1, B_3, etc., are the amplitudes of the fundamental and harmonic flux waves.

Then E.M.F. generated by rotation in flux density B_θ $\Big\} \propto B_\theta$

$\therefore$ corresponding value of eddy loss per cm³ $\Big\} \propto B_\theta^2$

$$= kB_\theta^2$$

where k is a constant.

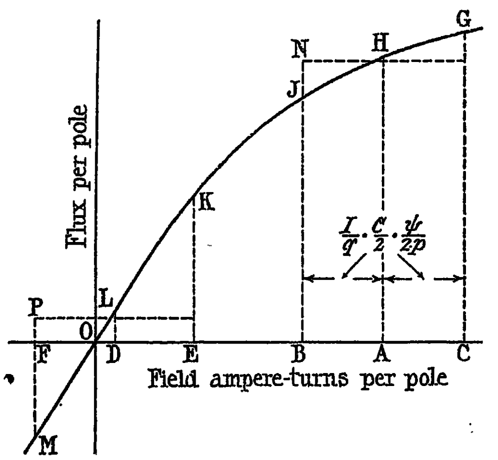

FIG. 15.

Hence average value of eddy loss per cm³ over pole pitch

$$= \frac{k}{\pi}\int_0^\pi B_\theta^2 d\theta$$

$$= \frac{k}{2}(B_1^2 + B_3^2 + B_5^2 + \ldots) \quad . \quad . \quad . \quad (1)$$

Again, instantaneous E.M.F. induced in teeth by transformer action

$$\propto \frac{d}{d\theta}B_\theta$$

$$\propto (B_1 \cos\theta \pm 3B_3 \cos 3\theta \pm 5B_5 \cos 5\theta \pm \ldots)$$

$\therefore$ corresponding value of eddy loss per cm³

$$= k_1(B_1 \cos\theta \pm 3B_3 \cos 3\theta \pm 5B_5 \cos 5\theta \pm \ldots)^2$$

where k_1 is another constant.

Hence average value of eddy loss per cm³ over pole pitch

$$= \frac{k_1}{\pi}\int_0^\pi (B_1 \cos\theta \pm 3B_3 \cos 3\theta \pm 5B_5 \cos 5\theta \pm \ldots)^2 d\theta$$

$$= \frac{k_1}{2}(B_1^2 + 9B_3^2 + 25B_5^2 + \ldots) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

A comparison of expressions (1) and (2) shows that harmonics in the flux wave have a much greater effect upon the eddy loss due to transformer action than upon that due to rotation.

Let us next consider the effect of distortion. If saturation were neglected, the distribution of the cross flux would be symmetrical and could be represented by an expression of the form

$$B_{c\theta} = B_{c1} \sin(\theta - 90) \pm B_{c3} \sin 3(\theta - 90) \pm B_{c5} \sin 5(\theta - 90) \pm \ldots$$
$$= B_{c1} \sin(\theta - 90) \pm B_{c3} \sin(3\theta + 90) \pm B_{c5} \sin(5\theta - 90) \pm \ldots$$

Hence the fundamental and the harmonics of the cross-flux wave are each in quadrature with the fundamental and respective harmonics of the main-flux wave.

$\therefore$ amplitude of resultant fundamental $= \sqrt{(B_1^2 + B_{c1}^2)}$

amplitude of resultant 3rd harmonic $= \sqrt{(B_3^2 + B_{c3}^2)}$

etc.

It can therefore be shown that the average value of eddy loss per cm³ due to rotation

$$= \tfrac{1}{2}k(B_1^2 + B_{c1}^2 + B_3^2 + B_{c3}^2 + \ldots)$$

and average value of eddy loss per cm³ due to transformer action

$$= \tfrac{1}{2}k_1\{B_1^2 + B_{c1}^2 + 9(B_3^2 + B_{c3}^2) + 25(B_5^2 + B_{c5}^2) + \ldots\}$$

It will be obvious from Figs. 13 and 14 that the wave of cross flux consists mainly of harmonics, so that a relatively large increase of eddy-current loss must result. But the amplitudes of these harmonics vary with every variation of the main-pole excitation, and the relation between the eddy loss due to transformer action and that due to rotation is not known and could only be calculated very crudely; consequently it would not be worth while to analyse the flux waves for any particular case. The principal deduction from the above analysis, however, is that the iron loss in the teeth increases rapidly with flux distortion, and may therefore be regarded as being dependent upon the maximum flux density; but the extent of this dependence can only be checked by experiment.

The flux distribution under the main pole of machine D was determined from the magnetization curve for each of the various field excitations and currents in the compensating winding. The flux density at the mid-section of a tooth was calculated under the strengthened pole-tip; and in those cases where the field under the other pole-tip was reversed, the corresponding flux density was also calculated.

If B_1 = flux density in kilolines/cm² at the mid-point of a tooth under the strengthened pole-tip,

B_2 = corresponding value for a tooth under the other pole-tip, when the flux is reversed as in Fig. 14,

and V_t = total volume of teeth in cm³,

then the iron loss in the teeth has been calculated from

$$W_t = 4{\cdot}2 \times 10^{-6} f^{1{\cdot}5} V_t (B_1^2 + B_2^2) \text{ watts.}$$

At a speed of 2 000 r.p.m.,

$$W_t = 4{\cdot}2 \times 10^{-6} \times \left(\frac{2\,000 \times 2}{60}\right)^{1{\cdot}5} \times 1\,880(B_1^2 + B_2^2)$$
$$= 4{\cdot}31(B_1^2 + B_2^2).$$

(c) *Iron loss in armature core.*—It has already been pointed out (page 43) that the C.P. flux appears to have no effect upon the loss due to the main flux. This is probably due partly to the main-pole flux causing a slight decrease of the C.P. flux and reducing the iron loss in the teeth under the commutating poles by about the same amount as any increase of the core loss; and partly to the C.P. flux altering the distribution of flux in the armature core rather than increasing the density in those parts where the density due to the main flux is already high.

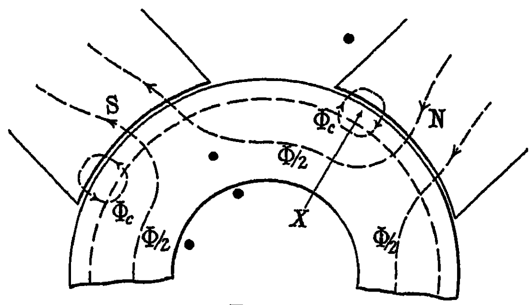

Fig. 16.

When the distribution is of the form indicated in Fig. 13, the flux density in the armature core is obtained from the total flux per pole represented by BN in Fig. 15. With such a distribution as that of Fig. 14, on the other hand, the flux which re-enters the pole-face has to be carried by a part of the armature core that is working at a comparatively high flux density, the distribution of flux over the cross-section being far from uniform.* Hence if Φ be the resultant flux per pole, Φ_c the cross-flux re-entering the pole-shoe, and A the sectional area per pole of the armature core, then average flux density at section X (Fig. 16)

$$= B_a = (\tfrac{1}{2}\Phi + \Phi_c) \div \tfrac{1}{2}A$$
$$= \frac{\Phi + 2\Phi_c}{A}$$

The value of Φ_c can be derived from Fig. 15 thus:—

Φ_c = average ordinate of curve OM(OF/FE)
$\doteqdot \tfrac{1}{2}$FM(OF/FE)

The value of Φ is given by FP, the average ordinate of curve MLK, as already explained on page 44.

* W. M. Thornton: "The Distribution of Magnetic Induction and Hysteresis Loss in Armatures," *Journal I.E.E.*, 1906, vol. 37, p. 125.

If B_a = flux density in kilolines/cm², and V_a = volume of armature core in cm³, then iron loss in armature core

$$= W_a = 4\cdot 2 \times 10^{-6} f^{1.5} B_a^2 V_a$$

At a speed of 2 000 r.p.m.,

$$W_a = 4\cdot 2 \times 10^{-6} \times \left(\frac{2\,000 \times 2}{60}\right)^{1\cdot 5} \times 6\,370 B_a^2$$

$$= 14\cdot 6 B_a^2$$

Comparison of calculated losses with measured losses.—The losses have been calculated for a speed of 2 000 r.p.m. and the results are incorporated in Table 6; and in order to show how the calculated values and the measured values compare over a wide range of speed, excitation and distortion, Table 7 has also been compiled. It will be seen that the figures agree remarkably well, considering the simple expressions employed and the very wide ranges covered. The agreement is as good as is required in the calculation of iron losses unless the conditions are exceptional.

It may be added that 200 amperes through the compensating winding of the machine under test corresponds to an armature loading of 214 ampere-conductors per cm of the periphery.

CONCLUSIONS.

Section 1.

(1) In a d.c. machine the hysteresis loss varies as B^x, where x lies between about 1·6 and 1·8, and the eddy-current loss varies as B^y, where y lies between about 2 and 2·4.

(2) The hysteresis loss in a toothed armature does not show any sign of decreasing with increasing flux densities of the values generally employed in d.c. armatures. Up to an apparent flux density of 23·5 kilolines/cm² at the tooth root, the hysteresis exponent remains constant over a large range of flux density; hence results obtained for rotational hysteresis loss are not applicable to armature teeth.

(3) The eddy-current exponent is generally greater than 2, even for comparatively low flux densities. This appears to be mainly due to the flux distribution in the armature core becoming less uniform with increasing excitation.

(4) Above about 50 periods per second, the eddy-current loss does not continue to increase as the square of the frequency.

(5) More consistent values of the exponents of B and f are obtained from the total iron loss than from the hysteresis and eddy-current losses separately; and the total iron loss can be calculated with fair accuracy over wide ranges of frequency and of flux density from the expression

$$W = kf^{1\cdot 5}(V_a B_a^2 + V_t B_t^2)$$

$$= k_1 f^{1\cdot 5} B_a^2 \text{ for a given armature,}$$

where B_a = flux density in armature core,

and B_t = mean flux density in teeth.

(6) The value of k for lohys laminations, 0·018 in. thick, may be taken as 3×10^{-6} when the flux density is in kilolines/cm² and the volume in cm³.

In terms of the weight in lb. of the armature core and teeth, the iron loss may be expressed as

$$W = k_2 f^{1\cdot 5}(W_a B_a^2 + W_t B_t^2)$$

where $k_2 = 58\cdot 2k$
$= 1\cdot 75 \times 10^{-4}$ for 0·018 in. lohys.

Thus for a flux density of 10 kilolines/cm² at 50 periods per second,

$$\text{Iron loss per lb.} = 1\cdot75 \times 10^{-4} \times (50)^{1\cdot5} \times (10)^2 = 6\cdot18 \text{ watts.}$$

It is of interest to note that the makers give the loss as 1·55 watts per lb. when the laminations are tested with an alternating flux under the most favourable conditions. It may also be pointed out that the value of the core loss to be found in most textbooks on dynamo design are much smaller than those given in this paper.

For convenience in the application of the above formulæ, the iron loss at different frequencies and flux densities has been plotted in Fig. 17.

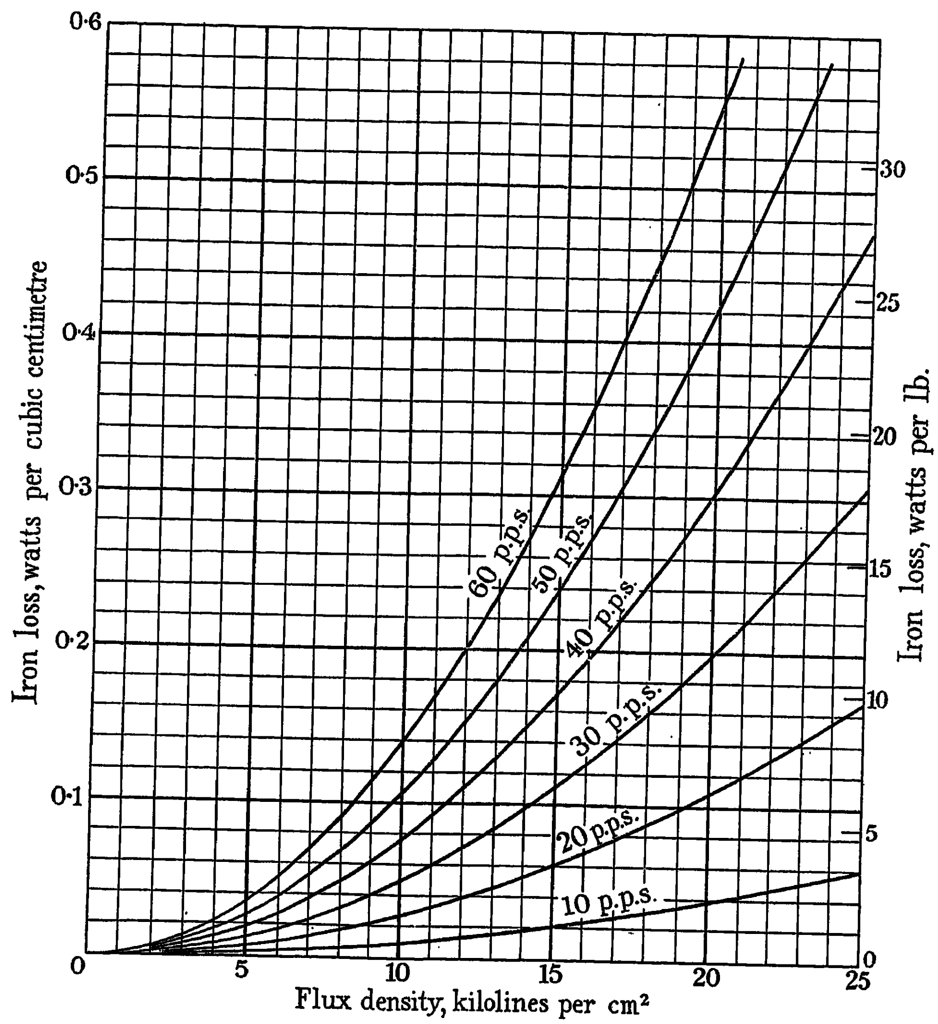

FIG. 17 —Iron loss in 0·018 in. lohys laminations for d.c. machines.

Section 2.

(1) The increase of iron loss due to a given current in the C.P. winding is independent of the flux in the main poles.

(2) The polarity of the commutating poles relatively to that of the main poles has no effect upon the loss due to the C.P. flux.

(3) The total iron loss with any degree of distortion is given fairly closely by the sum of the following losses :

(*a*) Tooth loss due to C.P. flux $= W_c = kf^{1\cdot5}B_t^2V_t'$

where k = constant derived for iron loss with undistorted field,
f = frequency of machine,
B_t = mean flux density in teeth under C.P.,
and V_t' = volume of teeth subjected to C.P. flux.

(*b*) When flux is not reversed at one pole-tip, tooth loss due to main-pole flux is

$$W_t = kf^{1\cdot5}B_1^2V_t$$

When flux is reversed at one pole-tip (Fig. 14), tooth loss due to main-pole flux is

$$W_t = kf^{1\cdot5}(B_1^2 + B_2^2)V_t,$$

where k = same constant as before,
V_t = total volume of teeth,
B_1 = mean flux density in tooth under strengthened pole-tip,

$$= \frac{\text{flux KE}}{\text{mean area of teeth carrying flux per pole for excitation OD (Fig. 15)}},$$

and B_2 = ditto under pole-tip at which flux is reversed

$$= \frac{\text{flux FM}}{\text{mean area of teeth carrying flux per pole for excitation OD.}}$$

(c) Loss in armature core $= W_a = kf^{1\cdot5}B_a^2 V_a$

where k = same constant as above,
V_a = volume of armature core carrying flux,
and

$$B_a = \frac{\Phi + 2\Phi_c}{A}$$

where Φ = resultant flux per pole,
Φ_c = cross flux (if any) re-entering pole-shoe, $\fallingdotseq \frac{1}{2}$FM(OF/FE) in Fig. 15,
and A = sectional area per pole of magnetic circuit through armature core.

Then total iron loss $= W_c + W_t + W_a$.

The author wishes to thank Prof. F. G. Baily for permission to carry out the tests on machines A to D at the Heriot-Watt College, Edinburgh. The remainder of the work was done at the Municipal Technical College, Brighton.

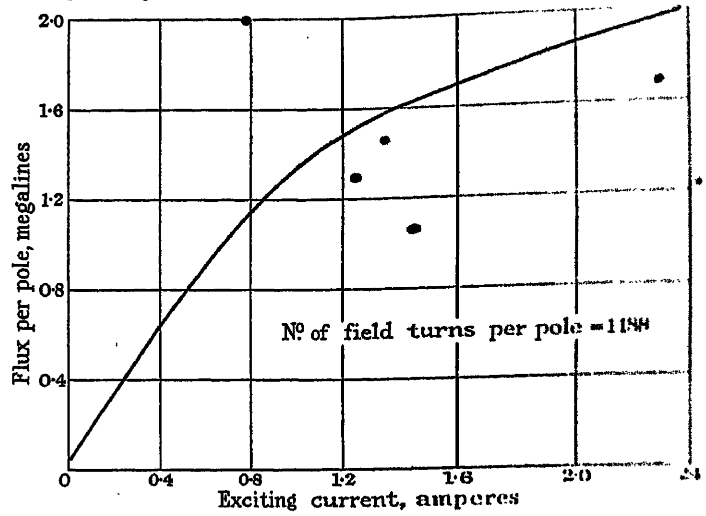

Fig. 18.

APPENDIX 1.

Note.—Particulars of the machines referred to in the paper.

Machine	A	B	C	D	E	F	G

The magnetization curve for Machine D is given in Fig. 18.

APPENDIX 2.

The tests described below were carried out on machine G to determine the effect of the C.P. flux upon the iron loss. Both the commutating poles and the main poles were separately excited, the iron loss being determined by measuring the input to the driving motor. The brushes of the machine under test were lifted, and correction was applied for the variation of the copper loss in the motor.

As the loss due to the C.P. flux was comparatively small and the supply voltage fluctuated a fair amount all the readings were repeated, the various points being indicated in the diagrams.

Curve A of Fig. 19 shows the input to the driving motor (after correction for copper loss) for different currents through the C.P. winding, the main poles being unexcited; and curve B shows the relation between the same quantities with full excitation on the main poles. It is evident from these curves that the iron loss due to the C.P. flux is independent of the polarity of the commutating poles relatively to that of

the main poles. Further, the two curves are so similar that we can conclude that the iron loss due to the C.P. flux is practically independent of the main-pole flux. Readings taken with a lower excitation on the main poles confirmed this conclusion.

The useful main-pole flux in the tests recorded in Fig. 19 was found to be 2·88 megalines, and the speed was maintained constant at 800 r.p.m. The corresponding flux density in the armature core is :—

$$B_a = \frac{2 \cdot 88 \times 1\,000}{290} = 9 \cdot 83 \text{ kilolines/cm}^2$$

From Fig. 19 the iron loss due to the main-pole excitation alone is 2 388 − 1 250 = 1 138 watts.

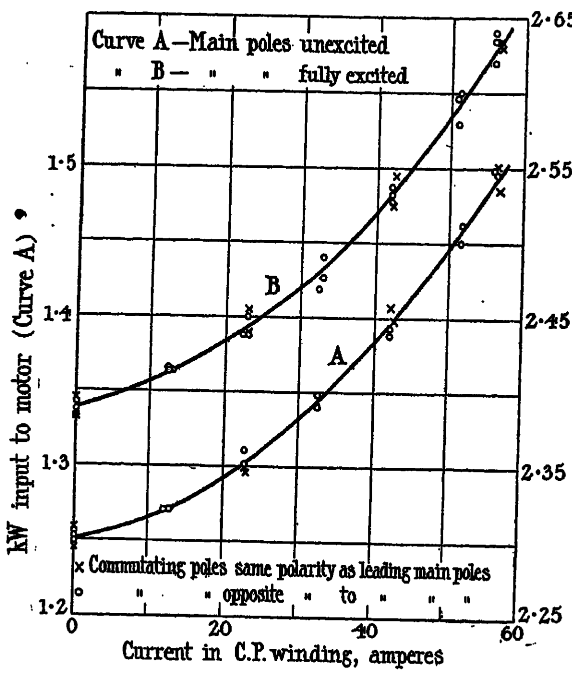

FIG. 19.

Hence from the expression on page 40 and the data in Appendix 1 we have

$$1\,138 = k \times \left(\frac{800 \times 2}{60}\right)^{1.5} \times (9 \cdot 83)^2 \times \left\{8\,920 + \left(\frac{290}{179 \cdot 2}\right)^2 \times 3\,340\right\}$$

$$\therefore k = 4 \cdot 7 \times 10^{-6}$$

At a flux of 2·26 megalines per pole the measured iron loss was 675 watts, and the corresponding value of k is $4 \cdot 56 \times 10^{-6}$. The average value of k may therefore be taken as $4 \cdot 6 \times 10^{-6}$.

Let us now see how the calculated values of the iron loss due to the C.P. flux compare with the measured values.

Full-load current of machine G = 85 amperes.

∴ Ampere-conductors per cm of periphery at full load = 191 and armature-turns per pole at full load = 2 480.

But ampere-turns per pole due to C.P. at full load

$$= 85 \times 44 = 3\,740.$$

∴ Net ampere-turns per pole acting on magnetic circuit of C.P. = 1 260.

Hence current through C.P. winding alone to produce same flux

$$\doteq 1\,260/44 = 28 \cdot 6 \text{ amperes.}$$

Let us therefore calculate the iron loss due to, say, 30 amperes through the C.P. winding alone.

Length of air-gap under C.P. = 0·30 cm (measured).

∴ Effective length of C.P. air-gap (see page 43)

$$= 0 \cdot 30 \times \frac{2 \cdot 66}{2 \cdot 66 - 0 \cdot 46 \times 1 \cdot 17} = 0 \cdot 376 \text{ cm.}$$

Flux density in C.P. air-gap

$$= \frac{30 \times 44}{0 \cdot 8 \times 0 \cdot 376} = 4\,390 \text{ lines/cm}^2.$$

∴ Flux density at mid-section of tooth

$$= 4\,390 \times \frac{\text{tooth pitch at tip}}{\text{average tooth width} \times 0 \cdot 9}$$

$$= 4\,390 \times \frac{2 \cdot 66}{1 \cdot 222 \times 0 \cdot 9} = 10\,600.$$

Axial length of C.P. shoe = 8·25 cm.

∴ Volume of teeth carrying C.P. flux

$$\doteq 3\,340 \times \frac{8 \cdot 25}{23 \cdot 5} = 1\,173 \text{ cm}^3.$$

Hence iron loss at 800 r.p.m.

$$= 4 \cdot 6 \times 10^{-6} \times \left(\frac{800 \times 2}{60}\right)^{1.5} \times (10 \cdot 6)^2 \times 1\,173 = 83 \cdot 8 \text{ watts.}$$

An estimate of the iron loss in the armature core due to the C.P. flux alone gave 1·8 watts, a negligible value compared with other losses.

The following table has been calculated on the assumption that the iron loss varies as the square of the current through the C.P. winding, and shows a fair agreement between the calculated and measured values.

Current in C.P. winding	Iron loss	
	Calculated	Measured
amperes	watts	watts
20	37·3	42
30	83·8	82
40	149	134
50	232	196

The application of these results has already been dealt with in Section 2 of the paper.

DIRECTIONS FOR THE STUDY OF NON-IGNITABLE AND SELF-EXTINGUISHING BOARDS AND MOULDINGS FOR ELECTRICAL PURPOSES.*

[REPORT (REF. A/S10) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

CONTENTS.

PREFACE.

Experience has shown that materials which purport to possess non-ignitable or self-extinguishing properties vary greatly in their ability to withstand a high temperature and exposure to atmospheric conditions.

These Directions have been drafted to meet the need for suitable tests to determine the merits of the many materials of this class on the market.

The materials covered by this specification have more or less well-defined electrical insulating characteristics in addition to their non-ignitable or self-extinguishing properties.

A large amount of experimental work has been carried out in proving the methods of test given herein, and the results of these tests will be embodied in a Report to be issued later.

With a view to the determination of the effect of ageing, an investigation has been put in hand, details of which are given in Clause 19.

The Director of the E.R.A. will value comments and criticism from those who have occasion to use this Specification.

I. DEFINITIONS AND CLASSIFICATION.

(a) *Definition of non-ignitable.*

A " non-ignitable " material is one which when heated under certain prescribed conditions neither burns itself nor gives off inflammable vapours.

(b) *Definition of self-extinguishing.*

A " self-extinguishing " material is one which, under certain prescribed conditions, does not continue in a state of combustion in air after the removal of the external source of heat.

(c) *Classification of non-ignitable and self-extinguishing boards and mouldings.*

Class A.—This includes non-ignitable asbestos boards and mouldings made of asbestos fibre and a binder of soapstone or other similar natural clay. The material withstands repeated exposure to an electric arc in air or a flame of high intensity, and at the same time possesses relatively high insulating characteristics both with regard to electric strength and resistance to surface breakdown. This class includes material used for arc shields on control apparatus and the like.

Class B.—This includes non-ignitable asbestos boards and mouldings made of asbestos fibre and a binder of Portland cement, lime or similar material. The material withstands repeated exposure to an electric arc in air or a flame of high intensity, and at the same time possesses relatively high insulating characteristics, both with regard to electric strength and resistance to surface breakdown. This class includes material used for arc shields on control apparatus and the like.

Class C.—This includes non-ignitable asbestos boards and mouldings of a material that withstands repeated exposure to an electric arc in air or flame of high intensity, but does not necessarily exhibit high insulating characteristics. This class includes materials suitable for a large number of structural purposes and as barriers in oil switches, cubicles, and the like. The majority of so-called asbestos cements on the market fall within this class.

Class D.—This includes self-extinguishing asbestos boards and mouldings of a material that withstands

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

the application of an electric arc in air or flame of high intensity for very short periods only, but possesses high insulating characteristics. This class includes the bitumen impregnated boards (frequently referred to as " Ebony " grades) which are suitable for terminal boards, relay boards, switchboards and the like.

Class E.—This includes asbestos millboard and similar materials made from asbestos fibre with the addition of a small amount of flexible binder. The material, although non-ignitable, is seriously affected with respect to its physical properties when subjected to repeated exposure to an electric arc in air or flame of high intensity.

NOTE.—It is to be understood that the classification of materials given above must be verified by the results of the tests outlined in this Specification.

II. METHODS OF TEST.

NOTE.—In view of the fact that individual specimens of the same material may vary greatly, it is necessary when determining a given property of the material to carry out tests on a sufficient number of specimens.

In the case of mouldings, the material for test shall be moulded into the form of a board not less than ¼ inch and not more than ½ inch thick, from which the specimens shall be cut.

1. CONDITIONING.

Before the tests specified in Clauses 2, 3, 4, 5, 6, 7, 8, 14, 15, 16, 17, and 18 are carried out the specimens shall be dried for 18 to 24 hours at a temperature from 75° C. to 80° C. for Classes A, B, C and E, and 40° C. to 45° C. for Class D. The test shall be conducted as soon as the temperature of the specimen has fallen to a value between 15° C. and 25° C.

2. DETERMINATION OF THICKNESS.

The specimen shall be conditioned in accordance with Clause 1 before the thickness is measured.

Measurements of thickness shall be made by means of a suitable micrometer at ten points equally spaced around the sides of the board. The maximum, minimum and mean values of thickness shall be stated.

3. DETERMINATION OF DENSITY.

The specimen shall be conditioned in accordance with Clause 1 before the density is determined.

A specimen 1½ inches square shall be used to determine the density of the material.

The area of the specimen shall be computed from the mean of five measurements of the length and the width respectively at points equally spaced along each of two edges at right angles. The thickness shall be determined by making ten measurements with a suitable micrometer equally spaced around the sides of the board, and the mean value shall be taken in computing the volume of the specimen.

The usual precautions shall be observed in weighing the specimen, and the weight shall be taken to the nearest milligramme.

The density shall be expressed in terms of weight in grammes per cm^3.

4. TENSILE STRENGTH, EXTENSION AND PLASTIC YIELD UNDER CONTINUOUS LOAD (NOT TO BE APPLIED TO CLASS E MATERIAL).

The specimen shall be conditioned in accordance with Clause 1 before the tests for tensile strength and extension are carried out.

The form and dimensions of the specimen shall be as shown in Fig. 1. The thickness of the test bar shall be the thickness of the material.

(*a*) The specimen shall be tested to ascertain the ultimate tensile strength and the extension on a 3-inch gauge length.

The load shall be increased steadily at such a rate that the specimen breaks in approximately two minutes from the time of the application of the load.

The ultimate tensile strength shall be expressed in lb. per square inch. The extension shall be expressed as a percentage on the original gauge length.

(*b*) The specimen shall be tested to ascertain the extension on a 3-inch gauge length when subjected

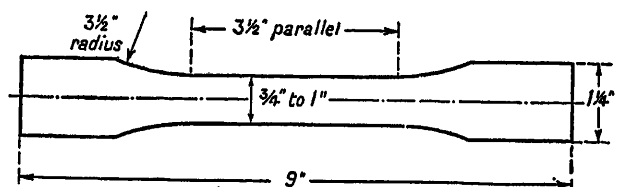

FIG. 1.—Specimen for Tensile Strength and Extension Tests.

continuously to a load of a value equal to one-third of the breaking load, determined by test (*a*). The load shall be maintained until the increase of strain ceases.

5. COMPRESSION STRENGTH (NOT TO BE APPLIED TO CLASS E MATERIAL).

The specimen shall be conditioned in accordance with Clause 1 before the compression strength test is carried out.

The dimensions of the specimen for test shall be 1 inch cube, the specimen being built up with several layers of the material when necessary. The layers of the material shall be bedded together by the application of an initial load of 300 lb. per square inch, and the first measurement of the length of the specimen shall be taken under this load, which shall be included in the load registered in each case.

A series of tests shall then be carried out at a temperature from 15° C. to 25° C. by the application of increasing loads of 1 500 lb. per square inch, each of which shall be maintained for one minute, and the yield of the specimen shall be measured at the end of each period. The tests shall be continued until the specimen has yielded 10 per cent of its original length, when measured as stated above, or the load has reached to about 6 tons per square inch.

6. SHEARING STRENGTH (NOT TO BE APPLIED TO CLASS E MATERIAL).

The specimen shall be conditioned in accordance with Clause 1 before the shearing strength test is carried out.

A specimen 5 inches long and 2½ inches wide shall be

clamped in a shear testing jig so that both ends of the specimen are sheared off simultaneously.

The load shall be applied steadily and shall be increased at a rate of approximately 100 lb. per minute for each 1/32 inch thickness of the specimen.

The pressure required to produce shear shall be computed on the total area of the sections sheared, and shall be expressed in lb. per square inch.

A suitable form of jig for the shear test is shown in Fig. 2.

200° C. to 205° C. for 24 hours, and shall then be subjected to an Impact Test as before, as soon as the temperature of the specimens has fallen to a value between 15° C. and 25° C.

8. Stiffness or Rigidity (not to be applied to Class E Material).

The specimen shall be conditioned in accordance with Clause 1 before the test for stiffness or rigidity is carried out.

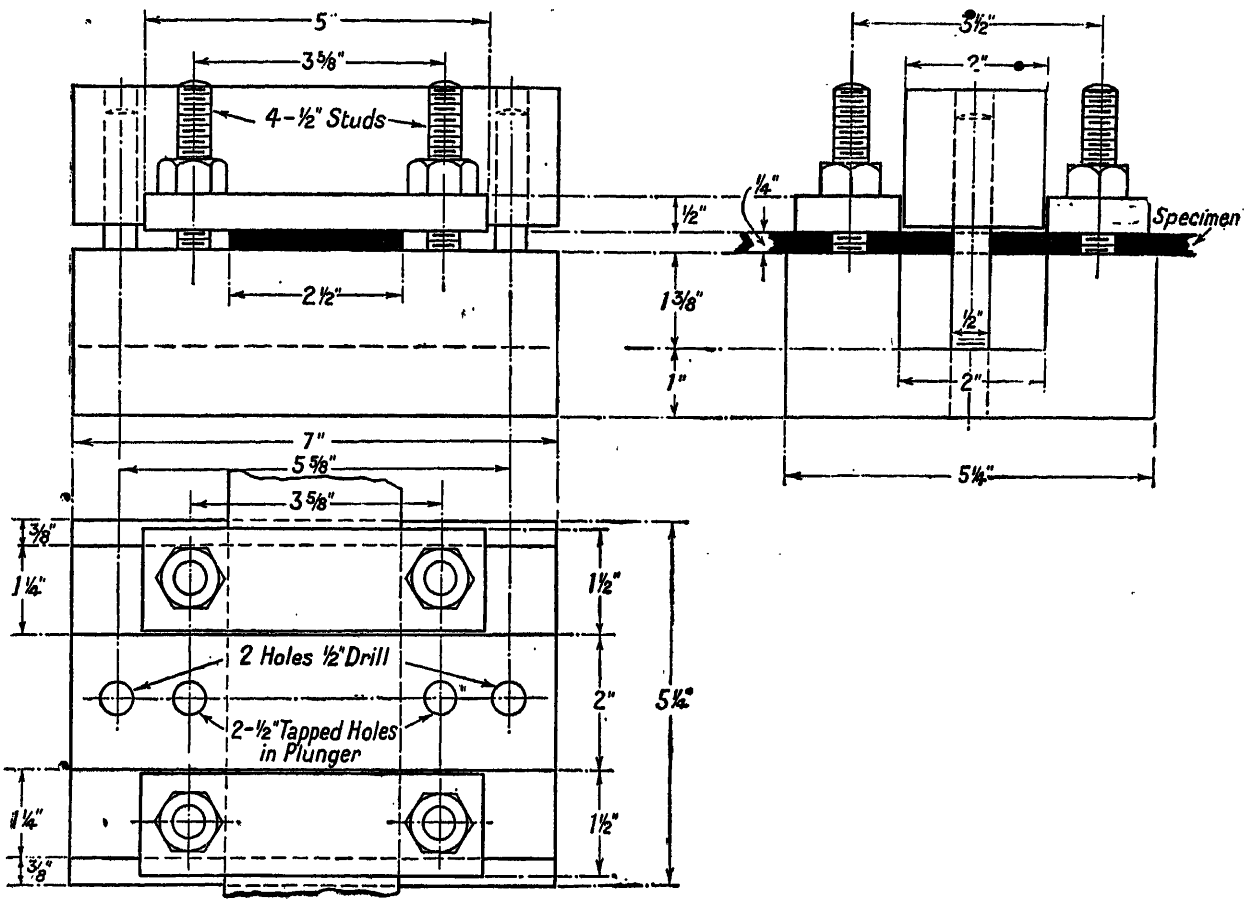

Fig. 2.—Form of Jig for the Shear Test.

7. Impact Test (Brittleness) (not to be applied to Class E Material).

The specimens shall be conditioned in accordance with Clause 1 before the impact test is carried out.

(a) Specimens 3 inches long and 2 inches wide shall be cut from the board. The thickness of the specimens shall be the thickness of the material.

The specimens shall be subjected to test in an impact testing machine of the Izod type. The natural surface of the material shall be in the plane at right angles to the direction of motion of the hammer.

The energy to cause fracture indicated by the machine shall be expressed in foot-lb. and the thickness of the specimens shall be stated.

(b) Specimens similar to those used in the test described above shall be heated at a temperature from

Materials shall be tested for stiffness or rigidity by the cantilever method as follows:—

(a) The form and arrangement of the test shall be in accordance with Figs. 3 and 4.

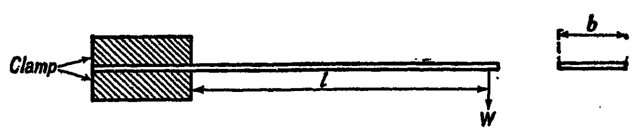

Fig. 3.—Form of Test for Stiffness or Rigidity.

The specimen shall be firmly fixed in clamps and the stirrup and scale pan placed in position as shown in Fig. 4. A measurement shall be made of the unsupported end below datum as follows:—

An inside micrometer shall be clamped above the

stirrup. The electric circuit shall be as shown in Fig. 4. The micrometer screw shall be turned until the circuit is closed (as indicated by the voltmeter) and the micrometer reading shall then be taken.

Small equal increments of load shall be applied and the corresponding increments in deflection measured immediately. Each increment of load shall be applied as soon as the deflection for the previous load increment has been read. Readings shall only be taken for the range during which the increment of load is proportional to the increment of deflection.

The dimensions of the specimen shall be as follows :—

The cantilever length shall be from 3 inches to 12 inches according to the stiffness of the material.

The breadth of the specimen shall be one-fifth of the cantilever length.

Young's Modulus E shall be computed from the following formula :—

$$E = \frac{4Wl^3}{bd^3y}$$

where W = average increment of load, lb.,
l = cantilever length, inches,
b = breadth of specimen, inches,
d = thickness of specimen, inches,
y = average increment of deflection, inches.

When the final increment of deflection has been measured as described above the load shall not be removed. The increment of deflection shall be re-measured after 1 minute, 10 minutes, 1 hour and 18 hours respectively.

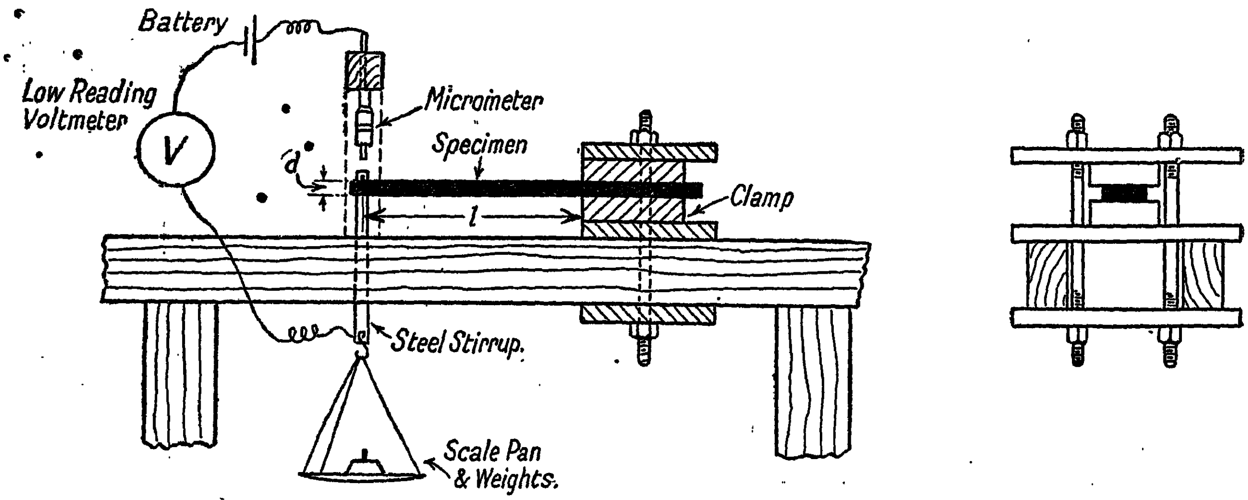

FIG. 4.—Arrangement of Cantilever Test.

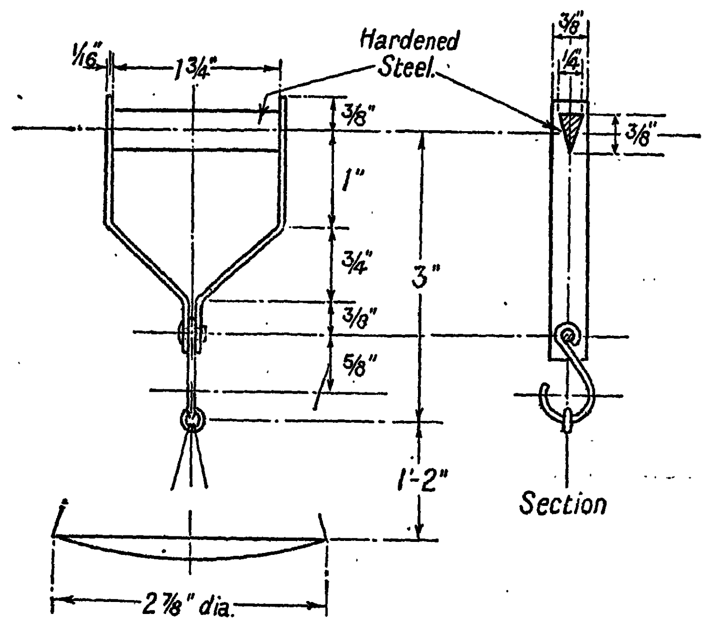

FIG. 5.—Form of Knife-edge Balance for Cantilever Test.

After the 18-hour test has been completed, tests at loads of 0·66 and 1·5 times the value of the load employed in the 18-hour test respectively shall be applied to the specimen, and the increments of deflection shall be re-measured as before in the prolonged test.

(*b*) Specimens similar to those used in the test described above shall be heated at a temperature from 200° C. to 205° C. for 24 hours, and shall then be subjected to a stiffness test as before, as soon as the temperature of the specimens has fallen to a value between 15° C. and 25° C.

NOTE:—A suitable form of knife-edge balance for use in the cantilever test is shown in Fig. 5.

9. ELECTRIC STRENGTH.

(*a*) *Conditioning of material.*

The electric strength test shall be carried out after the material has been subjected to the controlled atmospheres given below. The test shall be carried out whilst the specimen is in the controlled atmosphere in each case.

(i) *Normal condition.*

The specimen shall be subjected to a controlled atmosphere, relative humidity 75 per cent, at a temperature from 15° C. to 25° C. for 18 to 24 hours.*

(ii) *Damp condition.*

The specimen shall be subjected to a controlled atmosphere, relative humidity not less than 95 per cent, at a temperature from 15° C. to 25° C. for 18 to 24 hours.

(iii) *Hot condition.*

The specimen shall be subjected to a controlled atmosphere at a temperature from 180° C. to 185° C. for a sufficient period to ensure that the whole of the material has attained a temperature of 180° C.

(*b*) *Method of test.*

The output of the testing set shall be sufficient to maintain on the specimen the necessary potential difference for the maximum period required. The frequency of the potential difference shall be approximately 50 cycles, and if any other frequency is employed, its value shall be stated. The wave shape shall be as near sinusoidal as possible.

NOTE.—If the wave shape is not known to be satisfactory it should be checked whilst a specimen is under test and near the point of breakdown, and the necessary correction made to obtain R.M.S. values.

The potential difference should be regulated by means of a suitable resistance in series with the field of the alternator.

(*c*) *Electrodes.*

The upper electrode shall consist of a solid brass cylinder 1½ inches long and 1½ inches diameter. The lower electrode shall consist of a flat brass disc 3 inches diameter and ½ inch thick.

The sharp edges shall be removed from the electrodes but the radius of the edge shall not exceed 1/32 inch.

(*d*) *Method of expressing electric strength.*

A number of tests shall be carried out on each material to determine the potential difference required to puncture it after various periods from half a minute to such a time that the value of the potential difference is independent of the time. The results of the tests shall be plotted in the form of a time-voltage curve, and the electric strength in volts per mil at the end of one minute shall be computed.

* This value of relative humidity may be obtained by the use of a solution of calcium chloride in water, specific gravity 1·22 at 20° C.

10. SURFACE BREAKDOWN.

The surface breakdown shall be determined after the material has been subjected to the controlled atmospheres given below for 18 to 24 hours in each case.

The test shall be carried out whilst the specimen is in the controlled atmosphere.

Atmosphere.	Temperature, ° C.	Relative humidity, per cent
Normal	15 to 25	75 *
Dry	75 to 80	(See note below)
Damp	15 to 25	Not less than 95
Tropical	45 to 50	Not less than 90

NOTE.—To obtain the "Dry" atmosphere, air at an ordinary room temperature and humidity shall be heated to the temperature specified without artificial drying or humidifying.

The electrodes shall consist of either (*a*) two solid brass cylinders 1½ inches long and 1½ inches diameter, or (*b*) the electrodes specified for the electric strength test in Clause 9. The distance between the nearest surfaces of the two electrodes shall be 1½ inches in each case.

An alternating potential difference of 500 volts 50 cycles shall be applied between the electrodes, and shall be raised by increments of 250 volts each minute until the surface of the material indicates that an appreciable current is passing between the electrodes.

The highest potential difference reached in this test shall be recorded and, if practicable, a measurement made of the leakage current.

11. SHRINKAGE, WARPING AND SWELLING (NOT TO BE APPLIED TO CLASS E MATERIAL).

The tests for shrinkage, warping and swelling shall be carried out after the specimens have been subjected to a controlled atmosphere, relative humidity 75 per cent, at a temperature from 15° C. to 25° C. for 18 to 24 hours.*

(*a*) *Shrinkage.*

Shrinkage shall be determined as follows:

A specimen 4 inches square shall be cut from the material and the length, width and thickness measured after conditioning as specified above.

The length and width respectively of the specimen shall be the mean of ten measurements taken at points equally spaced along each of two edges at right angles.

The thickness of the specimen shall be the mean of ten measurements of thickness taken at points equally spaced around the edges.

The measurements shall be made by means of a micrometer or other suitable method.

The specimen shall be dried for 48 hours by heating

* This value of relative humidity may be obtained by the use of a solution of calcium chloride in water, specific gravity 1·22 at 20° C.

uniformly in an oven at a temperature from 105° C. to 110° C., and the length, width and thickness shall then be measured as before.

Comparison shall be made between the mean values of the dimensions before and after the heat treatment, and the percentage differences computed on the original mean values respectively shall be stated, the original mean values being given.

(*b*) *Warping*.

Warping shall be determined as follows:

A specimen 12 inches square shall be placed on a flat surface not less than 14 inches square, and a flat metal plate 12 inches square shall be placed on the specimen, so that the edges of the plate and the specimen coincide. The weight of the upper plate shall not exceed 1 lb. The distances between the four corners of the under surface of the upper plate and the corresponding points on the upper surface of the lower plate shall be measured.

The specimen shall be dried as specified in (*a*), then placed on the flat surface, and with the upper plate in position, the distances between the two surfaces shall be re-measured as before. Comparison shall be made between the sums of the four readings before and after drying, and the percentage increase computed on the sum of the original four readings shall be stated.

(*c*) *Swelling*.

Swelling shall be determined as follows:

The square specimen used in the shrinkage test shall be exposed to a jet of steam for six hours at a temperature from 105° C. to 110° C., and then the thickness shall be re-measured as before. Comparison shall be made between the mean thickness before and after the exposure to steam, and the percentage difference computed on the mean thickness after drying shall be stated.

12. Machining Properties (not to be applied to Mouldings).

The machining properties of material of Classes A, B, C and D shall be determined by sawing, shaping in a shaping machine and drilling with a drill of diameter equal to the thickness of the board.

In the case of Class E material, the sample shall be punched and cut with shears.

The effect on the material with regard to cracking, splitting, chipping or raggedness shall be stated.

13. Effect of Oil (not to be applied to Class D Material).

A specimen shall be immersed in mineral oil having a closed flash point not less than 250° C., for seven days continuously at a temperature from 200° C. to 205° C. The condition of the specimen after immersion shall be stated with respect to warping, splitting, swelling, blistering, softening or other deterioration.

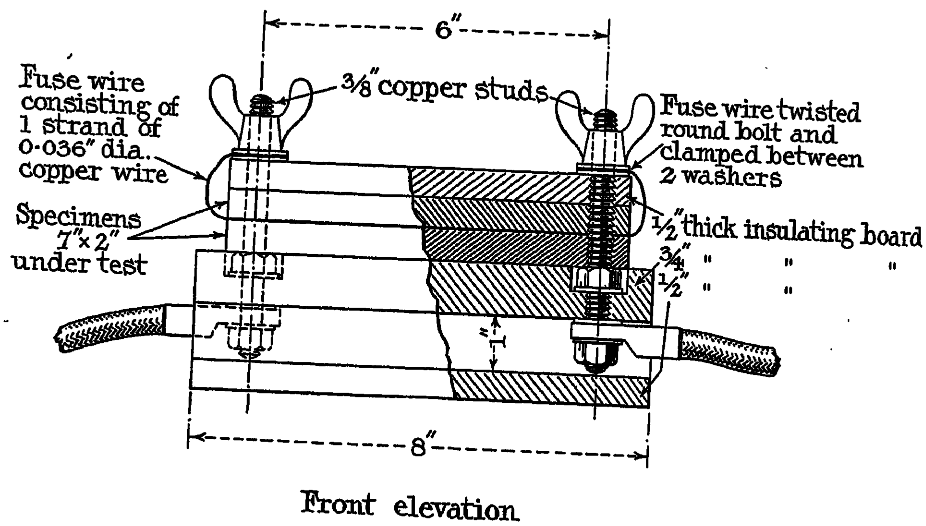

Fig. 6.—Arrangement of Fuse Wire Test.

14. Absorption of Water.

The specimen shall be conditioned in accordance with Clause 1 before the test for water absorption is carried out.

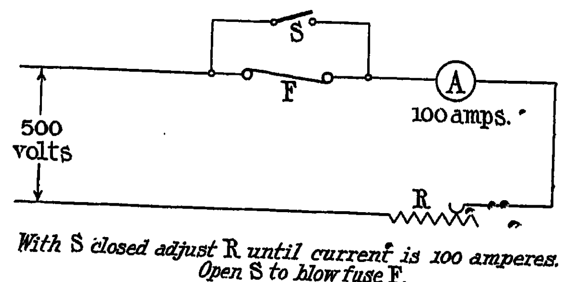

Fig. 7.—Diagram of Connections for Fuse Wire Test.

The dimensions of the specimen shall be 1½ inches square; and the four edges shall be freshly cut before the test is carried out.

The specimen shall be weighed and then immersed in water at a temperature from 15° C. to 25° C. After 24 hours' immersion it shall be taken from the water,

and, after removing the surface moisture by wiping, weighed again.

The specimen shall then be replaced in the water,

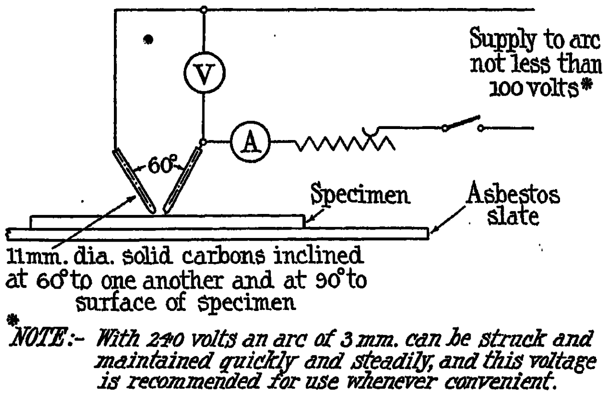

FIG. 8.—Arrangement of Carbon Arc Test.

and after six days' immersion re-weighed with the same precautions as before. The weight shall be taken to the nearest milligramme in each case.

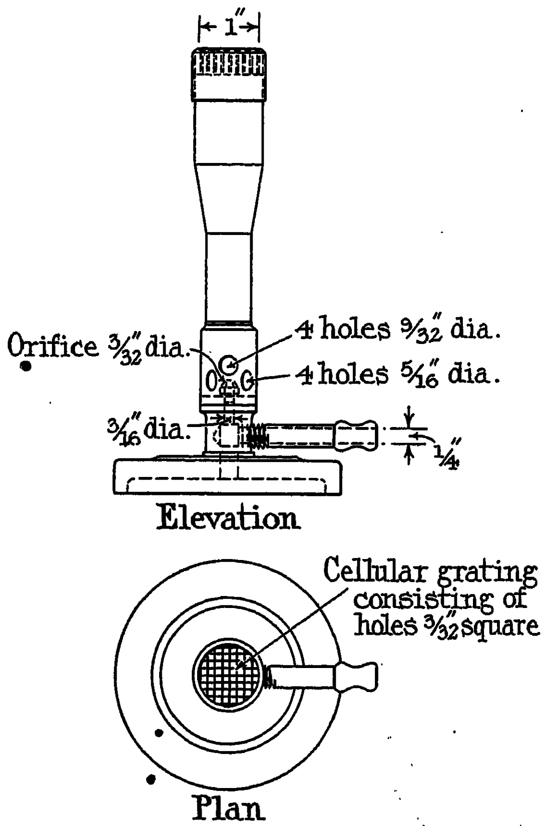

FIG. 9.—Dimensions of Méker Burner.

The percentage absorption of water in each case shall be computed on the original weight of the specimen; and the original thickness of the specimen shall be stated.

When it is desired to determine the absorption in the direction normal to the surface of the material, the edges of the specimen shall be coated with a waterproof varnish before the test for water absorption is carried out.

15. FUSE WIRE TEST.

The specimen shall be conditioned in accordance with Clause 1 before the fuse wire test is carried out.

The specimen shall consist of two pieces of the material each 7 inches long, 2 inches wide and not less than 3/16 inch thick, clamped together by two bolts 6 inches apart, the latter acting as terminals for the fuse wire. The fuse shall consist of a 0·036 inch diameter copper wire laid centrally between the two pieces of the material, the general arrangement being shown in Fig. 6. The wire shall be fused by being switched across a 500 volt d.c. circuit, in which there is a total non-inductive resistance of such a value as to limit the current to 100 amperes.

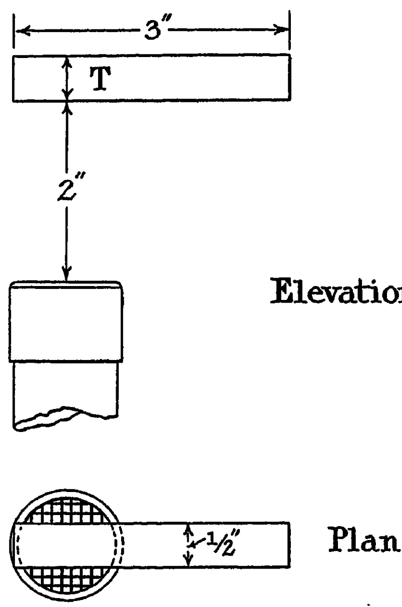

FIG. 10.—Arrangement of Méker Burner Test.

A convenient method for ensuring that the current through the fuse is of the required value is shown in Fig. 7.

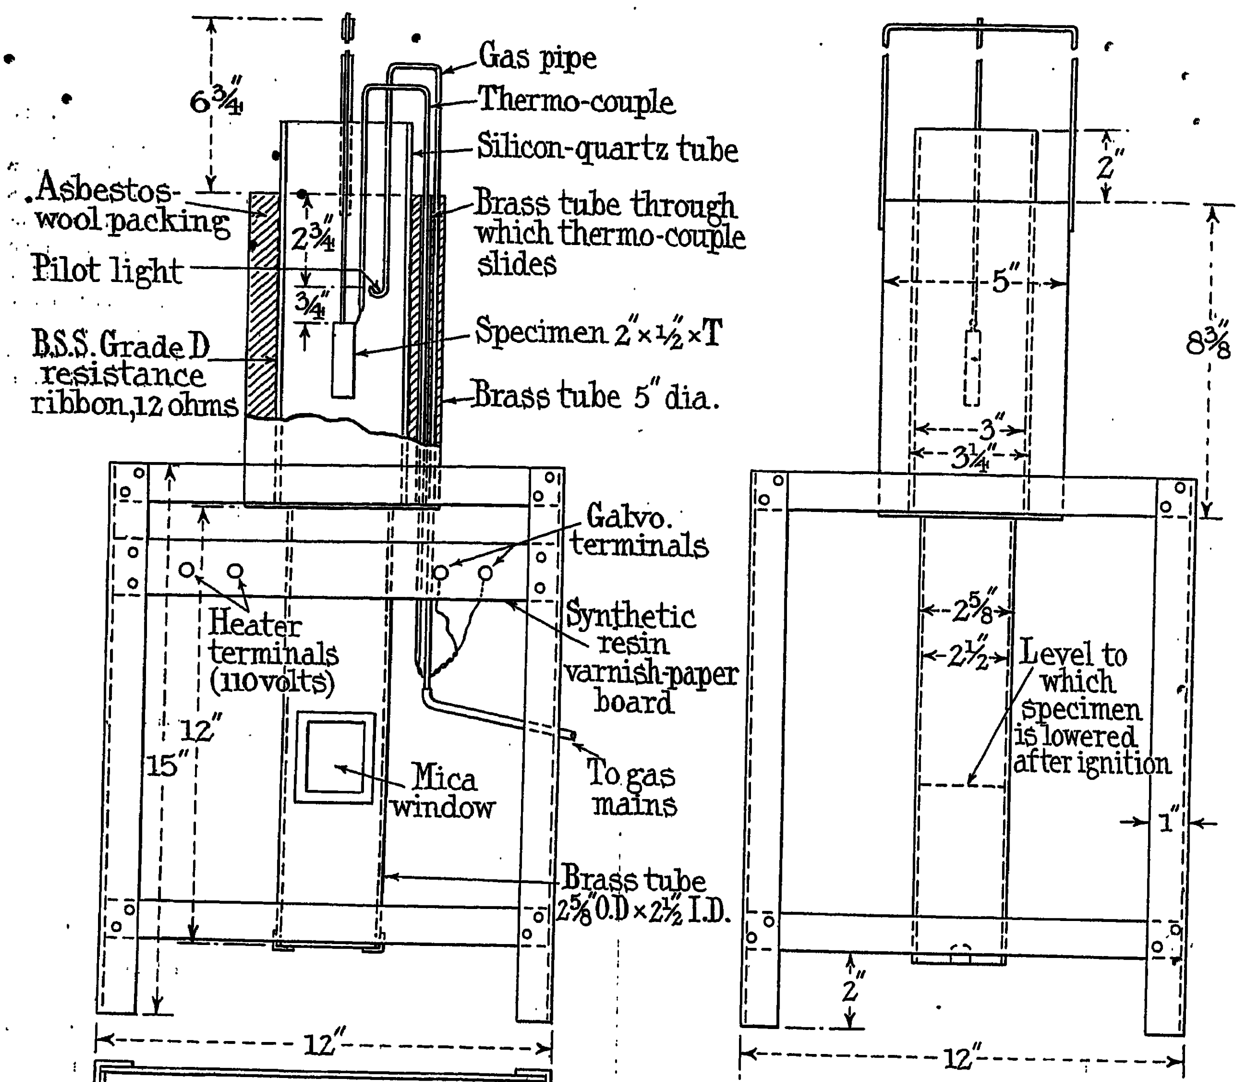
The test shall be repeated on the same specimen at intervals of two minutes until the material fails to extinguish the arc or its surface fuses, disintegrates or carbonizes. The number of times the fuse may be blown before this state is reached and the condition of the surface shall be recorded. If no disintegration has taken place after 10 tests, the condition shall be recorded at this stage.

For acceptance tests on materials for specific purposes the number of applications of the test which the material must withstand without showing a well-defined change shall be stated.

16. Carbon Arc Test.

The specimen shall be conditioned in accordance with Clause 1 before the carbon arc test is carried out.

Note.—When using material thinner than 3/16 inch for a given purpose, the sample tested should be of the thickness employed for that purpose.



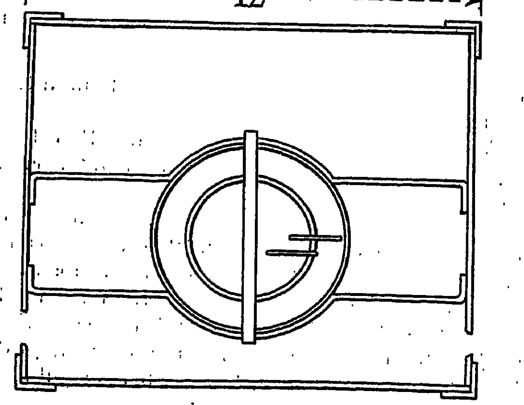


Fig. 11.—Arrangement of Radiant Heat Test.

The specimen shall consist of a flat sheet of the material. For testing the properties of a given material the sample shall be not less than 3/16 inch thick.

The specimen shall be placed on a horizontal base of asbestos slate or other similar heat-insulating material.

The arc shall be obtained between two solid carbons 11 mm diameter inclined at an angle of 60° to each other, with their plane set at an angle of 90° to the surface of the specimen, the carbons being arranged to travel just clear of the surface of the specimen. The arc is blown on to the specimen by the magnetic field established by the current in the inclined carbons.

The supply to the arc shall be connected through a switch, an adjustable resistance and an ammeter. A voltmeter shall be connected across the arc. The general arrangement of the test is shown in Fig. 8.

The carbons shall be operated by hand, the arc struck

and quickly adjusted to 10 amperes and 45 volts, being maintained steadily at this value, which corresponds to an arc length of approximately 3 mm. The effect of exposing the specimen to the arc for 15, 30, 60 seconds respectively, and if necessary for longer periods, shall be recorded.

For acceptance tests on materials for a specific purpose, the duration of applications of the arc shall be stated.

NOTE.—The mechanism and fittings of arc lamps sold for use in projection lanterns will be found suitable for the purpose.

17. MÉKER BURNER TEST.

The specimen shall be conditioned in accordance with Clause 1 before the Méker burner test is carried out.

The specimen shall consist of a piece of the material 3 inches long, $\frac{1}{2}$ inch wide and of thickness equal to the thickness of the material. The specimen shall be supported in the flame of a 1-inch Méker burner of the dimensions shown in Fig. 9. The specimen shall be placed with its axis horizontal and with the $\frac{1}{2}$-inch dimension facing the flame and 2 inches above the top of the burner, the end plane of the specimen being vertically above the edge of the burner as shown in Fig. 10.

The calorific value of the gas used must be known and shall be between 400 and 600 B.Th.U.'s per cubic foot.

The time before the specimen ignites shall be noted, and the constant K of the material shall be calculated from the following formula :—

$$K = \frac{TC}{500\,A}\left[\begin{array}{c}\text{Perimeter (inches) minus one horizontal}\\ \text{side (inches)}\end{array}\right]$$

where T = time in seconds before the specimen ignites,
C = calorific value of gas in B.Th.U.'s per cubic foot,
A = cross-sectional area of specimen in square inches.

18. RADIANT HEAT TEST.

The specimen shall be conditioned in accordance with Clause 1 before the radiant heat test is carried out.

The specimen shall be 2 inches long, $\frac{1}{2}$ inch wide, and of thickness equal to the thickness of the material, provided it is not more than $\frac{1}{2}$ inch thick. If the thickness of the material is over $\frac{1}{2}$ inch the specimen shall be cut down to $\frac{1}{2}$ inch thick.

The specimen shall be suspended in the apparatus shown in Fig. 11 so that its upper end is $5\frac{1}{2}$ inches below the top of the tube. The pilot flame shall be arranged $\frac{3}{8}$ inch above the upper end of the specimen. The air shutter shall be kept closed.

The temperature of the tube shall then be uniformly increased at a rate of 3 000° C. per hour and the temperature at which the material ignites shall be noted. When the material has ignited the specimen shall be lowered into the lower part of the apparatus to the level indicated in Fig. 11, and it shall be noted whether or not the material continues to burn. For this latter part of the test the air shutter shall be open.

NOTE.—If the apparatus is constructed to the dimensions and of the material indicated in Fig. 11 a constant current of about 9 amperes will give the correct rate of temperature rise.

19. AGEING.

NOTE.—The study of the effect of ageing on the materials covered by this specification is one of considerable importance, and boards of each class have been procured and are being stored in an ordinary atmosphere in an unheated building freely ventilated for periods of 6, 12, 18 and 24 months respectively.

To determine the effect of ageing the following investigation has been put in hand :—

The complete series of tests outlined in this specification is being carried out on representative materials at the commencement of the investigation, and will be again carried out at the end of two years. The following tests only will be made at the end of each six monthly period :—

Impact Test (Clause 7),
Carbon Arc Test (Clause 16),
Shrinkage Test as follows :—

A circle approximately 12 inches diameter to be inscribed on the sample, and the diameter measured accurately in the longitudinal and transverse directions respectively of the board, at the commencement of the investigation. The diameters of the circle to be measured again at the end of each of the six monthly periods, and the percentage shrinkage in the longitudinal and transverse directions respectively to be computed on the original values.

WIRELESS SECTION: CHAIRMAN'S ADDRESS

By E. H. Shaughnessy, O.B.E., Member.

(*Address delivered 5th November, 1924.*)

In my address last year* I gave particulars of the development of coupled circuits for arc transmitters of small power, and stated that the Post Office had decided to proceed with the installation of a coupled circuit for the 250-kW arc at Leafield. I am now able to say that we have completed and brought into commercial use the coupled circuit. To-day no trouble from "mush" or harmonics is observed and it is possible to receive broadcasting in close proximity to the station. The primary condenser is made of steel tanks containing 17 aluminium plates immersed in oil. Each unit has a capacity of 6 500 $\mu\mu$F, and four units are joined in parallel. The condenser contains 5 000 gallons of oil and weighs 25 tons. Under working conditions the condenser may handle as much as 260 amperes at 12 350 m. The working voltage (R.M.S.) is 68 000 (equivalent to a peak value of 96 000), and the energy handled is 18 000 kVA. The oil is cleaned and dried by a De Laval dehydrator and there has been no breakdown of the dielectric in use. The losses in the condenser are extremely small.

The primary coil is of copper strip made up in 8 flat spirals each containing 8 turns. The strip is carried direct on wooden spiders. The four lower spirals can be moved under the top four, the whole thus constituting a large variometer.

The coupling between the aerial circuit and the primary circuit is obtained by inserting a fixed coil of 4 turns of copper strip in the aerial circuit, and inside this a rotatable coil of 4 turns of copper strip which is connected to the primary circuit. This coupler is found to have a tendency to warm and is being replaced by one made of stranded wire.

It will be remembered that the examples which I dealt with last year were of coupled circuits applied to 25-kW and 40-kW arcs, and I mentioned that it had been found necessary to consume about 25 per cent more power than when the arcs were used on direct aerial circuits. It is therefore very interesting to note that with the 250-kW arcs at Leafield when used on 12 350 m there is no increase in the power consumed for the coupled circuit over that required for the plain aerial, while on 8 750 m the power consumption is actually less.

Typica lresults on 12 350 m are that with 237 kW input on plain aerial an aerial current of 254 amperes is obtained, whilst an input of 230 kW produces a primary circuit current of 220 amperes and an aerial current of 249 amperes.

Signalling is still done on the marking and spacing waves by varying the inductance of the primary circuit, the secondary or aerial circuit not being altered in tune.

* *Journal I.E.E.*, 1924, vol. 62, p. 51.

This is the largest coupled arc in existence working regularly and satisfactorily, and the constancy of the frequency is extremely good. The whole of the construction work was done by the Post Office Engineering Department and the arrangements are mainly due to Mr. A. J. Gill of that Department.

Aerial Tuning Coils.

It is generally understood that stranded wire is better for aerial tuning coils than copper strip, but, nevertheless, one sees copper-strip coils used and carrying several hundred amperes in high-power stations.

At the Northolt station a copper-tube coil was in use which had a very high resistance of about 3½ ohms. It was decided to replace this with a stranded-wire coil made up on wooden pancake spiders. The cable was made up of 729 strands of No. 33 S.W.G. enamel-insulated wire. When the cable was tested it was found that the insulation between wires and strands was faulty. It was decided to make up this cable into a coil and test its properties while a new length of similar cable with slightly thicker enamel insulation and silk insulation round each group of 81 wires was being manufactured.

When the faulty cable was made up into the coil and the spiders were adjusted to give an inductance of 1 680 μH its resistance was 2·05 ohms at a frequency of 43 kilocycles. A similar coil was then made with the new cable and when this was adjusted to have a value of 1 680 μH its resistance was only 0·776 ohm at 43 kilocycles. It will thus be seen that the insulation of the individual wires is a very important matter.

Table.

Decrements of Faulty and Good Cable.

Faulty cable		Good cable	
At frequency of		At frequency of	
20 kilocycles	40 kilocycles	25 kilocycles	50 kilocycles
0·0044	0·012	0·0044	0·0049

Tests on Dielectric Properties of Different Woods at High Frequencies.

Another matter of importance in the design of inductance coils for high-power stations is the selection of the material for supporting the cable, and an exhaustive test of various materials under high-

frequency stresses has shown that most of the insulating materials available tend to become hot and in many cases end in smoke under the prolonged application of high-frequency voltage. In the course of my address last year I showed samples of vitrified porcelain which had cracked and from which molten porcelain had oozed out, and I stated that good dry whitewood withstood the tests as well as anything else.

On the grounds of economy and also of ease of make-up, wood offers distinct advantages over other insulators for the manufacture of large inductance coils for use at radio frequencies. Unfortunately there appears to be no information available as to the properties of the various kinds of woods for this purpose, and accordingly, in order to obtain such information, samples of a number of different varieties of wood were obtained and subjected to a practical test.

The samples were all cut to a standard size, i.e. 1 in. × 1 in. × 4 in. long, and were arranged in a

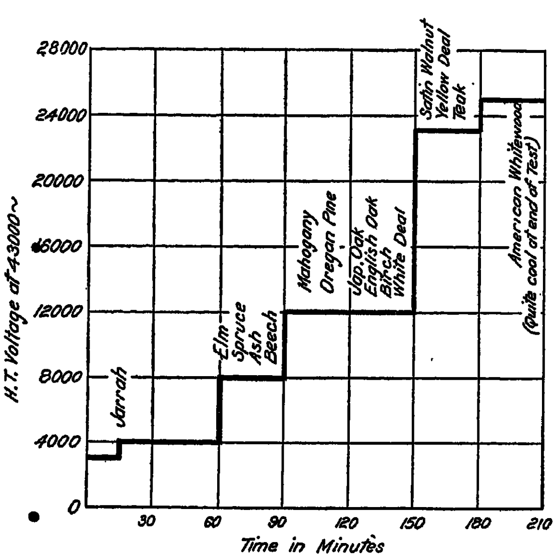

Fig. 1.

symmetrical manner between two copper plates connected across the tuning inductance of an arc oscillating circuit tuned to approximately 6 800 m.

The voltage was applied and increased gradually, until particular samples began to smoke and burn. These samples were then removed, and the voltage was further increased. Fig. 1 shows the steps in which the voltage was raised and the length of time during which each particular voltage was applied to the samples.

The point in the test at which each sample was removed on showing signs of failure is indicated by the point at which the name of the wood appears. It will be seen that the samples of American whitewood were superior to those of any other wood tested. Subsequent tests carried out on large numbers of samples of this wood at a voltage of approximately 35 000 amply confirm the results of these tests, and in no case has any charring or undue heating been observed.

In the case of one sample special arrangements were made to increase the voltage, and a flash-over occurred between the metal plates at 55 000 volts, the wood samples remaining undamaged.

Inductance coils have been made up using this kind of wood and have given every satisfaction under working conditions. Such a coil at Northolt radio station has proved itself capable of carrying a current of 115

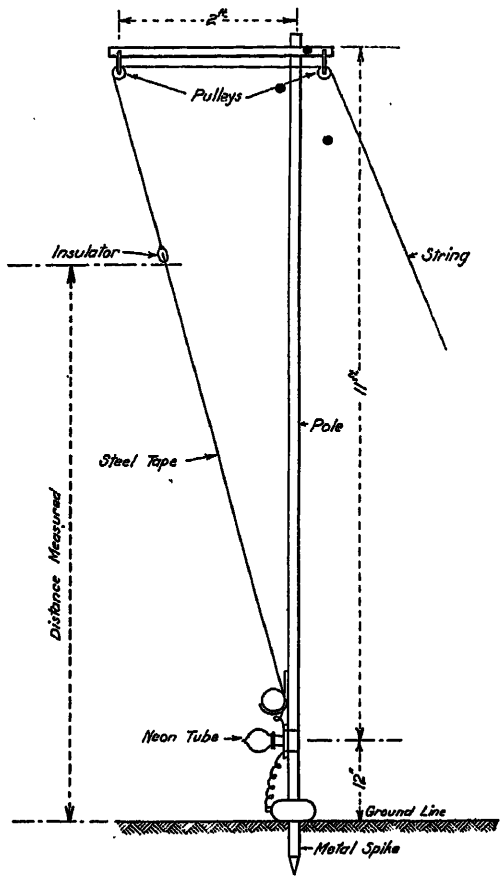

Fig. 2.

amperes, the voltage at the aerial end approximating to 60 000.

Method of Measuring the Electric Field under the Aerial.

So much has been written about the earth arrangements of various high-power stations that it would appear that very low resistance can be obtained from either elevated screen wires or buried earth wires led back on distributing elevated conductors with inductances inserted to balance the currents which each of these carries.

As a preliminary investigation into the character of these claims it was decided to explore the field under the aerial at Leafield. To this end the following experiment was carried out.

The fact that a neon tube, when held in a strong electric field with one electrode earthed and the other raised above the earth, glows when the potential drop

from the insulated electrode to earth equals the striking voltage of the tube, was used as the basis of the method of measuring the electric field. The strength of the electric field in volts per foot is obtained by dividing the striking voltage of the tube by the height in feet of the insulated electrode above the earth.

The apparatus devised for these measurements was as illustrated in Fig. 2. The neon tube was mounted 1 ft. from the base of a wooden pole 12 ft. long. One electrode was connected to the metal spike on the base of the pole, the other being attached to a steel tape which could be raised or lowered at will by means of a string passing over pulleys. The wooden cross-arm was necessary to prevent the tape from earthing on the pole, and also to minimize the capacity to earth between the tape and the pole.

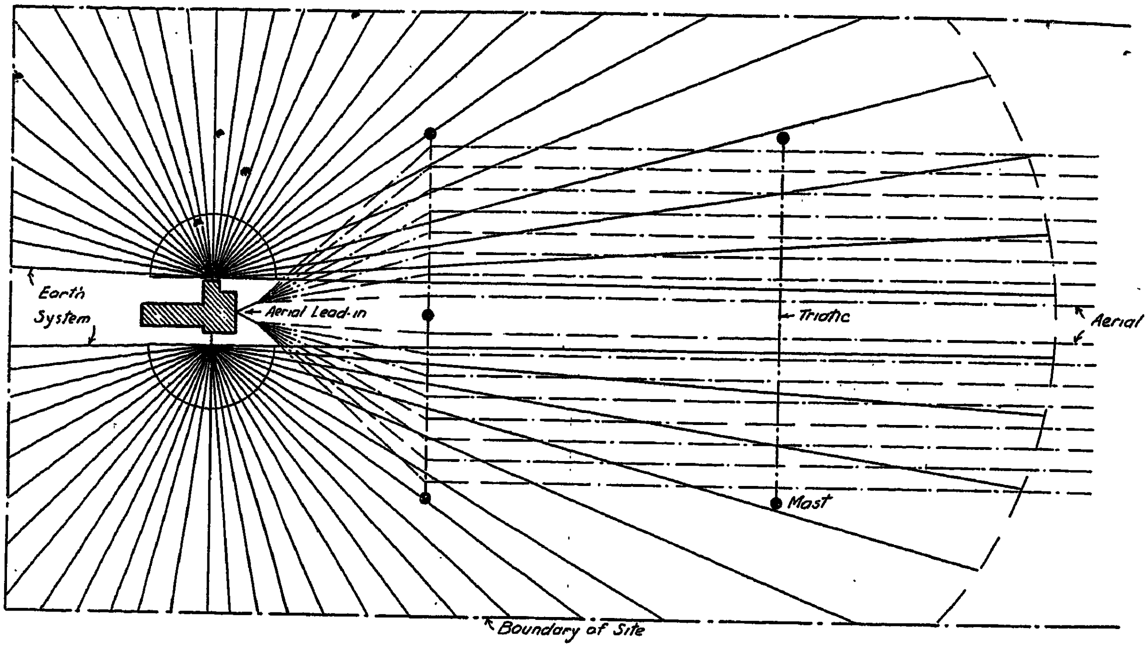

Fig. 3.

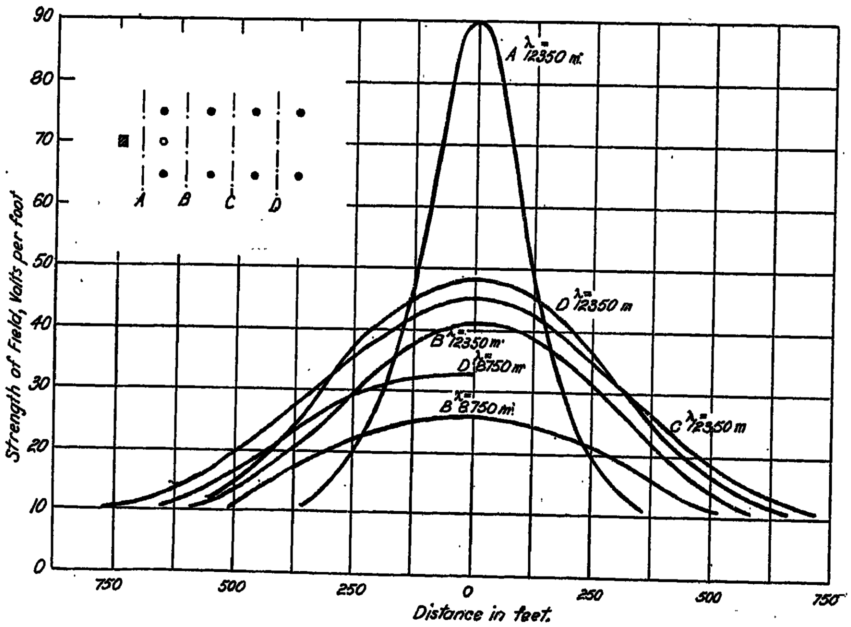

Fig. 4.

The method of making a measurement was as follows:—

The spike was driven into the ground, which sufficed to hold the pole in a vertical position. The observer

stood 4 paces from the pole and raised the tape until the tube commenced to glow intermittently and the keying could be read. The length of the tape which had been drawn out was noted, and the field strength was calculated as previously described. It was necessary for the observer to stand 4 yards from the pole, owing to his screening effect. At a shorter distance than this, when the tube was glowing any movement on the part of the observer towards the pole caused the light to go out.

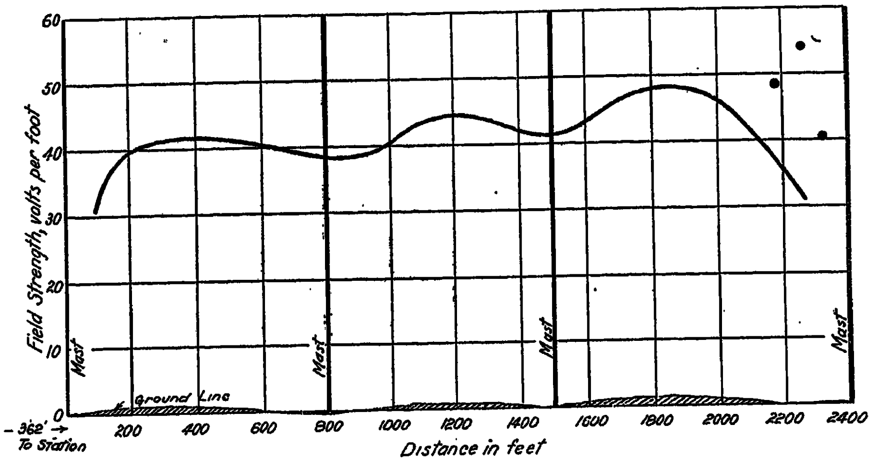

FIG. 5.

THE STRENGTH OF THE ELECTRIC FIELD UNDER THE LEAFIELD TRANSMITTING AERIAL.

The lettered dotted lines on the inset plan of the aerial system in Fig. 4 indicate the lines along which

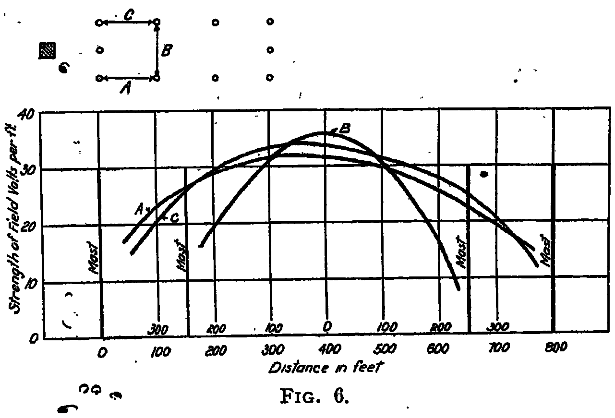

FIG. 6.

readings were taken, usually every 25 ft. The earth system, shown in Fig. 3, extends only so far as midway between the second and third pair of masts. From an inspection of the curves in Fig. 4 it will be observed that at a distance from the edge of the aerial equal to its height (300 ft.) there is a field of one-third the maximum intensity which occurs down the centre lines of the aerial. As would be expected, the field under the lead-in, curve A, is much stronger than elsewhere. It is apparent, therefore, from the curves B, C and D that the earth system has no appreciable effect on the distribution of the electric field under the aerial.

The curve in Fig. 5, taken down the centre line of the aerial, indicates a slight increase in the strength of the field towards the end furthest from the station. The effect of uneven ground on the field strength indicated that a rise in height of 5 ft., or 2 per cent of the total height of the aerial, caused a much greater percentage increase in the field strength.

The curves in Fig. 6 illustrate the screening effect of the masts and stays.

PROJECTED RUGBY STATION.

I should like now to say a few words about the Rugby station. The general design of this station is due to the Wireless Telegraph Commission, consisting of Dr. W. H. Eccles, Mr. L. B. Turner and myself, and the erection is being undertaken to this design by the Post Office Engineering Department.

The site is at Hillmorton, about 3 miles from Rugby, and is about 900 acres in extent. The wireless building is to be about the centre of the site. Twelve steel masts, 820 ft. high and spaced 1 320 ft. apart, are being erected. They are of lattice-steel construction, triangular in form with 10-ft. sides, and are being built by Messrs. Head, Wrightson and Co. of Thornaby-on-Tees. Each mast is supported on a ball-and-socket joint resting on a series of 12 porcelain insulators, the whole being supported on a granite block carried by a stanchion fixed to the foundations. A hoist is provided inside each mast with a platform at each position where stays are terminated, and there is also a continuous ladder from the bottom to the top. The mast is designed to stand a wind pressure of 60 lb. per sq. ft. of exposed surface and to support a horizontal load of 10 tons and a vertical load of 3 tons due to the antenna pull at the top.

The insulators are of special porcelain of flat circular shape, 8 in. diameter and $3\frac{1}{2}$ in. thick. Each insulator has to withstand a test pressure of 25 000 volts at 50 000 cycles per second for 6 hours without showing signs of heating and is, in addition, subjected to a test

load of 270 tons. Each mast will have three sets of five stays anchored at 200, 400 and 600 ft. Stays are made of 151 No. 10 S.W.G. wires laid up straight.

The aerial will consist of a continuous sausage of 12 ft. diameter, the supporting steel rope being carried down the centre of each mast and wound on a winch with slipping gear which will allow it to pay out when the tension exceeds 10 tons.

The primary circuit consists of a stranded wire cable inductance and Dubilier mica condensers. The aerial coil will also be of stranded cable. Three-phase power at 50 cycles per sec. and 12 000 volts is to be obtained from the Leicestershire and Warwickshire Electric Power Co.

Three motor-generators to give 6 000 volts each are arranged to be switched in series as required, so that any d.c. voltage up to 18 000 can be obtained. These machines are being made by the British Thomson-Houston Co. Water-cooled valves, each having an output of 10 kW and being made in this country by the Western Electric Co., will be used to make up the high-frequency generator.

General Review.

It is interesting to review the development of the art of radio engineering and to observe the influence of various workers in different parts of the world. In this country Marconi introduced the spark system with elevated aerial and connected earth system in 1896. Lodge in 1897 introduced the important principle of aerial tuning by means of a loading coil, and the Marconi Company's coupled-circuit spark system was developed so that, in 1913, spark stations dealing with about 300 kW were made. The Marconi Co. further developed the spark system so that, by timing the sparks, trains of waves were made to follow each other in correct phase and a continous-wave system was produced. The Stavanger station of about 200 kW power still works on this system. Suffice it to say that spark systems are now confined to small powers and special services such as ship and shore work.

In 1900 Duddell introduced the singing arc, which was developed by Poulsen for use at radio frequencies in 1903, and it is strange that very little development of this took place in Europe until after the Federal Telegraph Co. of America had built 100-kW arcs somewhere about 1912. During the war the arc was developed to modern sizes by the Federal Co., Mr. Elwell and others, and at present arcs having an output of from 200 kW to 1 000 kW are in commercial use.

In 1904 Fleming introduced the two-electrode valve as a detector; in 1907 De Forest introduced the third electrode into the valve and used an anode battery and found that the results obtained were better than with the two-electrode valve. Lieben and Reiss in 1911 showed an appreciation of the characteristics of a three-electrode valve by indicating how to use it for amplification without rectification. About the year 1913 Messrs. Round, Franklin, Armstrong, Langmuir and De Forest were investigating and developing the reaction properties of valves, and we know how rapidly these properties were adopted for use during the war for both sending and receiving. Valve sending stations up to an output of about 200 kW have been developed by the Marconi Co. in this country and by the American Telegraph and Telephone Co. in America.

In America Fessenden and Alexanderson proposed the construction of high-frequency alternators, and as far back as 1908 Alexanderson produced a 2-kW alternator which generated directly a frequency of 100 000 when running at 20 000 r.p.m. To-day the Telefunken Co. use high-frequency alternators with static frequency-changers, the Radio Corporation of America employ 200-kW Alexanderson alternators and the Société Française Radio-Electrique use Latour-Bethenod 200-kW and 500-kW alternators all running at reasonable speeds.

From this brief review it would seem that each of the four great companies has developed on its own lines, although I believe that a general interchange of the use of each other's patents is in operation.

The present practice of modern long-distance radio telegraphy has been the result of the efforts of many workers to establish the art on a basis where it can offer as good and speedy a service as any other form of communication, and in order to do that it is essential that ordinary telegrams should be sent over radio routes without any initial delay. It has been well known for many years that the ranges of stations are greater at night than during the day, and in order to extend the hours of reliable communication of the daylight hours—which are the business hours—higher powers and longer wave-lengths have been found to be more effective as the distances increased. These increases have certainly brought about improved results but have also appreciably increased the cost of erection of the aerial system of a high-power station. The cost of one 820-ft. mast may be anything from £12 000 to £15 000, and 12 such masts with aerial and earth systems complete may cost from £150 000 to £180 000. The total cost of a high-power world-wide station may be between £400 000 and £500 000, and in order to institute a service two stations are required. The interest and depreciation on these amounts are heavy annual charges and the total working expenses may amount to from £70 000 to £96 000 per station per annum, according to the amount of traffic dealt with.

To-day we have before us a choice of three systems for the internal equipment of high-power long-wave sending stations—by high-power I mean stations of over 200 kW—namely the high-frequency alternator, the Poulsen arc and the valve generator, and the art has not yet reached a stage where it can definitely be said which of these will best survive the test of time. The art of radio telegraphy is now about 30 years old and, as in the case of electric lighting and power, the monopoly due to fundamental patents has practically disappeared.

In view of the heavy cost of the aerial and earth systems the total cost of equipping a high-power station is not materially affected by the choice of any one of the above systems of internal sending plant. Speaking from experience, now that we have solved the problem of eliminating disturbances from the Poulsen-arc emissions, that system may be said to be by no means obsolete. It has advantages of its own in that it is very simple to work and maintain, can be started up

quickly and can have its working wave-length changed fairly rapidly.

Marconi, who, with Franklin, has been working with short waves since 1916, has recently described their latest development of the use of the beam system working on 92 m, and from his experiments concludes that with comparatively small powers and on short waves good communication can be obtained over extreme distances during the hours of darkness—an average of 7 hours per day—while over much shorter distances (2 670 miles) an average of 18 hours' communication per day can be obtained, the communication to be at the rate of 100 words per minute, exclusive of repetitions to secure accuracy.

The Post Office has entered into a contract with the Marconi Co. for the latter to provide a station to work to Canada as above at a cost of £50 420—the station to be capable of extensions to work to South Africa, India and Australia simultaneously, each extension costing £31 406.

It will be seen that, as the capital cost of these stations is low, depreciation and interest will be low and the power will also be comparatively low, but the cost of operating will depend upon the number of hours during which communication is satisfactory, and also upon the rate of working.

From our knowledge of the art it seems essential that high-power long-wave stations must be erected in order to provide for a full and regular Imperial telegraph service in which there shall be no initial delay due to ordinary telegrams having to be kept in hand until the favourable hours of working arrive, and also to be able to reach any and all parts of the Empire at any moment.

The erection of the short-wave beam stations will show to what extent they can assist in cheapening the cost of transmitting the less urgent forms of telegraph traffic and in reducing the number of high-power stations required in this country to meet the demands of a full Imperial radio-telegraph scheme.

INSTITUTION NOTES.

Honorary Member.

At the Ordinary Meeting of the Institution held on the 6th November the President announced that the Council had that day elected Sir Oliver Lodge, D.Sc., F.R.S., to be an Honorary Member of the Institution.

Summer Meeting, 1925.

The Council have accepted an invitation from the Chairman and Committee of the South Midland Centre for a Summer Meeting of the Institution to be held in the Midlands in June 1925. Full particulars will be announced later.

Norsk Elektroteknisk Forening.

At the request of the above Society the Council have agreed to the mutual granting of facilities and privileges as Visiting Members to members of the two societies visiting each other's country.

Members who intend to visit Norway and wish to avail themselves of this arrangement should apply to the Secretary of the Institution for a letter of introduction to the Norsk Elektroteknisk Forening, stating in what branch of the profession they are engaged and giving the name of the firm or company (if any) with which they are connected.

Gilbert's Treatise on the Magnet.

The Gilbert Club, which was recently wound up, was formed in the autumn of 1889 with the primary object of translating and publishing William Gilbert's classical work on the magnet, first published in Latin in 1600. Ten eminent scholars, including Mr. Latimer Clark, F.R.S., Sir Joseph Larmor, F.R.S., Prof. Meldola, F.R.S., and Prof. S. P. Thompson, F.R.S., undertook this work, which appeared in 1900. The title-page reads as follows:

> "William Gilbert of Colchester, Physician of London. On the Magnet, Magnetick Bodies also, and on the great magnet the earth; a new Physiology, demonstrated by many arguments and experiments. London, Imprinted at the Chiswick Press, anno MCM".

It is a page-for-page translation of the 1600 edition containing the numerous woodcuts, in facsimile, which appear in the original.

The edition, which was limited to 250 copies printed on hand-made paper, is a fine example of typography, and is bound in grey-blue boards with linen back.

On the winding up of the Club, it was decided to present its assets, consisting of a sum of £40 5s. 11d. and the last 34 copies of the treatise, to the Institution for the benefit of its Benevolent Fund. The Council are prepared to dispose of these volumes at a price of £5 5s. each, the full proceeds to be devoted to the Fund. In view of the small number of copies for disposal, members of the Institution are given the first opportunity of acquiring the work before it is brought to the notice of librarians. A copy is available for inspection in the Library of the Institution, and applications for copies should be addressed to the Secretary.

National Certificates and Diplomas in Electrical Engineering.

The following is a further list* of colleges, schools, etc., which have been approved under the scheme drawn up by the Board of Education and the Institution.

Approved for Ordinary Grade Certificates (Senior Part-time Course) :—

Birkenhead Technical School.
Bournemouth Municipal College.
Nelson Municipal Technical School.
Walsall Municipal Institute.
Wimbledon Technical Institute.

Approved for Higher Grade Certificates (Advanced Part-time Course) :—

Burnley Municipal College.
Gillingham Technical Institute.
Salford Royal Technical College—Apprentices' Day Course.

International Commission on Illumination.

REPORT BY LIEUT.-COL. K. EDGCUMBE ON THE CONFERENCE HELD AT GENEVA, 20–25 JULY, 1924.

Previous sessions.—The International Commission on Illumination held its first meeting in 1913 at Berlin, its second at Paris in 1921, the meeting at Geneva being the third.

Officers.—The present officers are as follows :—

President : Dr. E. P. Hyde (U.S.A.).

Hon. President : M. Th. Vautier (France).

Vice-Presidents : M. G. Semenza (Italy), Lt.-Col. K. Edgcumbe (Gt. Britain), M. Rouland (France).

Hon. Secretary and Treasurer : Mr. C. C. Paterson (Gt. Britain).

General Secretary : Mr. J. W. T. Walsh (Gt. Britain).

Constitution.—The constitution and working of the Commission are on similar lines to those of the International Electrotechnical Commission, except that the National Committee in each country is, by statute, constituted by a combination of the electrical interests, the gas interests and those of any society or body dealing particularly with illumination matters.

British National Committee.—The British National Committee is composed of five representatives from the Institution of Electrical Engineers, five from the Institution of Gas Engineers, five from the Illuminating Engineering Society and two from the National Physical Laboratory.

Delegates.—In the case of the British National Committee, the delegates to a plenary meeting are nominated by the representatives of each constituent Institution and are submitted to that Institution for approval. The nominees of the Institution of Electrical Engineers were Lt.-Col. K. Edgcumbe and Mr. P. Good. At the last moment, Mr. P. Good found it impossible to attend and, with the concurrence of the President, Mr. J. M. G. Trezise of the Post Office was nominated to fill the vacancy. The British delegation comprised five other members, in addition to Messrs. Paterson and Walsh who attended in their official capacities.

Other delegations.—In addition to Great Britain the following countries sent delegates : France, Italy, Japan, Poland, Switzerland and the United States of America. Belgium and Spain were unable to send representatives.

Proceedings at the meeting.—The subjects dealt with at the Conference may be grouped as follows :—

Nomenclature and symbols.
Photometry, with particular reference to the measurement of light differing in colour.
Standards of light.
Street and public lighting.
Lighting of schools and workshops.
Automobile headlights.
Industrial lighting generally.

A number of definitions were adopted, supplementing those agreed to in Paris in 1921. An International Committee was, moreover, set up to draft, in collaboration with the National Committees, an agreed vocabulary of terms used in the literature of illumination.

A comprehensive report on the subject of school and factory lighting was presented by the International Committee. Its recommendations were adopted and it was resolved that this report could usefully form the basis of any regulations which might be introduced in the various countries. It was strongly felt, however, that it was premature to lay down any legal minima.

The reports of the Motor Car Headlights Committees of France, Great Britain and the United States of America were closely studied, and it was agreed that to draw up any definite recommendations, in view of the present state of the industry, would be inadvisible. The International Committee was reappointed and all National Committees were asked to take up this question as an urgent matter, more particularly in view of the likelihood that an International Conference dealing with automobile matters might be summoned at an early date by the Governments concerned. Arrangements were discussed with a view to ensuring that the International Commission on Illumination should be effectively represented at any such conference.

The question of the education of engineers and the public generally in the advantages of good lighting aroused considerable interest, and it was agreed to allot to this subject an important place in the programme of the next meeting of the Commission.

Next meeting.—It was decided to hold the next plenary session of the Commission in 1927 in the United States of America.

Students' Visit to Lyons.

In August last the Students' Sections organized a visit to France at the invitation of the Société Française des Electriciens. It was decided to visit only one locality rather than travel from place to place as on previous occasions, and Lyons was chosen for the venue. Through the courtesy of Mr. J. Grosselin, Local Honorary Secretary of the Institution for France, and Mr. Dumont of the Société Française des Electriciens, a very attractive programme was arranged.

The party, numbering 26, left London on Sunday, 3rd August, arriving in Lyons the following morning, where they were met by Mr. Rivière, who acted as

* See *Institution Notes*, No. 39, p. 18; July, 1923 and *Journal I.E.E.*, 1924, vol. 62, pp. 209, 381 and 900.

guide to the party throughout the visit. The afternoon was spent in sight-seeing, after which the party visited the Lyons Fair, a large ferro-concrete building in which the Annual International Fair is held. The exhibits are arranged in three storys on each side of a central aisle, along which a rail track is laid for facilitating the installation of the exhibits. The visit concluded with a semi-official reception.

On the following morning a visit was paid to a Thury direct-current system operated by the Société Générale de Force et de Lumière, while the afternoon was occupied in an inspection of Mouche Central Station of the Compagnie du Gaz et de l'Électricité de Lyon, including a 70 000-volt outdoor transformer station.

On Wednesday morning the silk factory of Messrs. Vital Matthieu and Sons was inspected, after which the party was entertained by the Berliet Motor Company to lunch, followed by a tour of the works, where mass-production methods are employed.

On Thursday the party visited the Beaujolais vineyard, where they were entertained by the Société Française des Electriciens in the Château de Pizay.

On Friday there was an excursion to St. Etienne, where the 120 000-volt system of the Compagnie Électrique de la Loire et du Centre was inspected, followed by a visit to the coal mines of the Loire, the party being the guests of the company at lunch.

On Saturday morning an interesting visit was paid to the Lyons radio station. Saturday afternoon and Sunday were spent in individual expeditions to various local beauty spots, and the tour was brought to a conclusion by a farewell dinner at the Hôtel des Beaux Arts, at which a presentation was made to Mr. Rivière as a souvenir of a very enjoyable visit. A vote of thanks was also passed to Mr. J. H. Reyner, the Honorary Secretary of the London Students' Section, for his work in organizing the tour. The party left for London at 9.15 p.m.

The Committee wish to express their great appreciation of the courteous reception which they received everywhere in France, and, in particular, to the several firms and public bodies whose works they were privileged to visit. All who were present will carry with them a lasting memory of a very generous hospitality.

J. H. R.

Committees, 1924-1925.

Among the Committees appointed by the Council for 1924–25 are the following:—

Informal Meetings Committee.

The President.

Mr. A. H. Allen.
Mr. J. W. Beauchamp.
Mr. J. Coxon.
Mr. P. Dunsheath, O.B.E.
Mr. A. F. Harmer.
Mr. A. G. Hilling.
Mr. F. Pooley.
Mr. W. E. Warrilow.
Mr. H. T. Young.

Mr. F. Gill, O.B.E. (representing the General Purposes Committee).

The Chairman of the Papers Committee.

The Chairman of the London Students' Section.

Library and Museum Committee.

The President.

Col. R. E. Crompton, C.B.
Mr S. W. Melsom.
Mr. W. M. Mordey.
Col. T. F. Purves, O.B.E.

Local Centres Committee.

The President.

Mr. D. H. Bishop.
Mr. C. P. Coote-Cummins.
Sir J. Devonshire, K.B.E.
Lt.-Col. K. Edgcumbe, R.E. (T.A.).
Mr. F. Gill, O.B.E.
Mr. H. H. Harrison.
Mr. J. S. Highfield.
Mr. T. B. Johnson.
Mr. D. G. Jones.
Mr. H. C. Lamb.
Mr. W. Lawson.
Mr. A. Lindsay.
Mr. W. T. Maccall.
Mr. W. Nairn.
Mr. A. Page.
Mr. A. M. Paton.
Col. T. F. Purves, O.B.E.
Mr. T. R. Smith.
Mr. C. H. Wordingham, C.B.E.

"Science Abstracts" Committee.

The President.

Mr. Ll. B. Atkinson.
Mr. F. Gill, O.B.E.
Mr. W. M. Mordey.
Mr. C. C. Paterson, O.B.E.
Dr. D. Owen .. } Representing the Physical Society
Mr. T. Smith .. } of London.

Ship Electrical Equipment Committee.

The President.

Mr. A. G. S. Barnard.
Mr. J. H. Collie.
Mr. B. M. Drake.
Mr. A. Henderson.
Mr. J. W. Kempster.
Mr. J. F. Nielson.
Mr. N. W. Prangnell.
Mr. A. P. Pyne.
Mr. S. G. C. Russell.
Mr. T. A. Sedgwick.
Mr. H. D. Wight.
Mr. C. H. Wordingham, C.B.E.

And	*Representing*
Sir W. S. Abell, K.B.E. .. .. / Mr. H. Ruck Keene	Lloyd's Register of Shipping.
Mr. T. Carlton ..	Board of Trade.
Mr. W. Cross ..	Electrical Contractors' Association.
Mr. J. Foster King	British Corporation for the Survey and Registry of Shipping.
Mr. J. Lowson ..	Institution of Engineers and Shipbuilders in Scotland. Electrical Contractors' Association of Scotland.
Mr. A. W. Stewart	Institution of Naval Architects.
Mr. H. Walker, O.B.E. ..	N.E. Coast Institution of Engineers and Shipbuilders.

Wiring Rules Committee.

The President.

Mr. Ll. B. Atkinson.
Mr. H. J. Cash.
Mr. J. R. Cowie.
Mr. W. Cross.
Mr. J. Frith.
Dr. C. C. Garrard.
Mr. P. V. Hunter, C.B.E.
Mr. S. W. Melsom.
Mr. J. F. Nielson.
Mr. A. P. Pyne.
Mr. E. Ridley.
Mr. S. G. C. Russell.
Mr. C. P. Sparks, C.B.E.
Mr. C. H. Wordingham, C.B.E.

And	*Representing*
Mr. B. M. Drake..	Contractors (unofficially).
Sir T. O. Callender Mr. J. F. W. Hooper	Cable Makers (unofficially).
Mr. A. C. Cockburn Mr. A. L. Taylor..	Fire Offices (unofficially).
Mr. E. G. Batt .. Mr. H. H. Berry.. Mr. J. R. Dick .. Mr. A. R. Everest Mr. C. Rodgers ..	British Electrical and Allied Manufacturers' Association.
Mr. W. F. Bishop	Cable Makers' Association.
Mr. F. R. Baldock	Independent Cable Makers' Association.
Mr. R. A. Ure ..	Electrical Contractors' Association of Scotland.
Mr. J. Christie .. Mr. F. W. Purse ..	Incorporated Municipal Electrical Association.
Mr. E. T. Ruthven Murray	Incorporated Association of Electric Power Companies.
Mr. W. R. Rawlings Mr. S. H. Webb ..	Electrical Contractors' Association.
Mr. J. M. Crowdy..	Association of Supervising Electricians.
Mr. O. M. Andrews	Conference of Chief Officials of the London Electric Supply Companies.

Sectional Committees.

Lighting and Power.

The President.

Mr. J. W. Beauchamp.
Mr. R. A. Chattock.
Mr. J. M. Donaldson.
Viscount Falmouth.
Mr. A. F. Harmer.
Mr. A. Lindsay.

Prof. W. M. Thornton, O.B.E., D.Sc.

Traction.

The President.

Col. R. E. Crompton, C.B.
Mr. H. Jones.
Lt.-Col. F. A. Cortez Leigh.
Mr. F. Lydall.
Mr. W. Nairn.
Mr. G. W. Partridge.
Mr. F. Pooley.
Mr. J. Sayers.
Mr. Roger T. Smith.
Dr. S. P. Smith.
Mr. B. Welbourn.
Mr. H. T. Young.

Electro-Chemistry and Electro-Metallurgy.

The President.

Mr. D. F. Campbell.
Mr. W. A. Chamen.
Mr. W. R. Cooper.
Mr. S. S. Moore Ede.
Mr. S. E. Fedden.
Mr. E. M. Hollingsworth.
Mr. W. M. Morrison.
Mr. C. P. Sparks, C.B.E.
Mr. J. Swinburne, F.R.S.

Sectional Committees—*continued.*

Telegraphs and Telephones.

The President.

Mr. H. G. Brown.
Mr. W. W. Cook.
Dr. W. H. Eccles, F.R.S.
Mr. S. Evershed.
Mr. H. H. Harrison.
Mr. T. B. Johnson.
Mr. G. H. Nash, C.B.E.
Mr. F. Pooley.
Col. T. F. Purves, O.B.E.
Mr. J. Sayers.
Mr. C. W. Schaefer.
Mr. E. H. Shaughnessy, O.B.E.
Mr. F. Tremain.
Mr. H. T. Young.

Wireless Section.

The Committee of the Wireless Section for 1924-25 is constituted as follows:—

Mr. E. H. Shaughnessy, O.B.E. (*Chairman*).

The President.

Dr. S. Brydon.
Mr. R. C. Clinker.
Mr. C. F. Elwell.
Dr. J. Erskine-Murray.
Prof. C. L. Fortescue, O.B.E.
Mr. F. Gill, O.B.E.
Prof. G. W. O. Howe, D.Sc.
Captain N. Lea, B.Sc.
Mr. C. F. Phillips.
Captain H. R. Sankey, C.B., C.B.E., R.E.
Commander J. A. Slee, C.B.E., R.N.
Dr. R. L. Smith-Rose.
Mr. A. A. Campbell Swinton, F.R.S.
Mr. C. F. Trippe.

The Chairman of the Papers Committee (*ex-officio*).

And	*Representing*
Capt. C. E. Kennedy-Purvis, R.N.	Admiralty.
Major A. G. Lee, M.C., B.Sc. ..	Post Office.
Major H. P. T. Lefroy, D.S.O., M.C.	Air Ministry.
Major R. Chenevix Trench, O.B.E., M.C.	War Office.

The Benevolent Fund.

AN ELECTRIC HARMONIC ANALYSER.*

By J. D. COCKCROFT, R. T. COE, J. A. TYACKE, Students, and MILES WALKER, Member.

(*Paper first received 21st January, and in final form 22nd September*, 1924; *read before* THE INSTITUTION *6th November, before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE *17th November, and before the* SCOTTISH CENTRE *9th December*, 1924.)

SUMMARY.

The paper deals with the experimental harmonic analysis of electromotive force and current wave-forms. A brief outline of existing methods is given and their limitations are discussed. A modification of the dynamometer method, which allows a much higher degree of accuracy to be attained, and in which the properties of an oscillatory circuit are used to obtain a sinusoidal current wave of suitable frequency, is described. This current is passed through one coil of a dynamometer, whilst the wave to be analysed is passed through the other. The values of the coefficients in the Fourier series representing the wave-form being analysed are obtained from the readings of the dynamometer and an ammeter.

The final method advocated aims at analysing wave-forms up to at least the 23rd harmonic and correct to within 0·1 per cent of the fundamental. The accuracy of the method must be established by comparison with a method more accurate than the commonly employed oscillograph method, the accuracy of which is considerably improved upon. Such a standard method, which involves the use of a synchronously driven commutator, is dealt with in detail in the first part of the paper and its own accuracy is established. Most of the principles involved are common to the two succeeding methods. A full discussion of the errors involved in the three methods is given, and the design of the necessary instruments is considered. For convenience, most of the mathematics involved is given in appendixes and only the results are quoted in the paper itself.

TABLE OF CONTENTS.

LIST OF CHIEF SYMBOLS USED IN THE PAPER.

r, r'' = total effective resistance of oscillatory circuit without and with valve amplification respectively.

r_1, r_2 = resistances of separate inductance coils in oscillatory circuit.

L = total inductance in oscillatory circuit.

L_1, L_2 = inductances of separate coils in oscillatory circuit.

C = capacity of condenser in oscillatory circuit.

R = total resistance of non-inductive potential divider shunting fixed coil of dynamometer.

R_1 = non-inductive resistance used between oscillatory circuit and commutator in standard method.

r_p, L_p = resistance and inductance respectively of dynamometer pressure-coil alone.

R_p, C_p = external resistance and capacity respectively in pressure-coil circuit.

Z_n = impedance of pressure-coil circuit to nth harmonic current.

$\omega = 2\pi \times$ (frequency of fundamental).

n = order of harmonic to which oscillatory circuit is tuned.

x = order of any other harmonic.

i_1 = instantaneous value of current in pressure coil of dynamometer.

I_n, I_x = amplitudes of nth and xth harmonics respectively in pressure-coil current i_1.

i_2 = instantaneous value of the current in fixed coil of dynamometer (i.e. of oscillatory current).

I'_n, I'_x = amplitudes of nth and xth harmonics in oscillatory current i_2.

I''_n, I''_x = amplitudes of nth and xth harmonics in oscillatory current, after amplification by means of valve.

V_n, V_x = amplitudes of nth and xth harmonics in resonating voltage across main inductance.

E_n, E_x = amplitudes of nth and xth harmonics in E.M.F. applied to oscillatory circuit by means of commutator or coupling with neon-lamp current.

α = one-quarter of phase angle corresponding to each impulse of neon-lamp current.

ψ = calculated error as fraction of fundamental.

δ = calculated error as fraction of harmonic being found.

ϕ_n, ϕ'_n = phase angles of nth harmonic currents in pressure coil and fixed coil respectively of dynamometer.

$\theta_n = \phi_n - \phi'_n$ = difference of phase between nth harmonic currents in the two coils of dynamometer.

N = ampere-turns (R.M.S.) of nth harmonic in fixed coil of dynamometer.

D = dynamometer constant, giving deflection in terms of ampere-turns of fixed coil and current of moving coil, i_1.

k = dynamometer constant, giving deflection in terms of i_1 and i_2, the currents in the two coils.

K = dynamometer constant, giving the nth harmonic in the E.M.F. applied to the pressure coil in terms of the dynamometer deflection and the resonating voltage (R.M.S.) across the fixed coil of the dynamometer.

K_1 = dynamometer torque constant.

E_{dc} = d.c. voltage applied to commutator.

M_1, M = mutual inductances between the neon-lamp circuit and grid circuit of valve, respectively, and the oscillatory circuit.

g, a, h, b, u = coefficients defining the valve characteristics.

i_a, v_a, v_g = anode current, anode voltage and grid voltage respectively of the amplifying valve.

A = amplification factor, or ratio of amplified to unamplified nth harmonic currents in oscillatory circuit.

e', v', d' = reading of voltmeter across E.M.F. supply being analysed, reading of voltmeter across fixed coil of dynamometer, and deflection of dynamometer respectively, all taken before amplification.

e'', v'', d'' = readings of instruments as above, all taken with amplified oscillatory current.

e_n = nth harmonic (R.M.S.) in the E.M.F. wave under analysis.

1. Introduction.

Those members of the Institution who have sat under the late John Perry will remember that one of the topics which he used to discuss with such infectious enthusiasm was the behaviour of a wattmeter of the dynamometer type when fed with currents of varying frequencies.

After a lecture on the Fourier series, illustrated by references to common everyday experiences, he arrived at the expression

$$\left.\begin{aligned} F(t) = A_0 + A_1 \sin\ \omega t + B_1 \cos\ \omega t + \\ \dots + A_2 \sin 2\omega t + B_2 \cos 2\omega t + \\ \dots + A_n \sin n\omega t + B_n \cos n\omega t + \end{aligned}\right\} \quad . \quad . \quad (1)$$

where $F(t)$ is any one-valued periodic function of time satisfying certain very general conditions which may be taken to hold in all cases likely to interest the electrical engineer; n is the order of a particular harmonic; and A_n and B_n are numerical coefficients. The full meaning of this expression was illustrated by examples drawn from physics and engineering.

He then introduced his students to the elements of harmonic analysis. Multiplying both sides of Equation (1) by $\sin \omega t$ and integrating throughout a complete period, that is from $\omega t = 0$ to $\omega t = 2\pi$ radians, we saw that all the terms on the right-hand side disappeared, except the terms containing $\sin \omega t$, so that

$$\int_0^{\frac{2\pi}{\omega}} F(t) \sin \omega t\, dt = A_1 \int_0^{\frac{2\pi}{\omega}} \sin^2 \omega t\, dt = \frac{\pi}{\omega} A_1$$

or more generally

$$\int_0^{\frac{2\pi}{\omega}} F(t) \sin n\omega t\, dt = \frac{\pi}{\omega} A_n$$

From this it is seen that any of the coefficients can be determined by the method of multiplying the function by $\sin n\omega t$, or $\cos n\omega t$ as the case may be, and integrating the product throughout a complete period.

He then pointed out that in the case of an electric current following a periodic function, $F(t)$, of the time, the process of multiplying and integrating could be carried out on a wattmeter of the dynamometer type. For if the current to be analysed is passed through the moving coil of a wattmeter while another current following the law $I_n' \sin n\omega t$ is passed through the stationary coil, the torque on the coil is at every instant equal to the product of $F(t)$ and $I_n' \sin n\omega t$, and the steady deflection of the coil gives the integrated value of all the instantaneous torques. Thus the deflection of the wattmeter is proportional to I_n' and to A_n. The constant of the wattmeter and the value of I_n' being known, A_n can be calculated.

Whether John Perry ever constructed an electric harmonic analyser on this plan is not on record. He no doubt recognized the initial difficulty of generating the analysing current $I_n' \sin n\omega t$ and keeping it accurately in phase, especially where the value of n is high. Many of his old students have no doubt wished for an opportunity to carry out the idea.

The advent of wireless telegraphy, and the familiarity which it has given us with swinging electric circuits, has brought just what was wanted for supplying the analysing current $I_n' \sin n\omega t$. For when an inductance of low resistance is placed in series with a capacity and the circuit is excited in a suitable way, the current in it naturally assumes the sine law, and there is no difficulty in making it of any desired frequency by choosing suitable values for L and C. Moreover, if the exciting pulses are controlled by the current to be analysed and the tuning is sufficiently close, the swinging current assumes the exact frequency of the impressed vibration and its phase is also under control, so that we have all the characteristics necessary for a successful analyser.

In this paper various methods of supplying the analysing current $I_n' \sin n\omega t$ are described. The advantages and disadvantages are discussed and the errors arising in the different cases are set out.

2. Consideration of Previous Methods.

Before proceeding to discuss the dynamometer method in full it will probably be of interest to summarize briefly the various methods of experimental harmonic analysis which have been proposed or described in the past.

These methods may be divided into two broad classes. The first class, which we may describe as "Indirect methods," consists of those methods in which the analysis is carried out in two distinct stages. The wave-form of the supply being analysed is first determined, so that the relation $e = F(t)$ can be expressed graphically; this wave-form is then analysed by one of the usual methods of approximate harmonic analysis.

Various methods of determining the wave-form exist. They depend in general on the Joubert contact principle or on the oscillograph.

Variations of the Joubert contact method have been

described in papers by Duncan,* Ryan,† Goldschmidt ‡ and Laws.§

In Duncan's and Ryan's method the current under analysis is passed through one coil of a dynamometer instrument, while a current is passed through the other coil only at that instant in each half cycle for which the reading is required. The latter current is controlled either by a synchronously driven commutator or by using a saturated transformer having a very sharply peaked secondary E.M.F., thus giving the necessary two impulses per cycle to the dynamometer.

In Goldschmidt's method the current under analysis is passed through one coil of a transformer whose magnetic circuit is completed for a short period in each half cycle. The measuring instrument is connected to a second coil on the core and may therefore be used to determine the values of the primary current at any desired point on the cycle. Laws's method is similar in principle.

In all these methods the duration of the impulse on the measuring instrument has to be made very small to obtain accurate values of the instantaneous E.M.F. The sensitivity of the instruments used is therefore much reduced and errors may be large.

The oscillograph may be considered to trace out the applied wave-shape sufficiently accurately, provided that the frequency of the highest harmonic under determination is not greater than one-tenth the natural frequency of the oscillograph. With the type of oscillograph generally in use, the error in the recording of a high-frequency tooth ripple might be of the order of 5 to 10 per cent.

Having determined the wave-form with sufficient accuracy the analysis may be carried out in three ways :—

(1) By Coradi or other type of mechanical analyser.
(2) By graphical methods.
(3) By calculation from measurement of selected ordinates.

A list of these methods is given in the bibliography to the paper. A general discussion of their accuracy was given by A. E. Clayton in a recent paper.‖ In general it may be stated that the probable accuracy of the "indirect method" of harmonic analysis cannot be greater than 1 per cent of the fundamental term.

The second class of methods, the "Direct methods," determine the values of the coefficients directly from the readings of one or more instruments. We shall discuss three of these methods.

(1) *Resonance Methods.*¶

This method consists generally in applying the E.M.F. under analysis to a circuit containing a choke coil and a condenser in series. By tuning the circuit so that resonance occurs with any particular harmonic, and measuring the voltage across either the choke coil or condenser, the value of the harmonic to whose frequency the circuit is tuned may be calculated, if the constants of the circuit are known.

The chief errors in this method are due to :—

(*a*) The readings obtained for one harmonic being influenced by the other harmonics, in particular by those harmonics whose orders are nearest to that of the harmonic under measurement. To reduce this interference to a negligible amount it is necessary to construct a choke coil with a very low damping factor, the ratio of self-induction to *effective* resistance being not less than 0·1. This necessitates using an iron-cored coil or a large weight of copper (of the order of 200 lb.).

(*b*) Having obtained this low damping factor, difficulty arises in obtaining accurate readings for the peak values of current, due to small variations from exact resonance frequency. Thus a variation of 0·5 per cent from exact resonance frequency would mean a decrease in resonating current to one-sixth of the peak value, when determining the 21st harmonic of a 50-cycle wave.

(*c*) The effect of eddy-current losses in iron and copper and of hysteresis losses in iron and dielectric. These cause a change in effective resistance with frequency and, since the E.M.F. across the coil varies inversely as the *effective* resistance, serious errors are introduced. For accuracy, the circuit has to be calibrated for the whole range of frequencies.

(2) *Rectifying Methods.*

This class of method has been fully treated in papers by Lyle,* Bedell † and Labouret.‡ They depend on the same principle as Fischer-Hinnen's method of approximate analysis by selected ordinates (see Bibliography). If i_t be the instantaneous value of current at time t, and T be the period of the wave, we have

$$\begin{aligned} i_t &= I_0 + I_1 \sin(\omega t - \phi_1) + I_2 \sin(2\omega t - \phi_2) \\ &\quad + \ldots I_n \sin(n\omega t - \phi_n) \ldots \\ i_{t+T/(2n)} &= I_0 + I_1 \sin\{\omega[t + T/(2n)] - \phi_1\} \\ &\quad + I_2 \sin\{2\omega[t + T/(2n)] - \phi_2\} \\ &\quad + \ldots I_n \sin\{n\omega[t + T/(2n)] - \phi_n\} + \ldots \end{aligned}$$

and it may easily be shown that

$$\begin{aligned} & i_t - i_{t+T/(2n)} + i_{t+2T/(2n)} - i_{t+3T/(2n)} + \ldots \\ & \quad - i_{t+(2n-1)T/(2n)} = 2n[I_n \sin(n\omega t - \phi_n) \\ & \quad + I_{3n} \sin(3n\omega t - \phi_{3n}) \\ & \quad + \ldots I_{kn} \sin(kn\omega t - \phi_{kn}) + \ldots \end{aligned}$$

i.e. the sum of the series

$$i_t - i_{t+T/(2n)} + i_{t+2T/(2n)} + \ldots \quad (2)$$

will depend only on the harmonics of order n, $3n$, $5n$, etc.

The methods described in the above-mentioned papers perform the summation (2) mechanically by means of a synchronously driven commutator. If therefore the

highest appreciable harmonic is of order xn, in the determination of the nth harmonic the amplitudes and phase angles of the harmonics of orders $3n$, $5n$, . . . xn have to be determined. The commutator has therefore to be capable of reversing the direction of current xn times per cycle.

It will be seen that for the determination of one particular harmonic this method is very laborious.

(3) *A Potentiometer Method.**

The alternating-current potentiometer is used for the analysis. If the phase of one of the currents in the potentiometer circuit be shifted by 120° from the phase giving no deflection in the vibration galvanometer, a current will flow due to all the harmonics except the 3rd, 9th, 15th, etc., assuming the even harmonics to be negligible. Similarly by shifting the phase by 72° the harmonics of order $5n$ will produce no effect. Hence by taking a number of readings with different settings of the phase shifter, it is possible to establish a series of equations with the amplitudes of the harmonics as unknowns and on solving these to determine these amplitudes.

The method is not very accurate, since the potentiometer is not being used in a nul method, and in addition the calculation becomes very cumbersome if the order of harmonic which it is desired to determine much exceeds the 13th.

3(a). Theory of the Dynamometer Method.

The simplest direct method, from the theoretical point of view, is undoubtedly the dynamometer method. As we have shown in the introduction, the current to be analysed, or a current proportional to the E.M.F. if an E.M.F. wave is to be analysed, is passed through one coil of a dynamometer, whilst an "analysing" sinusoidal current of the frequency of the harmonic to be found is passed through the other coil.

Let the current under analysis be denoted by i_1, and the analysing current by i_2, and let

$$i_1 = I_0 + I_1 \sin(\omega t - \phi_1) + I_2 \sin(2\omega t - \phi_2) + \ldots I_n \sin(n\omega t - \phi_n)$$

and
$$i_2 = I_n' \sin(n\omega t - \phi_n')$$

Then the instantaneous torque on the moving coil is

$$\begin{aligned}\tau &= K_1 i_1 i_2 \\ &= K_1 I_n' \sin(n\omega t - \phi_n')\{I_0 + I_1 \sin(\omega t - \phi_1) + \ldots \\ &\qquad + I_n \sin(n\omega t - \phi_n) + \ldots\}\end{aligned}$$

If now the natural period of the instrument is large compared with the period $2\pi/\omega$, the deflection d will be proportional to the mean torque and is given by

$$\begin{aligned}d &= k\frac{\omega}{2\pi}\int_0^{2\pi/\omega} I_n' \sin(n\omega t - \phi_n')\{I_0 + I_1 \sin(\omega t - \phi_1) \\ &\qquad + \ldots I_n \sin(n\omega t - \phi_n) + \ldots\}dt \\ &= \tfrac{1}{2}kI_nI_n' \cos(\phi_n - \phi_n') \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)\end{aligned}$$

Thus, k and I_n' being fixed, the deflection depends only on the amplitude of the harmonic in the complex wave having the same frequency as the analysing current. By controlling the phase of the analysing current, ϕ_n' can be varied until d is a maximum, which occurs when $\phi_n = \phi_n'$. I_n' is measured and k is known; hence I_n may be calculated.

Alternatively, we may alter the phase of the analysing current by a quarter of a cycle and obtain a new deflection

$$d_0 = \tfrac{1}{2}kI_nI_n' \sin(\phi_n - \phi_n') \quad . \quad . \quad . \quad (3a)$$

From (3) and (3a) we may eliminate $(\phi_n - \phi_n')$ and determine I_n.

Thus
$$I_n = \frac{2\sqrt{(d^2 + d_0^2)}}{kI_n'} \quad . \quad . \quad . \quad . \quad (3b)$$

If the analysing current does not coincide exactly in frequency with any harmonic and is given by

$$i_2 = I_n' \sin\{(n\omega - \sigma)t - \phi_n'\}$$

where σ is small compared with ω, we have for the torque on the moving system

$$\begin{aligned}\tau = \tfrac{1}{2}K_1 I_n I_n' [&\cos(\sigma t + \phi_n' - \phi_n) \\ &- \cos\{(2n\omega - \sigma)t - (\phi_n' + \phi_n)\}] + R_n\end{aligned}$$

where R_n contains only terms of periodicity higher than or equal to $(\omega - \sigma)$. The only term influencing the deflection will therefore be that involving σt, and therefore

$$d = \tfrac{1}{2}kI_nI_n' \cos(\sigma t + \phi_n' - \phi_n) \quad . \quad . \quad (3c)$$

k being unchanged, provided σ is small compared with the natural periodicity of the moving system. The deflection will therefore vary harmonically with period $2\pi/\sigma$, and from observations of the maximum deflection we might determine I_n.

The difficulty in practice is to obtain a perfectly sinusoidal current of suitable frequency. We therefore proceed to discuss the error introduced by the analysing current not being exactly sinusoidal.

3(b). The Errors Introduced by an Imperfect Analysing Wave.

For a correct appreciation of these errors it is necessary to discuss briefly the probable size of the coefficients we are measuring.

In the first place we know from observations by means of an oscillograph that the wave-forms of most alternating-current generators are roughly sinusoidal and that the amplitude of the harmonics is considerably less than the amplitude of the fundamental, except in very special cases when the harmonics have been exaggerated by resonance.

The smallness of the amplitude of the harmonics arises from the effort of the designer of the machinery to suppress them as much as possible, and in this effort he is greatly aided by the following circumstances:—

Most alternating-current machines have north and south poles of similar conformation, so that the positive lobe of the wave-form is the same shape as the negative lobe. When they are identical the even harmonics disappear altogether and we are left with only the odd

* Quattrosoldi: *L'Elettrotecnica*, 1915, vol. 2, p. 616.

harmonics. That is to say, in most cases n has only odd values and

$$e = E_1 \sin(\omega t - \phi_1) + E_3 \sin(3\omega t - \phi_3) + \ldots$$

In the next place, the shape of the field-form of most a.c. machines is roughly sinusoidal, so that if the flux density B in the gap at any point is expressed as a function of the angular position, θ, of the point (taken as a two-pole machine)

$$B = B_1 \sin(\theta - \psi_1) + B_3 \sin(3\theta - \psi_3) + \ldots$$

it will be found that, upon the whole, the higher harmonics of B have smaller and smaller amplitudes as their order increases. For instance, if we take the case of a rectangular field-form (and most field-forms in practice are a good deal more favourable than the rectangular form), we have

$$\frac{B_n}{B_1} = \frac{1}{n}$$

Where, however, there are teeth upon the field magnet, as in the case of some turbo-generators, some of the higher harmonics in the field-form may be more pronounced.

A further cause of the smallness of the higher harmonics in the E.M.F. wave-form is the spread of the coils on the armature of the a.c. machine. The effect of the spread is usually expressed by means of the "breadth coefficients" or "distribution factors," f_1, f_3, f_5, corresponding to the various harmonics. With a perfectly distributed winding, we get as the general expression for the distribution factor

$$f_n = \frac{\sin n\sigma}{n\sigma}$$

where σ is half the angle of the coil spread. The value of this becomes rapidly smaller and smaller as n is increased. Where, however, the winding lies in m slots whose angular spacing is γ, the general expression for the distribution factor becomes

$$f_{ns} = \frac{\sin nm(\gamma/2)}{m \sin n(\gamma/2)}$$

For most values of n this expression becomes smaller as n is increased, but in the special case where there are Q slots per pole (Q being an integer) and $n = 2KQ \pm 1$, the value of the distribution factor becomes equal to the distribution factor for the fundamental. By making Q fractional, this condition can be avoided. If this is inconvenient in the design of the machine, care is usually taken to make B_n very small for the harmonic in question. As the amplitude of the harmonic in the E.M.F. wave-form E_n is proportional to the product of f_n and B_n, we may take it that, as a rule, E_n/E_1 is less than $1/n$. An exception to this may occur when the winding lies in an integral number of slots per pole and the corresponding value of B_n is very pronounced.

A further source of high-frequency harmonics is the effect of flux-swing resulting from the passage of stator and rotor teeth. Again we have harmonics of order $2Q \pm 1$. It should be noted that this number is not necessarily integral, as for example when there is not an integral number of slots per pole-pair. In this case the E.M.F. is periodic in the time of revolution of the shaft and not in the time of passage of the pole-pairs, and we should therefore take the former as our fundamental period to conform to the usual notation of harmonic analysis. Thus, what is usually known as the fundamental would be the 2nd, 3rd or higher harmonic, according to the number of pole-pairs.

When the dynamometer analyser is employed to determine the magnitude of the commutator ripples in rotary converters and d.c. machines, we have in general to measure an E.M.F. of single frequency.

Another application is in the analysis of current wave-forms such as the magnetizing current of transformers. No general indication can of course be given as to the probable order of magnitude of the harmonics in these cases. Numerous other applications will no doubt suggest themselves.

In the discussion of the errors of the method it is proposed to deal mainly with the first and most frequent case—the wave-forms likely to be given by commercial alternators. We shall discuss, therefore, the case in which only odd harmonics exist in the wave-shape and in which the ratio of the amplitude of harmonics of order n to that of the fundamental is less than $1/n$.

Let the imperfect analysing current used in the determination of the nth harmonic contain other harmonics than the nth. Let us suppose that

$$I_2 = i'_0 + I'_1 \sin(\omega t - \phi'_1) + I'_2 \sin(2\omega t - \phi'_2) + \ldots + I'_n \sin(n\omega t - \phi'_n) + \ldots + I'_x \sin(x\omega t - \phi'_x) + \ldots$$

and the current under analysis, i_1, is given by

$$i_1 = I_1 \sin(\omega t - \phi_1) + I_3 \sin(3\omega t - \phi_3) + \ldots + I_n \sin(n\omega t - \phi_n) + \ldots + I_x \sin(x\omega t - \phi_x) + \ldots$$

Then if d_1 be the actual reading of the dynamometer under these imperfect conditions, we find

$$d_1 = \tfrac{1}{2}k[I_1 I'_1 \cos\theta_1 + I_3 I'_3 \cos\theta_3 + \ldots I_n I'_n + \ldots + I_x I'_x \cos\theta_x + \ldots] \quad (3d)$$

where $\theta_1 = \phi_1 - \phi'_1$, etc.

If d be the reading which would be given, using a perfect analysing wave, then $d = \frac{1}{2}kI_nI'_n$.

The absolute magnitude of the error, δ, is therefore given by

$$\delta = \frac{2(d_1 - d)}{kI'_n}$$

and the magnitude of the error ψ relative to the magnitude of the fundamental is given by

$$\psi = \frac{2(d_1 - d)}{kI'_n I_1} = \frac{I'_1}{I'_n}\cos\theta_1 + \frac{I_3 I'_3}{I_1 I'_n}\cos\theta_3 + \ldots \frac{I'_{n-2} I_{n-2}}{I_1 I'_n}\cos\theta_{n-2} + \sum_{r=1}^{\infty} \frac{I_{n+2r} I'_{n+2r}}{I_1 I'_n}\cos\theta_{n+2r} \quad (3e)$$

The relative error ψ is thus represented by the sum of an infinite series whose terms depend, first, on the magnitudes of the ratios I_x/I_1, i.e. on the relative magnitudes of the harmonics in the wave under analysis, and, secondly, on the ratios I'_x/I'_n, i.e. on the freedom or otherwise of the analysing wave-form from impurities. It is essential, therefore, that these latter ratios should be small.

The convergency and limits of the series for ψ will be discussed later.

4. The Use of an Oscillatory Circuit to Obtain a Sinusoidal Analysing Current.

One of the first investigators to use the dynamometer method of analysis was Descoudres.* He obtained a sinusoidal E.M.F. of variable frequency by rotating a coil in the uniform field of a solenoid, the frequency being varied by driving the coil through gear wheels from a synchronous rotor. This apparatus was apparently quite satisfactory for harmonics up to the order of 9, but difficulties would probably arise in the extension of the method to harmonics of the order of 23, as a result of the high speed of rotation which would be necessary.

Dina † advocated the use of a multi-rotor alternator of the inductor type for generating the analysing current. The effect of the shape of the rotor and stator teeth on the wave-form would have to be closely studied before constructing such an alternator.

If the frequency of the wave under analysis were exactly constant, it would be a perfectly simple matter to generate a suitable analysing current by means of a triode oscillator. Unfortunately, however, in the majority of cases the variation in frequency of the supply under analysis would be sufficiently large to cause a periodic variation in the dynamometer deflection, as shown in (3c). Generally, as will be shown later, the frequency of this variation will be too high for any accurate results to be obtained. It is therefore necessary, in whatever method is adopted, to ensure that the frequency of the analysing wave is maintained at an exact multiple of the fundamental frequency of the wave under analysis.

The principal modification in the dynamometer method of analysis introduced in this paper consists in the application of the selective properties of an oscillatory circuit to obtain a sinusoidal current. We shall assume in the first place that it is possible to generate a complex wave-form of E.M.F.

$$e = \sum_{x=1}^{x=\infty} E_x \sin (x\omega t - \phi_x)$$

such that some harmonic of frequency $n\omega/(2\pi)$ has exactly the same frequency as one of the harmonics we wish to determine in a given wave-form.

We now proceed to consider the effect of applying this complex wave to the circuit represented in Fig. 1 when it is tuned to a frequency $n\omega/(2\pi)$.

The circuit consists of a choke coil, a high resistance and condenser in parallel, connected to the source of E.M.F. through a large non-inductive resistance.

Let L, r_1 = self-induction and resistance of choke coil.
C = capacity of condenser.
R_1 = non-inductive resistance of from 6 000 ohms to 50 000 ohms.
R = non-inductive resistance used as potential divider—200 000 ohms.

$$e = \sum_{n=1}^{n=\infty} E_n \sin n\omega t = \text{E.M.F. applied to AB.}$$

$$v = \sum_{n=1}^{n=\infty} V_n \sin (n\omega t - \phi_n) = \text{E.M.F. across DE.}$$

$$i = \sum_{n=1}^{n=\infty} I'_n \sin (n\omega t - \phi'_n) = \text{current in choke coil.}$$

We expect to find the current of frequency $n\omega$ in the choke coil predominant. We proceed to calculate,

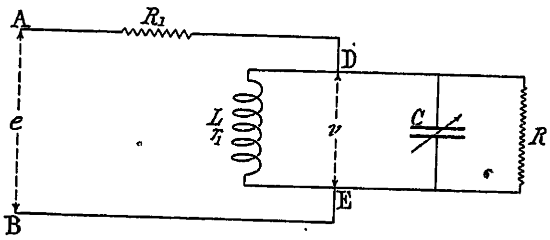

Fig. 1.—Diagram of circuit carrying a swinging current excited by voltage applied at AB.

first, the amplitude of the voltage V_n of frequency $n\omega$ across the terminals of the choke coil, and secondly the ratio of the amplitude of current of frequency $n\omega$ to that of any other frequency $x\omega$ in the choke coil, or I'_n/I'_x. It is evident that this ratio gives us the measure of the selective properties of the circuit.

It is shown in Appendix 1 that, with the above notation,

$$V_n = \frac{E_n}{1 + rR_1C/L} \quad . \quad . \quad . \quad . \quad (4)$$

where $\quad r = r_1 + \frac{1}{R} \cdot \frac{L}{C}$ (see Fig. 1)

and

$$\frac{I'_n}{I'_x} = \frac{E_n}{E_x} \cdot \frac{x^2 - n^2}{n} \cdot \frac{R_1\omega C}{1 + R_1rC/L} \text{ (approx.)} \quad . \quad (4a)$$

so that, as R_1 is increased to make R_1rC/L large compared with unity,

$$\frac{I'_n}{I'_x} = \frac{\omega L}{r} \cdot \frac{E_n}{E_x} \cdot \frac{x^2 - n^2}{n} \text{ (approx.)} \quad . \quad . \quad (4b)$$

To make the ratio I'_n/I'_x as large as possible and at the same time to keep V_n as large as possible, it is advisable to choose R_1 so that R_1Cr/L is of the order of three. It is also necessary to make the factor L/r

* *Elektrotechnische Zeitschrift*, 1900, vol. 21, pp. 752 and 900.
† *Elettrotecnica*, 1916, vol. 3, p. 3.

as large as possible. The limiting factor governing this ratio is the weight of copper required for the coil. We shall assume that it is possible to obtain a ratio L/r of the order of 1/15. If we now write

$$\frac{I'_n}{I'_x} = \lambda_{nx}\frac{E_n}{E_x}$$

we can tabulate values of λ_{nx} for a few typical values of n and x, assuming $\omega = 314$.

TABLE 1.

Values of λ_{nx} for Circuit 1.

n	x	λ_{nx}	n	x	λ_{nx}
1	3	128	5	1	77
	5	384		3	51
	11	1 920		7	77
	23	8 430		23	1 620
3	1	43	23	1	368
	5	85		5	351
	7	214		21	61
	23	2 800		25	67

It is therefore clear that even if all the harmonics in the applied wave were equal, the resulting current wave in the choke coil would possess very few harmonics greater than 1 per cent of the amplitude of the harmonic to which the circuit was tuned.

5. A Standard Method of Analysis in which the Analysing Current is Obtained from a D.C. Supply by the Use of a Multi-Part Commutator and Gear Wheels.

(*a*) The first method which was developed for producing the forced oscillations of the desired range of

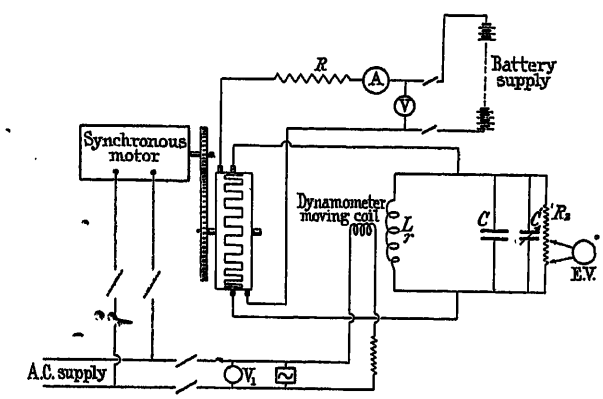

FIG. 2.—Commutator method of excitation.

frequencies, was to use a 46-part commutator driven at some fraction of the fundamental frequency by a synchronous motor and gear wheels. The outer rings of the commutator were connected to a d.c. supply, and the circuit in use was connected to the segments by a pair of brushes. The arrangement is illustrated diagrammatically in Fig. 2. The wave-form of the applied E.M.F. is then rectangular or trapezoidal in shape, as shown in Figs. 3 and 4.

If the frequency of the commutator is $[1/(2\pi)](n\omega/23)$, the frequency of the rectangular wave will be $n\omega/(2\pi)$. Each of these wave-shapes, as is well known, may be expressed as a Fourier series, and, if E_{dc} is the maximum

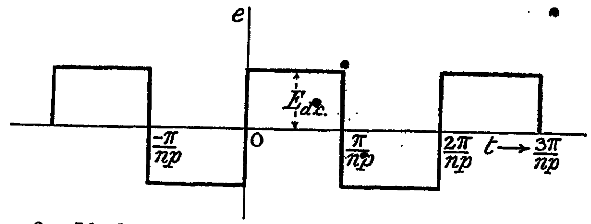

FIG. 3.—Ideal wave-shape of E.M.F. given by commutator.

value of the wave, we have for the rectangular shape of wave

$$e = \frac{4}{\pi}E_{dc}\left(\sin n\omega t + \frac{1}{3}\sin 3n\omega t + \ldots \frac{1}{x}\sin xn\omega t + \ldots\right) \quad . \quad (5)$$

and for the wave of trapezoidal shape

$$e = \frac{4}{\pi}E_{dc}\left(\frac{\sin\alpha}{\alpha}\sin n\omega t + \frac{1}{3}\cdot\frac{\sin 3\alpha}{3\alpha}\sin 3n\omega t + \ldots + \frac{1}{x}\cdot\frac{\sin x\alpha}{x\alpha}\sin xn\omega t + \ldots\right) \quad . \quad (5a)$$

Thus if $\omega = 314$ and $n = 1$, i.e. for a commutator speed of 3 000/23 r.p.m.,

$$e = \frac{4}{\pi}E_{dc}\left(\sin\omega t + \frac{1}{3}\sin 3\omega t + \ldots \frac{1}{x}\sin x\omega t + \ldots\right) \quad . \quad (5b)$$

whilst for $n = 3$, or a commutator speed of 9 000/23 r.p.m.,

$$e = \frac{4}{\pi}E_{dc}\left(\sin 3\omega t + \frac{1}{3}\sin 9\omega t + \ldots + \frac{1}{x}\sin 3x\omega t + \ldots\right) \quad . \quad (5c)$$

and for a commutator speed of 3 000 r.p.m.,

$$e = \frac{4}{\pi}E_{dc}\left(\sin 23\omega t + \frac{1}{3}\sin 69\omega t + \ldots + \frac{1}{x}\sin 23x\omega t - \ldots\right)$$

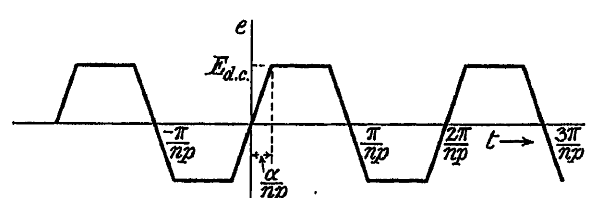

FIG. 4.—Possible wave-shape of E.M.F. given by commutator.

At first sight it might be thought that the gear wheels could be dispensed with altogether, simply using the impressed wave given by (5*b*) and tuning the circuit in turn to the various harmonics in it. It would be found, however, on calculating the magnitude of the fundamental component resulting in the analysing wave, that the error term, ψ, as found from (3*e*) would

be altogether too great. This results from the large magnitude of the ratio E_1/E_n in the impressed wave.

If, however, we change the commutator speed for each harmonic and tune the circuit to the fundamental of the rectangular wave in each case, we entirely eliminate the effect of the fundamental term in the wave under analysis. Thus if n be the order of the harmonic, the only harmonics in the auxiliary current will be those of order n, $3n$, $5n$, etc. In the determination of the 7th harmonic, for example, the error series will be given by

$$\psi = \frac{I_{21}}{I_1} \cdot \frac{I'_{21}}{I'_7} \cos \theta_{21} + \frac{I_{35}}{I_1} \cdot \frac{I'_{35}}{I'_7} \cos \theta_{35} + \ldots \quad (5d)$$

Thus, in addition to eliminating the effect of the fundamental, the number of important terms in the error series is reduced.

(*b*) *Forecast of errors.*—We have shown that the error is given by

$$\psi = \sum_{x=1}^{x=\infty} \frac{I_{xn} I'_{xn}}{I_1 I'_n} \cos \theta_{xn}$$

We may substitute from (4*a*), values of I'_{xn}/I'_n. Thus

$$\frac{I'_{xn}}{I'_n} = \frac{1}{\lambda_{nx}} \cdot \frac{E_{xn}}{E_n}$$

whilst from (5*a*),

$$\frac{E_{xn}}{E_n} \leq \frac{1}{x} \text{ (for odd values of } x)$$

and $E_{xn} = 0$ for even values of x.

It is shown in Appendix 2 that the resulting series for ψ is convergent for all values of n and that

$$\psi < \frac{1}{500} \times \text{max. value of } \frac{I_{xn}}{I_n} \quad . \quad . \quad . \quad (5e)$$

Thus, even if we had, in the wave under analysis, harmonics of the order (xn) having amplitudes equal to 25 per cent of the fundamental, we should still be in a position to measure any harmonic to within 0·05 per cent of the fundamental term.

We have already seen that this ratio of I_{xn}/I_n is never likely to be exceeded in any commercial alternator. Generally it will be less than $1/(xn)$; this will have a maximum value of $\frac{1}{9}$ for the case when $n = 3$ and $x = 3$, so that ψ will be less than 1/4 500.

We may therefore conclude that in the analysis of pressure waves of alternators by this method, the error introduced by the departure from the sinusoidal of the analysing wave will be negligibly small.

(*c*) *Details of apparatus.*—The complete diagram of apparatus used for the analysis is given in Fig. 2. The construction of the commutator does not require much description. It is built up from two brass castings with interlocking fingers, insulated from each other by mica. The castings are mounted on a steel shaft and insulated from this by a bakelite brush. The shaft is fitted with ball bearings and a U-shaped casting made to take these. The brushes are $\frac{1}{16}$ in. diameter hard-grade graphite pencils, and are held in small tubes attached to the brush rocker which fits over the bearing housings. The brushes can be displaced through any desired arc by a spring-and-screw adjustment.

The gear wheels were cut to a diametrical pitch of 48 to 1 in., the pitch diameters varying from $\frac{3}{4}$ in. to $5\frac{3}{4}$ in.

A ring-wound two-pole d.c. motor was adapted for use as a synchronous motor, and gave satisfactory service apart from a tendency to phase-swing. The motor and commutator were mounted on a bedplate, slotted to allow of adjustment for the various gear wheels.

The main considerations governing the design of the oscillatory circuit were:—

(i) The ratio of effective resistance to self-induction, r/L, had not to be much greater than 15.
(ii) The circuit had to be capable of oscillating at all frequencies from 30 to 1 100 cycles per second.

The choke coil was therefore designed to satisfy the following conditions:—

(i) To have a minimum self-induction of the order of 0·004 henry and to enable simple multiples of this to be obtained.
(ii) To have a ratio of resistance to self-induction, when measured with direct current, of the order of 10.
(iii) To have as low as possible a ratio of effective resistance at a frequency of 1 100 to resistance measured with direct current.

Details of the calculation for a similar coil constructed later are given in Appendix 3. To obtain the required ratio of r/L, about 170 lb. weight of copper was used, whilst to keep the eddy-current loss at high frequencies low, the coil was wound with 0·018 in. wire. The variation in self-induction was obtained by a series—parallel grouping of the layers, each layer being brought out to separate terminals. To obtain a low figure for the minimum self-induction with all the layers connected in parallel, it was necessary to wind four strands in parallel. The exact number of turns per layer was calculated, so that the mutual inductance between any one layer and the remainder of the coil was the same for all the layers, thus ensuring approximately equal distribution of current at all frequencies. It was further found that to obtain the maximum value of L/r for a given weight of copper, the section of the coil had to be rectangular and not square as in the case of direct current.

It is shown later that the dimensions of the coil might have been much reduced by the use of a valve as a negative resistance.

The large capacity C in the oscillatory circuit was subdivided into steps of 40, 20, 20, 10, 5, and 5 μF, giving a total of 100 μF, and was suitable for continuous working at 100 volts. The small tuning condenser C′ covered a range from 0·1 to 8·0 μF in convenient steps.

It is essential that the condensers used shall have a small dielectric loss. The effect of this loss on the effective ratio r/L for the circuit is easily found. Thus

when the power factor of the condensers is small we have

$$\cos\phi = r_c\omega C \text{ (approx.)}$$

where r_c is the effective resistance of the condensers. Also, for resonance

$$\omega C = 1/(\omega L) \text{ (approx.)}$$

so that

$$r_c/L = \omega \cos\phi$$

The power factor of good paper condensers does not vary much with frequency and in the range of frequencies from 50 to 2 000 and for the large capacity condensers used was of the order of 0·0025. Their contribution to the effective r/L of the circuit was therefore of the order of 20 at a frequency of 1 100. To reduce this addition to the loss still further, it would be necessary to use mica condensers. These, however, were not available at the time, and so the effective resistance at the higher frequencies was larger than had been desired.

To show the necessity for care in this matter, the power factor of one set of condensers in use in the laboratory proved to be of the order of 0·03. The use of these in the oscillatory circuit would have resulted in an addition to the effective ratio r/L of about 200 at the higher frequencies.

Design of instruments.—It has been shown previously that the calculation of the amplitude of a harmonic is made from the readings of the dynamometer and of the instrument measuring the analysing current. A good way of measuring this current is to measure the voltage across the terminals of the choke coil.

It was essential in the first place that the instrument used should not increase the effective resistance of the circuit to any great extent, and its power consumption had therefore to be small. The most suitable instrument available in the laboratory for the measurement of the analysing current was a reflecting-type electrostatic voltmeter, giving full-scale deflection for 10 volts. This was used in conjunction with a 200 000-ohm-resistance potential divider to measure the E.M.F. across the oscillatory circuit. The frequency and self-induction of the choke coil being known, the current in the choke coil can be calculated from the formula $I_n' = V_n/(n\omega L)$, since the error caused by neglecting the effect of the resistance of the coil can easily be shown to be negligible for the given r/L of the coil. It has since been shown that the Moullin thermionic voltmeter possesses satisfactory properties for the purpose.

To eliminate the losses which would have been inevitable in the use of a separate dynamometer instrument, the choke-coil was so designed that it could be used as the fixed coil of the dynamometer. A moving coil with a bifilar suspension was placed inside the fixed coil, the magnetic axes of the two coils being at right angles. As the flux density at the middle of the large coil could not be large, the deflection of the moving coil is small and necessitates the use of an optical system for the measurement of the deflection. Thus, a concave mirror of 2 m radius was fixed to the moving coil and the reflection of an illuminated scale observed by means of a telescope immediately above the latter, the scale and telescope being 3·3 m. from the moving coil. The moving coil was constructed to have a small radius of gyration, the natural period being about 0·5 second. It was wound on a former 21 × 1·1 × 0·4 cm, using 200 turns of 0·0076 in. wire. The bifilar suspension was 5 cm long, spaced 0·7 cm. To make the movement dead-beat, an oil-immersed paddle was attached. A non-inductive resistance of 1 000 ohms was included in the moving-coil circuit so that it could be used on a 100-volt circuit.

A sketch of the moving coil of the dynamometer system is given in Fig. 5, and details of the movement in Appendix 3.

Sensitivity.—It is clear that the sensitivity obtainable depends on the number of ampere-turns it is possible to have in the fixed coil. This in turn is limited by the voltage it is possible to obtain across the resonating circuit. The rating of the condensers and the limiting potential difference it is possible to use between adjacent commutator segments fix this at a maximum of about 100 volts (R.M.S.)

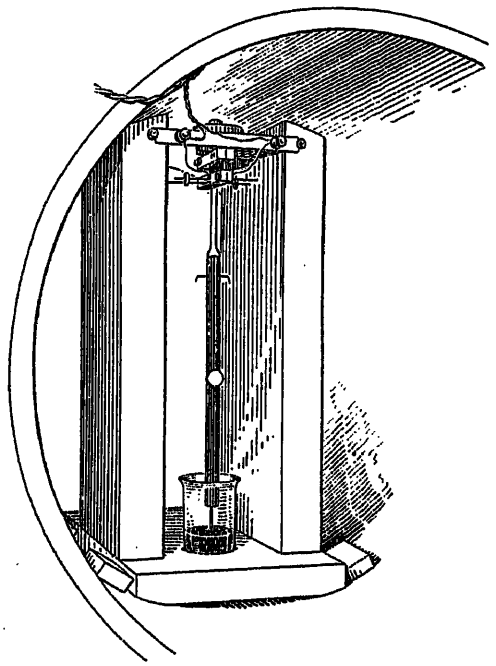

FIG. 5.—Sketch of dynamometer moving-coil.

If now T be the number of turns in series in the coil, and L the self-induction, we have $L = bT^2$, where b is a constant, so that

$$\text{Ampere-turns} = \frac{E}{\omega L}T = \frac{E}{b\omega T}$$

Thus for a maximum number of ampere-turns we require the minimum self-induction and the maximum capacity for any frequency. The factor limiting the possible capacity is the weight and portability of the condensers used, so that 100 μF may be taken to be a maximum. At the higher frequencies the limiting factor is the minimum self-induction it is possible to obtain with all the layers of the coil in parallel. This was reduced

as far as possible by winding the coil with four strands in parallel, giving a minimum self-induction of 0·0036 henry.

At a frequency of 1 150 it was therefore possible to obtain 400 ampere-turns in the fixed coil, giving an R.M.S. flux density at the centre of the coil of the order of 12 C.G.S. units. With the moving coil constructed, an E.M.F. of 1 volt across the terminals of the moving-coil circuit would give a torque of about 6 dyne-cm on the coil, resulting in a deflection of 0·1°, or 1 cm on the scale.

Since we can certainly read the scale to 0·05 cm, the value of a harmonic should be determinable to within 0·05 per cent of the fundamental. The sensitivity could, if necessary, be still further increased at the expense of the time period of the moving coil, by reducing the controlling torque.

Calibration.—The dynamometer was calibrated with direct current, care being taken to correct for the earth's field.

If e_n be the R.M.S. value of the harmonic under determination, Z_n the impedance of the moving-coil circuit to this harmonic, N the number of ampere-turns in the fixed coil and d the deflection of the dynamometer when the phase of the analysing current is adjusted to give a maximum, then

$$d = D\frac{e_n}{Z_n}N \quad . \quad . \quad . \quad . \quad . \quad . \quad (5f)$$

where D is the dynamometer constant.

Possible sources of error.—The sources of error in the methods of measurement adopted above are as follows :—

(i) The electrostatic voltmeter deflection is proportional to the sum of the square of the amplitudes of all the harmonics present in the voltage across the oscillatory circuit, and not simply to the square of the amplitude of the harmonic under determination.

(ii) The impedance of the moving-coil circuit is not quite independent of frequency, the self-induction being of the order of 6 mH. At a frequency of 1 150 the error introduced by this will only be of the order of 0·1 per cent.

(iii) The mutual induction between the fixed and the moving coils of the dynamometer causes an error proportionate to the square of the frequency and so may be important for the higher harmonics.

(iv) The distribution of current in the fixed coil may change slightly with frequency and so affect the constants of the instrument.

These sources of error are considered in Appendix 4, and are there shown to be negligible.

(*d*) *Method followed in the analysis of a voltage wave-form.*—The diagram of connections is given in Fig. 2. The brush gear on the commutator is first adjusted so that the inner brushes are in exactly corresponding positions on oppositely connected segments of the commutator. The outer brushes are connected to a battery supply giving up to 250 volts, a non-inductive resistance of the order of 50 000 ohms being connected between the battery and commutator. The gear wheels necessary for the particular harmonic under measurement are fitted and the motor run up to speed and synchronized with the machine or supply whose wave-form is to be analysed.

The value of capacity required in the resonating circuit is calculated, the layers of the choke coil being connected to give the largest possible value of capacity for the given frequency. The supply switch to the commutator is closed, and the oscillatory circuit tuned to give approximately a maximum reading on the electrostatic voltmeter.

The moving-coil circuit is closed and the brush rocker on the commutator moved until a maximum reading is obtained on the dynamometer scale. Before taking a final reading, the tuning of the oscillatory circuit is adjusted to the exact resonance point. The R.M.S. voltage of the supply under test is read by an ordinary precision voltmeter, and the frequency determined either by a frequency meter or a tachometer. The ampere-turns of the fixed coil are calculated from the reading of the electrostatic voltmeter, and the amplitude of the harmonics are then determined from (5*f*). Thus we have:

$$E_n = \frac{1}{D} \cdot \frac{Z_n}{N}$$

The greatest source of trouble in this method is the effect of sparking at the commutator segments, the carbon deposited from the brushes causing partial short-circuits as a result of the high potential difference existing between segments. The difficulty was partly overcome by making small sleeves of copper gauze to slip over the tips of the pencils, but this could not be regarded as a satisfactory permanent arrangement.

Phase-swinging of the synchronous motor was a further source of trouble. It results in a periodic variation in θ_n, the angle of phase difference between the analysing current flux and harmonic current. The variation is of course worse for the higher harmonics, since a change of 1° in θ, the phase difference for the fundamental, means a change of 23° in θ for the 23rd harmonic. Since the deflection of the dynamometer is proportional to cos θ_n, the amplitude of the variation for small values of θ_n is proportional to sin θ_n and is small when θ_n is small. Thus when the brushes were adjusted to give a maximum reading on the dynamometer scale, the variation became small and it was in all cases possible to obtain readings with an accuracy of 1 to 2 per cent of the full deflection. It would no doubt be possible to reduce this source of trouble very considerably by using a properly designed motor. The motor used had solid poles, but no dampers.

(*e*) *Tests on completed apparatus.*—The tests carried out on the completed apparatus were as follows :—

(i) Oscillographic investigation of current and voltage wave-forms in various parts of the circuit.

(ii) Analysis of oscillograms of analysing current wave.

(iii) Analysis of open-circuit pressure wave of Kolben three-phase alternator, and comparison of results with analysis of oscillograms recording the same waves.

(iv) Experimental proof of the accuracy of the method.

During the course of the tests it was found that the effective ratio r/L of the circuit increased from the d.c. value of 10 to a limiting value of the order of 50 for the higher harmonics. This was probably due in part to defective insulation in the large coil. The tests were proceeded with, but it is to be expected, from the theoretical discussion given above, that the errors obtaining will be of a higher order than would have been obtained had the ratio r/L been 15, as anticipated.

Test (*i*).—Fig. 7 shows the E.M.F. wave given by the commutator when running at a frequency of 50. The oscillograph used was the Duddell type having a natural frequency of 3 000.

Fig. 8, curve A, shows the wave-form of the current flowing into the condenser of the oscillatory circuit.

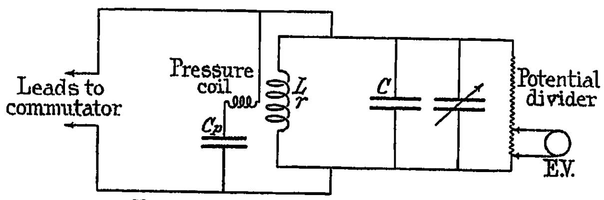

FIG. 6.—Connections for test (iv).

C_p = small-capacity condenser (0·1 μF)
E.V. = electrostatic voltmeter.

The ripples show the points where the condenser receives energy from the commutator. Curve B is the wave-form of the analysing current in the choke coil.

Fig. 9 records the rate of change of the current in the choke coil. It was obtained by connecting a small search coil to the oscillograph elements and approaching this coil to the choke coil until a sufficient deflection was obtained on the oscillograph. By this means any harmonics in the analysing wave will be magnified in proportion to their order. It will be seen that it is remarkably free from higher harmonics.

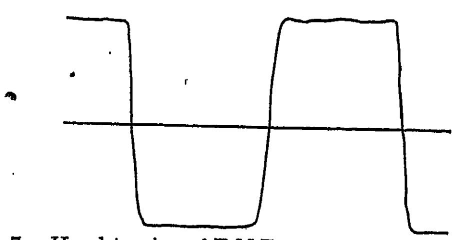

FIG. 7.—Hand tracing of E.M.F. wave-form from commutator.

Test (*ii*) : *Analysis of Fig.* 9.—Fig. 9 was analysed by the Runge method, using 14 ordinates per half-cycle. No harmonic greater than 0·1 per cent of the fundamental was found to exist in the actual current wave.

Test (*iii*) : *Analysis of phase and line voltage of* 30-*kW Kolben alternator for fixed load and excitation.*—This machine forms part of the equipment of the electrical laboratories of the Manchester College of Technology. It has 6 slots per pole in the armature and might therefore be expected to have predominant 11th and 13th harmonics. The only load on the machine during the test was due to the synchronous motor, and since this was of the order of 0·4 kW it would have very little effect on the wave-form.

The phase-voltage and line-voltage waves were analysed by the dynamometer, and oscillograms of the same waves were taken by two separate oscillographs. Both oscillographs were of the Duddell type, having natural frequencies of 3 000 and 7 000 respectively. The oscillograms were analysed by Clayton's modification of the Runge method, using 26 ordinates per half-cycle. The results are given in Table 2.

The probable order of accuracy of the results for the dynamometer method is indicated in each case, the figures being based on the steadiness and consistency of the readings obtained. It will be noted that for the most part they lie within the limits $\pm$ 0·1 per cent of the fundamental. The oscillograms were not enlarged for analysis, and greater accuracy than to within 1 per cent of the fundamental could hardly be hoped for.

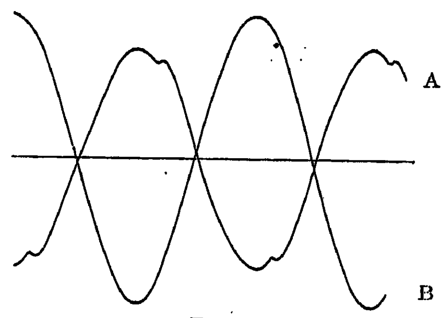

FIG. 8.

Curve A, current in condenser of oscillatory circuit.
Curve B, current in choke coil.

It will be noted, on comparing the figures for the harmonics in the phase and line pressures respectively, that the 3rd and 9th harmonics do not quite disappear in the line pressure. This is probably due to lack of balance in the phases.

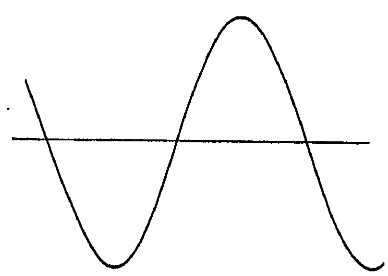

FIG. 9.—Rate of change of current in choke coil.

The 15th and 21st harmonics were not determined, as gear wheels corresponding to these orders had not been cut.

Figs. 10 and 11 show the oscillograms of the two wave-forms analysed.

Test (*iv*) : *Experimental proof of the accuracy of the method.*—If we can prove:—

(i) That the reading obtained on the dynamometer for any harmonic is independent of the values of all the other harmonics; and

(ii) That the method gives a correct value for the amplitude of an E.M.F. wave of any single frequency,

it follows that the reading obtained for any harmonic of a complex wave is correct.

To prove (i), let us suppose that the reading obtained for the nth harmonic *is* affected by the other harmonics.

TABLE 2.

Analysis of Phase and Line Voltage of Three-Phase Kolben Alternator at 45 Cycles per sec.

	Line voltage, per cent			Phase voltage, per cent		
Order of harmonic	By dynamometer	By low-frequency oscillograph	By high-frequency oscillograph	By dynamometer	By low-frequency oscillograph	By high-frequency oscillograph
	per cent	per cent	per cent	per cent	per cent	per cent
1	100	100	100	100	100	100
3	0·53 ± 0·01	0·0	0·6	10·0 ± 0·05	11	11
5	5·7 ± 0·1	5·6	5·6	6·0 ± 0·20	4·3	4·1
7	0·20 ± 0·03	1·8	0·6	0·24 ± 0·03	1·4	0·5
9	0·04 ± 0·01	0·0	0·3	7·5 ± 0·1	5·6	8·3
11	—	3·3	1·6	2·7 ± 0·05	0·4	2·3
13	5·2 ± 0·1	5·2	5·2	5·1 ± 0·1	2·9	4·5
15	—	—	—	—	—	—
17	0·66 ± 0·03	0·9	0·8	0·62 ± 0·03	0·5	0·6
19	0·63 ± 0·03	0·4	0·5	—	—	—
21	—	—	—	—	—	—
23	2·4 ± 0·1	1·2	2·0	2·4 ± 0·1	0·4	2·2

We have

$$d_n = \mu_n E_n + \mu_1 E_1 + \mu_3 E_3 + \ldots + \mu_x E_x + \ldots$$

where $E_1, E_3 \ldots E_n$ are the amplitudes of the various

FIG. 10.—Line voltage of Kolben alternator.

harmonics of E.M.F. applied to the moving-coil circuit of the dynamometer, and $\mu_1, \mu_3, \mu_5 \ldots \mu_n$ are constants

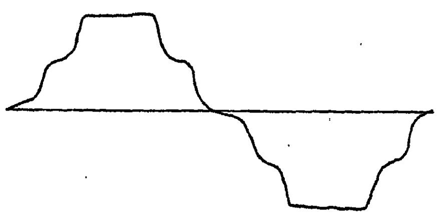

FIG. 11.—Phase voltage of Kolben alternator.

for fixed conditions of the oscillatory circuit and fixed impedance of the moving-coil circuit.

Suppose now that we substitute a small-capacity series condenser for the series resistance of the moving-coil circuit, so that the impedance of the circuit becomes approximately $1/(n\omega C_p)$ to the nth harmonic (see Fig. 6); and suppose then the phase of the analysing current was readjusted to give a maximum reading of the dynamometer, the amplitude of the current being maintained constant.

Then let d_n' be the new deflection obtained; for μ_x we must write $\mu_x r x\omega C\lambda_x$ and for μ_n, $\mu_n rn\omega C$, the factor λ_x being necessary since the phase relations between flux and current of frequency $x\omega$ are no longer the same.

Thus we have

$$d_n' = r\omega C(n\mu_n E_n + \mu_1 E_1\lambda_1 + 3\mu_3 E_3\lambda_3 + \ldots + x\mu_x E_x\lambda_x)$$

and

$$\frac{1}{rn\omega C}\cdot\frac{d_n'}{d_n} = \frac{E_n + \frac{1}{n}\cdot\frac{\mu_1}{\mu_n}\lambda_1 E_1 + \frac{3}{n}\cdot\frac{\mu_3}{\mu_n}\lambda_3 E_3 + \ldots\frac{x}{n}\cdot\frac{\mu_x}{\mu_n}\lambda_x E_x}{E_n + \frac{\mu_1}{\mu_n}E_1 + \frac{\mu_3}{\mu_n}E_3 + \ldots\frac{\mu_x}{\mu_n}E_x} \quad (5g)$$

If now we can find experimentally $\frac{1}{rn\omega C}\cdot\frac{d_n'}{d_n}$ for various values of n and show it to be equal to unity in all cases, within the limits of experimental error, then the only reasonable conclusion is that

$$\mu_1 = \mu_3 = \mu_5 = \ldots \mu_x = 0 \neq \mu_n$$

In other words, the reading obtained for any one harmonic is independent of the values of all the other harmonics.

In carrying out this test it should be noted that when using a series condenser in the moving-coil circuit the error due to the mutual induction between fixed and moving coils of the dynamometer is greatly increased, since the induced current in the moving coil is brought

into phase with the inducing flux. The magnitude of the error has therefore to be found at all positions on the scale and for all frequencies, and the correction applied.

The results obtained are given in Table 3.

TABLE 3.

Order of harmonic, n	d_n	$\frac{1}{rn\omega C}d'_n$
3	10·0 ± 0·05	10·1
5	6·0 ± 0·2	5·8
7	0·24 ± 0·03	0·20
9	7·5 ± 0·10	7·6
11	2·7 ± 0·05	2·7
17	0·62 ± 0·03	0·63

Within the limits of experimental error $\frac{1}{rn\omega C}\cdot\frac{d'_n}{d_n}$ is equal to unity and we may therefore take it that to a sufficient degree of approximation the reading obtained on the dynamometer for one harmonic is independent of the values of all the other harmonics.

To prove (ii), the amplitude of the E.M.F. across the oscillatory circuit when tuned to the 19th harmonic was measured by the dynamometer and the result compared with the value given by a direct reading on the electrostatic voltmeter. The connections for this test are given in Fig. 6.

It is necessary to replace the series resistance in the moving-coil circuit of the dynamometer by a small-capacity series condenser in order to bring the moving-coil current into phase with the fixed-coil flux.

It was shown that with a deflection of 90 cm on the scale the current as calculated from the dynamometer reading and that calculated from the reading of the electrostatic voltmeter agreed to within ± 1 per cent. This would in general be within 0·1 per cent of the fundamental.

We have therefore proved that this dynamometer method will give values for the harmonics of a complex wave correct within the limits ± 0·1 per cent, provided the dynamometer and electrostatic voltmeter can be read to this degree of accuracy. Generally the limiting factor in the accuracy attainable is the unsteadiness of the deflections obtained.

(*f*) *Conclusions.*—The method of analysis outlined above is one which allows a much higher degree of accuracy to be obtained in the determination of harmonics of orders up to 30 than has been possible previously. Results should in general be accurate to within 0·1 per cent of the fundamental, whilst harmonics of amplitudes less than 1 per cent of the fundamental may be measured to within 0·05 per cent of the fundamental.

The figures obtained in the tests given above would undoubtedly have been improved upon had the effective ratio r/L for the oscillatory circuit been of the order of 15 instead of 50. The apparatus with the commutator is, however, too complicated for general commercial use and its principal value will probably be to act as a standard against which other methods may be checked as they are developed.

The authors therefore proceeded to design a simpler apparatus.

6. A METHOD OF ANALYSIS IN WHICH THE ANALYSING CURRENT IS OBTAINED FROM THE A.C. SUPPLY BEING ANALYSED.

(*a*) *General principles of method.*—In Section 5 it was shown that, by using the dynamometer principle and obtaining the necessary sinusoidal analysing current by tuning an oscillatory circuit to the fundamental of a rectangular E.M.F. wave of suitable frequency, a method is obtained which possesses very considerable accuracy and which may therefore be termed a standard method. The rectangular E.M.F. wave for this method must have the frequency of the harmonic being found, and is obtained from a d.c. supply by means of a multi-part commutator driven at an appropriate speed, which will of course be different for the different harmonics.

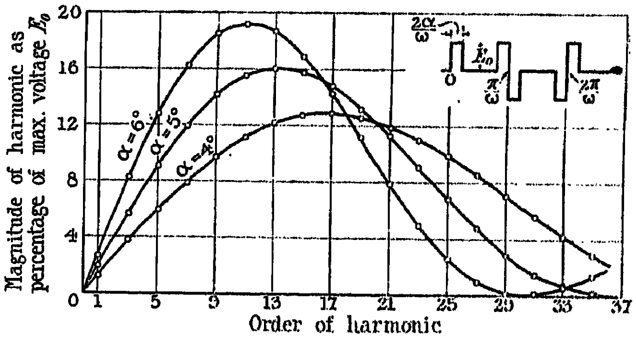

FIG. 12.—Curves showing the magnitudes of the various harmonics in the given wave-form for several values of α.

The method of analysis now to be described was developed from this standard method by two important modifications. In the first place, to avoid the necessity of inducing in the oscillatory circuit an E.M.F. wave of a different frequency for each harmonic to be found, the oscillatory circuit was tuned to the various harmonics in a single E.M.F. wave of a suitable form. In the second place, to avoid introducing the inherent drawbacks of a commutator and the need for a separate d.c. supply of energy, this special E.M.F. wave was obtained from the a.c. supply being analysed, by the use of a saturated transformer and neon-filled glow-lamps.

Since the fundamental frequency of the induced E.M.F. wave will be that of the wave being analysed, the series for the dynamometer error will have terms corresponding to each harmonic in the wave under analysis. In this series the term due to the presence in the analysing current of a harmonic of fundamental frequency will in general be by far the most important, and so from general considerations an E.M.F. wave is required in which the fundamental is small compared with the lower harmonics.

As it is difficult to obtain a practical wave-form with

no fundamental, the most convenient wave for our purpose is one in which the magnitudes of the lower harmonics are approximately proportional to their orders. The simplest of such wave-forms is that shown in Fig. 12, which contains only odd harmonics and no cosine terms.

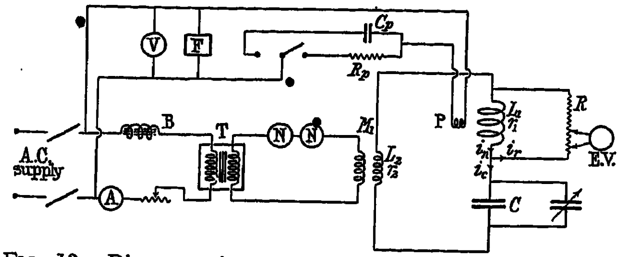

FIG. 13.—Diagram of connections for neon-lamp method of analysis.

B = adjustable choke coil.
T = saturated transformer.
N = neon-filled glow-lamp.
M_1 = air-core mutual inductance.
P = pressure coil of dynamometer.
C_p = small-capacity condenser (0·1 μF).
R_p = non-inductive resistance (1 000 ohms).
F = frequency meter.
E.V. = electrostatic voltmeter.

By the usual process for determining the Fourier coefficients of a periodic wave, we have

$$A_n = \text{amplitude of } n\text{th harmonic} = \frac{\omega}{\pi}\int_0^{2\pi/\omega} f(t) \sin n\omega t\, dt$$

$$= \frac{8E_0}{\pi} \cdot \frac{\sin^2 n\alpha}{n}$$

where $f(t)$ gives the form of the E.M.F. wave;

E_0 = max. value of E.M.F.; and
$\alpha = \frac{1}{4}$ phase angle of duration of each complete impulse of E.M.F.

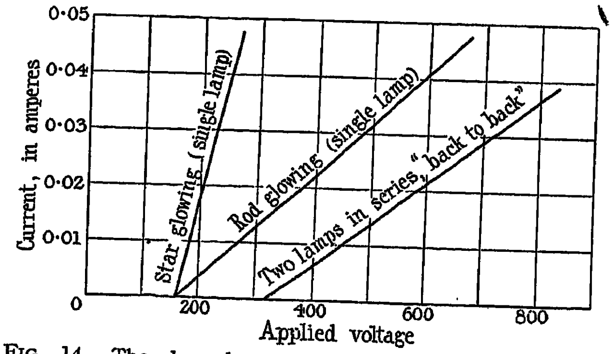

FIG. 14.—The d.c. characteristic of an "Osglim" neon-filled lamp, neglecting a small hysteresis effect.

The amplitudes of the various harmonics in this wave-form for several values of α are shown in Fig. 12. The method of obtaining the analysing current from the a.c. supply being analysed will now be dealt with; it has for its object the induction in the oscillatory circuit of an E.M.F. wave approximating to the one just considered.

(*b*) *A method of inducing a suitable E.M.F. wave in the oscillatory circuit by the use of a saturated transformer and neon-filled glow-lamps.*—The desired E.M.F. wave may be induced in the oscillatory circuit by means of the circuit shown in Fig. 13. The primary of a saturated transformer is connected to the a.c. supply to be analysed through a choke coil such that the current is maintained almost sinusoidal, and saturation takes place early in each half-cycle.

The wave-form of E.M.F. given by the secondary of the transformer is as shown in Fig. 15(*a*).

The secondary circuit of the transformer is completed through several neon-filled glow-lamps, and the primary of an air-core coupling with the oscillatory circuit.

The characteristic of the neon lamp enables us to utilize only the sharp peaks of the secondary E.M.F. wave from the transformer, and thereby to keep to a minimum the magnitude of the fundamental in the resultant current wave.

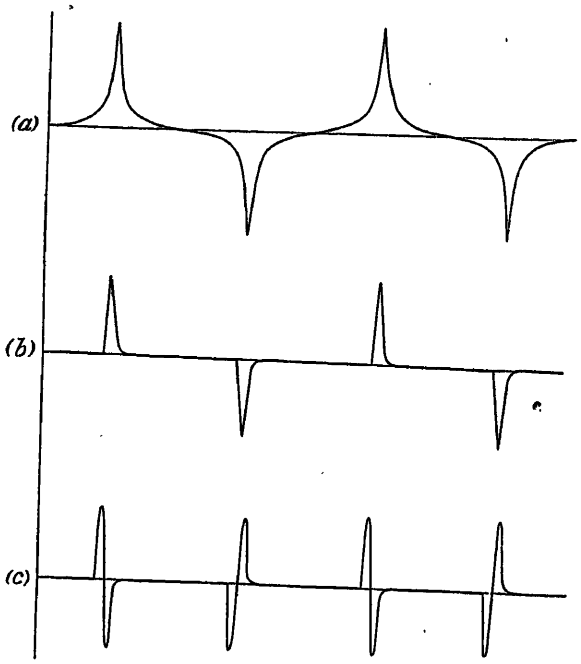

FIG. 15.—Reproductions from oscillogram records taken with Duddell high-frequency oscillograph.

(*a*) Secondary voltage of saturated transformer.
(*b*) Neon-lamp current.
(*c*) E.M.F. induced in oscillatory circuit.

The d.c. characteristic of the neon lamp is such that a definite E.M.F. e is required to start the current in either direction. For an applied E.M.F. less than e there is no current, while for a greater E.M.F. the lamp behaves as a large non-inductive resistance where the effective E.M.F. is equal to the applied E.M.F. minus the starting E.M.F. e. This gives practically a straight-line characteristic, neglecting a small hysteresis effect.

In the actual lamps manufactured, owing to dissimilar electrodes the effective resistance is different for the two directions of current. However, by always using these lamps in pairs, with those of each pair "back to back," a single characteristic can be obtained as shown in Fig. 14. If it is required to make α (see Fig. 12) small, it may be necessary to use four neon lamps in series.

The starting E.M.F. is about 160 volts for each lamp, so that the maximum E.M.F. given by the transformer

may have to exceed 1 500 volts if four neon lamps are used in series.

A current having an almost triangular wave-form over a small part only of each half-cycle, as shown in Fig. 15 (*b*), is obtained in the neon-lamp circuit. This current induces an E.M.F. approximating to the desired wave-form [Fig. 15 (*c*)] in the oscillatory circuit.

(*c*) ***The harmonics in the E.M.F. wave induced in the oscillatory circuit.***—The wave-form of E.M.F. induced in the oscillatory circuit is similar to the theoretical wave already considered, except that the corners are considerably rounded off. It is to be expected from this that the higher harmonics will be smaller and will fall off more rapidly than in this theoretical wave.

(ii) By the analysis of an oscillogram record of the given E.M.F. wave obtained with the Duddell high-frequency oscillograph, by the Clayton modification of the Runge method, using selected ordinates.

The magnitudes of the harmonics found by these two methods are shown in Fig. 16. A reproduction of the oscillogram of this E.M.F. wave is also given. The harmonics in the limiting forms, rectangular and triangular, of the E.M.F. wave shown in Fig. 17 are also indicated by the dotted curves for comparison purposes.

It can easily be shown by the ordinary process for determining the Fourier coefficients of a wave-form,

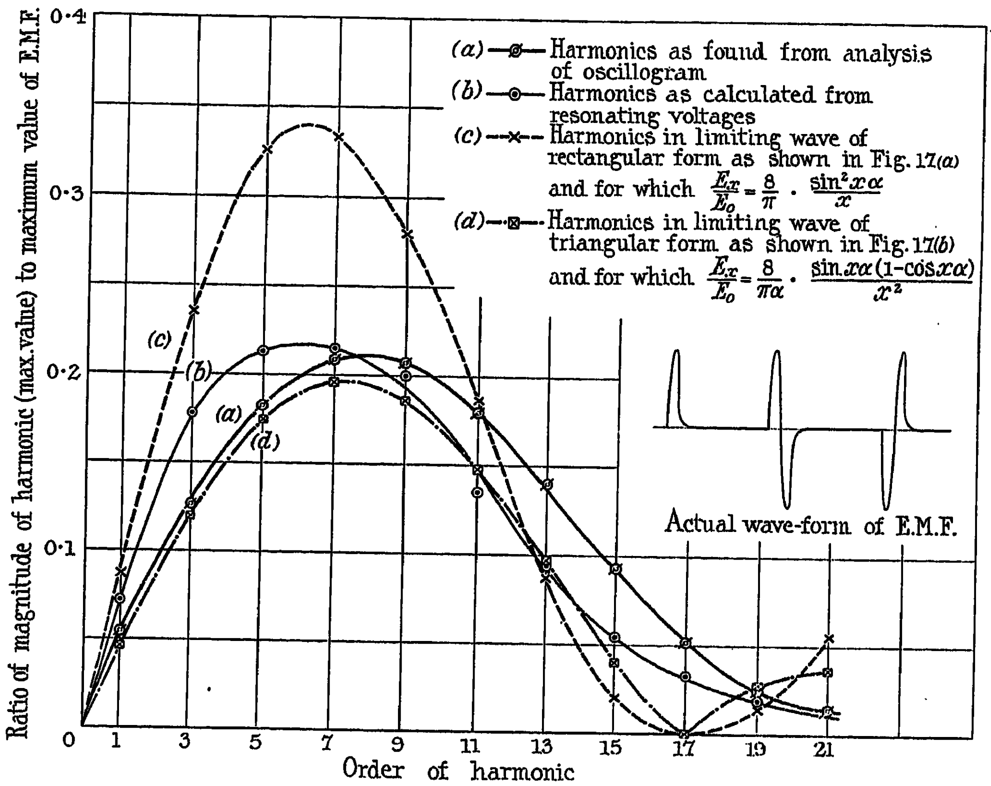

FIG. 16.—The harmonics in the E.M.F. wave induced in the oscillatory circuit.
NOTE :—Only odd harmonics in the wave-forms represented.

From the symmetry of the wave we can predict that no even harmonics will be present, and that the cosine terms will be negligibly small compared with the sine terms if time is measured from the instant of zero E.M.F. at the middle of the double impulse.

The actual harmonics in the E.M.F. wave obtained, for a given setting of the transformer primary and secondary circuits, were calculated :

(i) From the magnitudes of the resonating voltages across the main coil, with the circuit tuned in turn to the various harmonics in the E.M.F. wave, by the use of the formula

$$E_n = V_n\left(\frac{r_1 + r_2}{n\omega L_1} + \frac{n\omega L_1}{R}\right)^*$$

* See Appendix 6, Equation (31).

that for the rectangular wave [Fig. 17 (*a*)] the *x*th harmonic, where *x* is odd, is

$$A_x = \frac{8E_0}{\pi} \cdot \frac{\sin^2 x\alpha}{x}$$

and for the triangular wave [Fig. 17 (*b*)] the *x*th harmonic is

$$B_x = \frac{8E_0}{\pi\alpha} \cdot \frac{\sin x\alpha(1 - \cos x\alpha)}{x^2}$$

All the even harmonics are zero for both these wave-forms.

Curves (*c*) and (*d*) in Fig. 16 were plotted from these expressions, the value of α taken being the mean value found from the oscillogram record, which in this case was 0·185 radian = 10·6°.

It is seen that for $x < 11$, i.e. for $x\alpha < 110°$, the actual harmonics in the E.M.F. wave are intermediate between the corresponding harmonics in the two limiting wave-forms. The actual harmonics are, however, so much nearer to those in the triangular than to those in the rectangular form of the limiting wave, that the former may be taken as quite a fair approximation to the actual wave up to $x\alpha = 140°$.

To measure harmonics up to the 23rd, the supply to the oscillatory circuit must be so adjusted that the value of α for the induced E.M.F. is about 6°, this giving a wave-form in which the maximum harmonic is in the neighbourhood of the 11th or 13th, and the first negligibly small harmonic near the 29th or 31st. The graphs could not be given for this case as experimental figures were not available.

(*d*) *The harmonics in the analysing current of the dynamometer and the theoretical error due to them.*—The oscillatory current will be the analysing current that passes through one coil of the dynamometer, whether the main inductance be used as the fixed coil of the dynamometer or whether the latter be an entirely separate instrument.

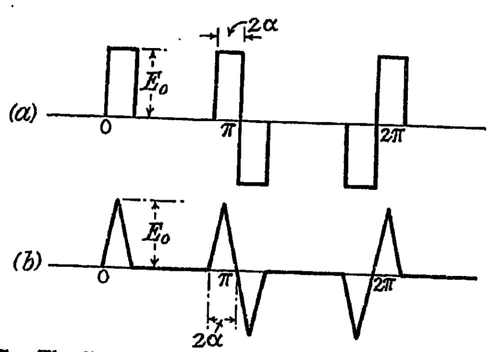

FIG. 17.—The limiting forms of the E.M.F. wave induced in the oscillatory circuit.

Let n = order of harmonic being found, which is also the order of the harmonic in the E.M.F. wave to which the oscillatory circuit is tuned.

x = order of any other harmonic.

E_n, I'_n = nth harmonics (maximum values) of induced E.M.F. and resultant current respectively, in oscillatory circuit.

E_x, I'_x = harmonics of E.M.F. and current of order x.

For the given oscillatory circuit we have, from Equation (29) Appendix 6,

$$\frac{I'_n}{I'_x} = \frac{E_n}{E_x} \cdot \frac{\omega L}{r} \cdot \frac{x^2 - n^2}{x} \text{ (to a 1st approximation)}$$

where L = total inductance in oscillatory circuit $= L_l + L_2$
and r = total effective resistance of oscillatory circuit $= r_1 + r_2 + n^2\omega^2 L_1^2/R$

As it is impossible to make an exact calculation of the error, the above approximation for I'_n/I'_x will suffice for our purpose.

It has already been shown [see 3(*e*)] that for the dynamometer the error due to the analysing current not being sinusoidal is given in terms of the fundamental by

$$\psi = \sum_{x=1}^{x=\infty} \frac{I_x}{I_1} \cdot \frac{I'_x}{I'_n} \cos \theta_x$$

(noting that, by definition, x cannot equal n).

An upper limit is found to the maximum possible value of this series by replacing $\cos \theta_x$ by unity in each term, substituting for I'_x/I'_n, and then summing the series in two sections corresponding to ranges of x from 1 to x_0 and from $(x_0 + 2)$ to ∞, where x_0 is chosen greater than the highest value of n required.

$$\frac{I'_x}{I'_n} = \frac{E_x}{E_n} \cdot \frac{r}{\omega L} \cdot \frac{x}{x^2 - n^2} \text{ approx.}$$

from Equation (29), Appendix 6, and so

$$\psi \leqslant \frac{r}{\omega L} \sum_{x=1}^{x=x_0} \frac{I_x}{I_1} \cdot \frac{E_x}{E_n} \cdot \frac{x}{x^2 - n^2} + \frac{r}{\omega L} \sum_{x=x_0+2}^{x=\infty} \frac{I_x}{I_1} \cdot \frac{E_x}{E_n} \cdot \frac{x}{x^2 - n^2}$$

The lower section is summed term by term to give as good an approximation as possible, while for the higher section a general upper limit can be found for all cases.

Thus from Equation (21), Appendix 5, we have

$$\psi_2 = \frac{r}{\omega L} \sum_{x=x_0+2}^{x=\infty} \frac{I_x}{I_1} \cdot \frac{E_x}{E_n} \cdot \frac{x}{x^2 - n^2}$$
$$\leqslant \frac{r}{\omega L} \cdot \frac{0 \cdot 577a}{\sin n\alpha(1 - \cos n\alpha)} \log_{10} \frac{1}{1 - (n/x_0)^2}$$
$$\therefore \ \psi = \psi_1 + \psi_2$$
$$\leqslant \frac{r}{wL} \left\{ \left(\sum_{x=1}^{x=x_0} \frac{I_x}{I_1} \cdot \frac{E_x}{E_n} \cdot \frac{x}{x^2 - n^2} \right) + \left(\frac{0 \cdot 577a}{\sin n\alpha(1 - \cos n\alpha)} \log_{10} \frac{1}{1 - (n/x_0)^2} \right) \right\} \quad . \quad (6)$$

In evaluating the separate terms of the lower section of the series, E_x/E_n may be replaced by A_x/A_n, the ratio of corresponding harmonics in the limiting triangular wave, with a close degree of approximation, provided that x and n are less than 27 if α is taken as 6°. The slight error introduced by taking A_x/A_n for E_x/E_n in the terms for which $x = 27$ and $x = 29$ will not appreciably affect the value of the total error, as the major portion of this is due in most cases to the terms of the fundamental and lower harmonics.

The maximum possible value of the total error depends of course on the magnitudes of the various harmonics in the wave-form being analysed, and so this maximum value of ψ has been worked out for five, more or less standard, cases for an r/L of 15 and a fundamental frequency of 50.

The five particular wave-forms considered are as follows :—

(i) The rectangular wave in which $I_x/I_1 = 1/x$. It has been shown previously that this wave-form is much worse than any likely to be met with in practice.

(ii) A wave in which all the harmonics up to and including the 19th are 5 per cent of the fundamental, and the remainder have the same amplitudes as in the rectangular wave, i.e. $(100/x)$ per cent of the fundamental.

(iii) A wave in which all the harmonics except the 9th, 11th, 19th, 21st and 29th are less than 1 per cent or $(100/x)$ per cent of the fundamental, whichever is the smaller, while these five particular harmonics have amplitudes $(100/x)$ per cent of the fundamental.

For all these cases x_0 has been taken as 29 when finding harmonics up to and including the 17th, while for the 19th, 21st and 23rd harmonics it has been taken as 35 in order to keep to a fairly close degree of approximation throughout.

Since the factor $\cos \theta_x$ in each term of the series for the actual error may have any value between -1 and $+1$, it is probable that in general the actual error will not exceed about one-fourth of the maximum value calculated. Thus, with perhaps the exception of the third harmonic, the error anticipated will not exceed about 0·1 per cent of the fundamental for a ratio r/L of 15 for the oscillatory circuit and a frequency of 50 for the wave under analysis. In the determination of the 9th and higher harmonics the actual error may conceivably be much less than 0·1 per cent of the fundamental, as the maximum possible error will not in general exceed 0·25 per cent of the fundamental.

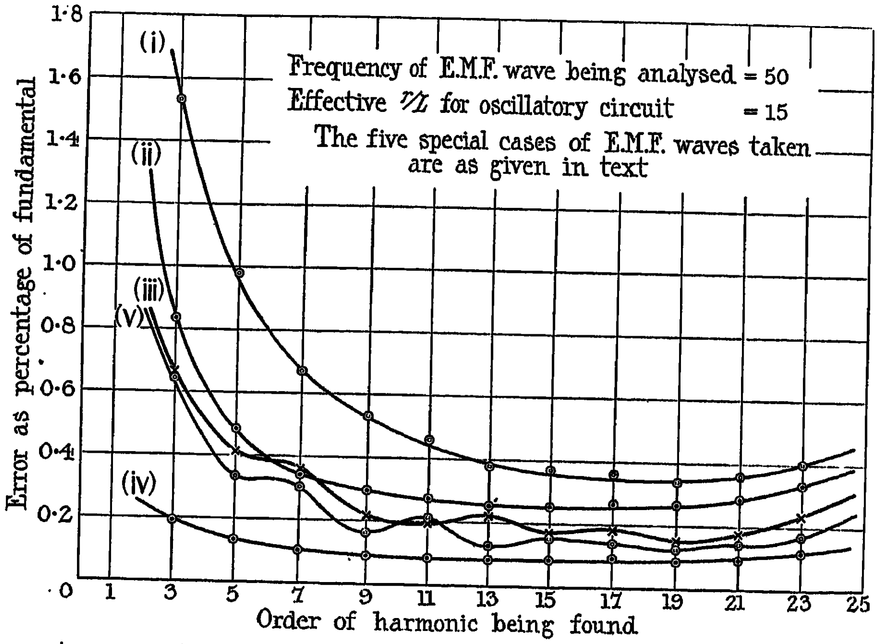

FIG. 18.—The maximum error in the dynamometer reading, due to the analysing current not being sinusoidal, given for the analysis of several different E.M.F. waves.

This case might be considered to correspond to that of an alternator having a very pronounced tooth ripple of low order. The lower the order the greater is likely to be the error introduced.

(iv) A wave in which all the harmonics are less than 1 per cent or $(100/x)$ per cent of the fundamental, whichever is the smaller.

(v) The wave-form of phase voltage of the three-phase Kolben alternator as analysed by the standard method. The results given in Table 2 are taken for harmonics up to the 23rd, and beyond this it is assumed that the harmonics do not exceed 3 per cent or $(100/x)$ per cent of the fundamental, whichever may be the smaller. The results giving the error as a percentage of the fundamental are embodied in Fig. 18.

(e) *Note on wave-form of analysing current.*—Oscillograph records of the resonating voltage across the main inductance for the oscillatory circuit tuned to various harmonics in the induced E.M.F. wave are given later in Fig. 19. From these it is seen that the form of the resonating voltage and therefore of the analysing current is in general that of a series of trains of damped oscillations, each train commencing with the impulse of E.M.F. induced in the circuit.

During the period between two successive impulses the circuit oscillates at its natural frequency, the current following a law of the form

$$i = I_0 e^{-r/2L} \sin n'\omega t$$

where $n' = \sqrt{\{n^2 - r^2/(4\omega^2 L^2)\}}$, and so differs very little from n, the order of the harmonic to which the circuit is tuned. Thus the current gradually changes its phase

with regard to the corresponding harmonic in the induced E.M.F. wave, until with the next impulse of E.M.F. the initial phase relations are again restored.

It might at first be thought that our previous theory is invalid, since there we considered undamped waves throughout. It will be seen, however, that the wave-form of oscillatory current is periodic in twice the time between two successive impulses of E.M.F., and hence, taking this as the fundamental period, we may resolve the trains of damped oscillations into their undamped Fourier components, to which the preceding theory does apply without modification.

(*f*) *Details of apparatus and experimental methods.*—The final method of analysis adopted, in which the whole apparatus is portable, is based on the neon-lamp method at present being described. In this original neon-lamp method serviceability and portability were not premier considerations, as it was only desired to obtain practical results to verify the principles underlying the method. The actual form of the apparatus used, in which essentially laboratory methods of measurement were employed, will here be described.

The temporary apparatus used for the justification of this method differed from that used in the standard method employing a commutator, but only in the means of excitation of the oscillatory circuit.

The full diagram of connections is shown in Fig. 13. The transformer used was a small instrument transformer, rewound to give a high secondary voltage, with a ratio of transformation of 1 to 12. The choke coil in the primary circuit was such that with no rheostat resistance in circuit a current of about 10 amperes was taken from the a.c. supply at about 200 volts, this being sufficient to saturate the core of the transformer over the greater part of the cycle, and giving an R.M.S. voltage of about 30 volts across the primary winding. A maximum secondary voltage of about 2 000 was obtained, owing to the very peaked nature of the wave-form.

The neon-filled glow-lamps employed were the 5-watt "Osglim" lamps for use on a 220-volt d.c. circuit. It was found convenient to use four of these in series, two pairs, with those of each pair "back to back," this enabling us to induce a symmetrical E.M.F. wave in the oscillatory circuit, as already explained.

The air-core mutual inductance, by means of which the desired E.M.F. wave was induced in the oscillatory circuit, consisted of a primary coil having about 5 000 turns of fine wire and a mean diameter of about 15 cm, a secondary with about 30 turns of stranded wire, and a d.c. resistance of 0·12 ohm. As previously pointed out, owing to short-circuits that developed in the main coil this had a ratio r/L of 50 instead of 10, for which it was designed. The ratio r/L for the whole oscillatory circuit was increased to 70 by the secondary of the coupling when the large coil was connected with all its layers in parallel to give a minimum self-inductance.

The remainder of the apparatus was as in the standard method, the resonating voltage across the main inductance being observed by the use of an electrostatic voltmeter in conjunction with a potential divider, while the deflection of the dynamometer whose fixed coil was the main inductance of the oscillatory circuit was observed by means of the reflecting system already described.

The general method of test for the analysis of an E.M.F. wave is as follows :—

The transformer is energized from the same source of a.c. supply as the wave-form being analysed. The choke coil in the primary circuit is adjusted so that a

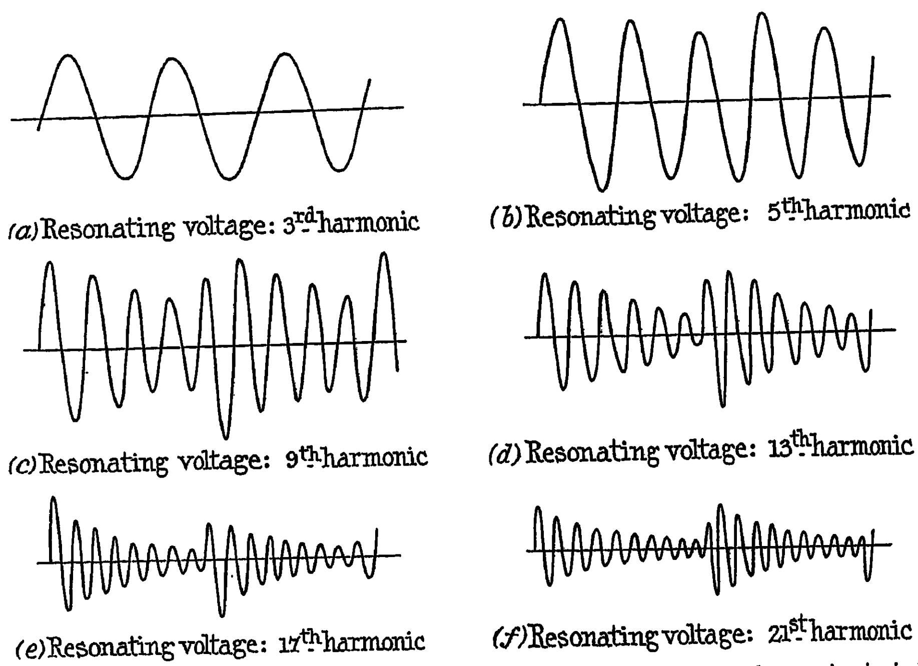

FIG. 19.—Wave-forms of resonating voltage, with oscillatory circuit tuned to various harmonics in induced E.M.F.

current sufficient to saturate the core is obtained, in this case about 10 amperes. The peaks in the wave-form of voltage across either of the transformer windings are most pronounced when the primary current is maintained as nearly as possible sinusoidal. Thus we use a choke coil in the primary circuit in preference to a resistance, and also keep the R.M.S. voltage across the primary of the transformer less than about 20 per cent of the supply voltage. This necessitates an a.c. supply at about 200 volts for the particular transformer used. Should the supply voltage be much less than this, it may be advisable to have it stepped up first by an ordinary transformer.

The number of neon lamps used in the secondary circuit of the transformer must be such that the maximum harmonic in the E.M.F. wave induced in the oscillatory circuit is about the 11th or 13th.

The oscillatory circuit is tuned to the harmonic in the induced E.M.F. of the same order as that to be found in the wave under analysis, the electrostatic voltmeter giving a maximum reading when the circuit is exactly tuned.

The magnitude of the harmonic is found from the resonating voltage and the reading of the dynamometer. We may eliminate the term $\cos(\phi_n - \phi_n')$ either by adjusting the phase of the current in the primary circuit of the transformer until the dynamometer reading is a maximum (a non-inductive resistance being in series with the pressure coil), or by taking two readings of the dynamometer with a non-inductive resistance and a small-capacity condenser respectively in series with the pressure coil.

In the former case the phase of the current is changed by introducing resistance into the primary circuit of the transformer; and at the same time reducing the reactance of the choke coil to keep the current constant.

Then with the same notation as in Equation (5*f*) of Section 5 we have :—

$$d_{max.} = DN\frac{e_n}{Z}$$

N can be found from the resonating voltage V_n, thus

$$N = \frac{V_n}{n\omega L} \times (\text{No. of turns in series})$$

and hence e_n can be determined.

In the second case in which the double-reading method is employed, if d_1 and d_0 are the two dynamometer readings obtained with series resistance and capacity respectively, we have :—

$$d_1 = DN\frac{e_n}{Z_1}\cos\theta_n$$

$$d_0 = DN\frac{e_n}{Z_2}\cos(\theta_n + \tfrac{1}{2}\pi) \text{ approx.}$$

$$= DN\frac{e_n}{Z_2}\sin\theta_n$$

If $$\frac{d_1 Z_1}{DN} = e_1 \quad\text{and}\quad \frac{d_0 Z_2}{DN} = e_2$$

then $$e_n = \sqrt{(e_1^2 + e_2^2)}$$

Although the latter method was used throughout the tests made with this neon-lamp method of analysis, it was used only because it was more convenient at the time, for it was found rather difficult to change the phase of the current by adjusting the resistance and choke coil so that the magnitude of the current remained unaltered, and at the same time to watch for the maximum dynamometer deflection through the telescope.

In the final method of analysis adopted, the phase-changing method is recommended for obtaining the dynamometer deflection. The advantage of this method is that only one reading is necessary for each harmonic, and the possible error is not greatly increased if the reading is taken with the resonating current not quite at its maximum value, whereas with the double-reading method it is essential to tune the circuit exactly for each of the two readings, as otherwise there may be quite an appreciable change in the phase of the resonating current if the frequency changes slightly.

(*g*) *Further possible sources of error.*

(i) In the latter method of finding the harmonic by a double reading of the dynamometer an error will be introduced, due to the phase of current in the pressure coil circuit not being changed by quite 90°.

It can be shown that the fractional error due to this cause lies between the limits $\pm \frac{1}{2}\sin\beta$, where β = angle of phase difference from perfect quadrature. Details of the calculation involved are not given, as this double-reading method was finally superseded.

On inserting the values of the pressure-coil constants, β was found to be 6° 41′ for the 23rd harmonic, giving an error of 5·8 per cent of this harmonic.

As this error increases with the order of the harmonic, it is in general quite small compared with the error due to unsinusoidal analysing current, which for the higher harmonics may have been as much as 0·5 per cent of the fundamental for the inductance coil used.

An additional error may be caused in this method if the frequency changes between the two readings, for in this case the circuit has to be re-tuned for the second reading and the phase of the current may be changed by a small amount relative to that of the induced E.M.F., owing to the fact that it is impossible to ensure that the current is exactly in phase with the E.M.F. in either of the two cases. The amount of this possible phase-change depends on the sensitivity of the instrument measuring the resonating voltage. For an instrument that can be observed to 1 part in 500 the maximum possible error may be increased for all harmonics by about 3 per cent of the harmonic. Even this, however, is not serious.

(ii) When using a condenser in series with the pressure coil we alter I_x/I_1 from its value when employing the series resistance, and so alter the terms in the expression for the error in the dynamometer reading. For all values of x less than n the terms are decreased, while for all values of x greater than n they are increased. This ratio of increase of corresponding terms has, however, an upper limit of $(R_p + r_p)/r_p$.

Thus, since in the original expression for the error the term due to the fundamental is perhaps the most important, it is reasonable to suppose that the resultant

error will not be increased when capacity is substituted for resistance in the pressure-coil circuit.

(iii) When using a series condenser in the pressure-coil circuit the current induced in this circuit by the fixed-coil flux is almost in phase with this latter, and so the mutual-inductance error may be relatively much more important than for the case of a series resistance, dealt with for the standard method in Appendix 4 (ii).

To ascertain whether this error was appreciable for the particular dynamometer and series condenser used, the most convenient method was adopted, namely, that of short-circuiting the pressure coil and its series condenser, passing a known current through the fixed coil, and observing the deflection of the moving coil for various initial positions.

The extra deflection observed was in all cases inappreciable and so the error due to this cause could be neglected.

(iv) All other possible sources of error have already been dealt with in connection with the standard method of analysis, it being shown that the magnitude of the error introduced is in every case negligible.

(*h*) *Results of tests.*—Oscillogram records of the resonating voltages across the main coil were obtained for most of the harmonics. The element of the oscillograph was connected direct to a small search coil which was placed sufficiently near to the end of the main inductance to give a reasonable deflection. Reproductions from the original tracings obtained with a Duddell low-frequency oscillograph are shown in Fig. 19.

Two E.M.F. waves were analysed by the neon-lamp method described, namely the phase and line voltages of the three-phase Kolben alternator, as analysed by the standard method. The supply to the saturated transformer was the only load on the machine during the tests.

The analysis was not carried beyond the 17th harmonic in either case, as sufficiently large resonating currents could not be obtained. This was due to the fact that at the time of the test the primary and secondary circuits of the saturated transformer had not been properly adjusted to give a sufficiently small arc of current in the latter circuit, with the result that the higher harmonics in the E.M.F. wave induced in the oscillatory circuit decreased far too rapidly.

The results obtained are given in Table 4. The results obtained by the standard method of analysis are, for purposes of comparison, also included in this table.

(*i*) *Conclusions.*—From the results it is seen that the error is less than 0·5 per cent of the fundamental except in the case of the 17th harmonic, for which it is 0·54 per cent. The larger error for the higher harmonics can be attributed partly to imperfect quadrature adjustment and partly to the experimental error of reading, since for these harmonics the dynamometer deflections were comparatively small. Also, owing to inferior dielectric, the losses in the small tuning condenser were much larger than originally anticipated. From a previous discussion of this point in connection with the standard method it is probable that for the particular condensers used the increase in the effective ratio r/L for the oscillatory circuit may easily have been as much as 50 per cent at the frequency of the 17th harmonic.

As already pointed out, the first error can be eliminated altogether in the final method if we use that method of dynamometer reading in which the phase of the primary current of the saturated transformer is adjusted to give a maximum dynamometer deflection.

The most important information derived from the test-results is the relation between the maximum error and the effective r/L for the circuit. Thus a maximum error of 0·5 per cent of the fundamental was obtained for a ratio r/L of not less than 70 at a fundamental frequency of 45. From this we may deduce that to measure the harmonics in an E.M.F. wave correct to within 0·1 per cent of the fundamental, we require an oscillatory circuit with an effective ratio r/L of 15.

That method of obtaining the dynamometer reading in which the phase of the current is changed will be used as before mentioned, and the sensitivity of the dynamometer will be increased so much that a telescope will no longer be required.

The actual readings of the dynamometer and the voltmeter measuring the resonating voltage, and in fact the actual design of these instruments, will depend on the magnitudes of the resonating currents that it is possible to obtain for the various harmonics, and so mention will here be made of the chief factors limiting the resonating current.

The relative magnitudes of the resonating currents that can be obtained for the various harmonics depend on the harmonics in the induced E.M.F. wave. This question has already been dealt with.

The actual magnitude of any harmonic in the oscillatory circuit with this tuned to a given harmonic will depend largely on the original E.M.F. in the neon-lamp circuit, modified by the back E.M.F. induced in this circuit by the harmonic of current being considered in the oscillatory circuit. The former depends on the peak voltage given by the secondary of the transformer, while the latter depends on the magnitude

of the coupling between the neon-lamp and oscillatory circuits.

For all harmonics other than that to which the oscillatory circuit is tuned, the current in the oscillatory circuit is comparatively small, so that the back E.M.F. induced in the neon-lamp circuit is negligible compared with the corresponding harmonic in the E.M.F. given by the saturated transformer. Thus the given harmonic of current in the neon-lamp circuit remains unaltered, and the current of the same harmonic in the oscillatory circuit is proportional to the coupling or mutual inductances M_1.

In the case of the resonating harmonic, however, the back E.M.F. becomes the predominating factor if M_1 is too large; for then the neon-lamp current of the resonating harmonic is reduced, and so in the oscillatory circuit the resonating harmonic current is reduced relative to the other harmonics. This is equivalent to an increase in the effective ratio r/L for the oscillatory circuit, and this is to be avoided as far as possible. For this reason it will not be advisable to increase M_1 to such a value that the back E.M.F. is appreciable, i.e. the coupling must not be increased beyond the point at which the resonating current is proportional to the value of M.

It is interesting to note that the magnitude of the back E.M.F. induced in the neon-lamp circuit by the oscillatory current is not as great as might at first sight be anticipated, for owing to the peculiar characteristic of the neon lamp this reaction is only effective over approximately that small part of the cycle during which current flows in the lamp circuit. As a result of this it can be shown, by resolving this discontinuous reaction into its various harmonics, that the back E.M.F. is the same as with a coupling for which the inductance $M_1' = M_1 \frac{4}{\pi}\left(a - \frac{\sin 4na}{4n}\right)$ where the reaction is effective over the whole cycle. Thus for $a = 6°$ and $n = 3$, $M_1' = 0{\cdot}032\, M_1$; while for $n = 23$, $M_1' = 0{\cdot}146\ M_1$. Thus the reaction is less for the lower harmonics.

Whilst it is possible to work out theoretically the value of M_1 which must not be exceeded, it is much simpler to ascertain it experimentally by varying the coupling and finding the corresponding values of the resonating voltage for given conditions in the neon-lamp circuit.

Thus it was found that the coupling used in the tests described in this section by no means represented the limit possible. The ultimate limit could not be found, owing to lack of sufficient suitable inductance, but it was shown to be greater than 8 times the inductance of the coupling used in the tests.

With more power available in the oscillatory circuit it should be possible to use less sensitive and therefore more portable forms of instruments without greatly increasing the damping of the oscillatory circuit.

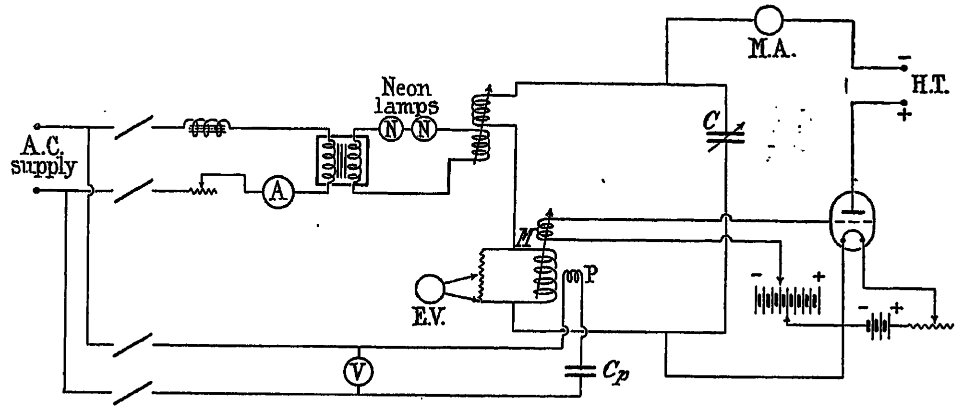

FIG. 20.—Diagram of circuit used in the tests.

7. THE FINAL METHOD OF ANALYSIS, WHICH IS ESSENTIALLY THE NEON-LAMP METHOD MADE PORTABLE BY THE USE OF A VALVE AMPLIFIER.

(*a*) *Introduction.*—The accuracy of the neon-lamp method of analysis has already been shown to depend on the effective ratio r/L for the oscillatory circuit, and so this accuracy can be increased considerably by using a 3-electrode valve circuit which, as is well known, can be made to act as a negative resistance. At the same time, as the oscillatory circuit can be designed for a much larger r/L than was before possible for the required accuracy, the whole apparatus can be made portable.

The discussion in this section of the paper will be chiefly limited to the establishing, theoretically and practically, of the fact that the 3-electrode valve can be used for the desired purpose.

While the apparatus used in the tests has been changed considerably from that of the previous methods, slight modifications in details have still to be made in order that it shall meet ordinary commercial requirements, and so a minute description of the apparatus will not be attempted.

(*b*) *The valve circuit employed, and the theoretical effect of this circuit on the effective ratio r/L for the oscillatory circuit.*—The valve circuit used is shown in Fig. 20. This is perhaps the simplest of all the

possible valve circuits, but it was also found to be the most suitable, both from theoretical considerations and as a result of practical familiarity with the various alternative circuits. Theoretically this is the best circuit, as it is the only one in which the effective resistance of the oscillatory circuit is independent of small changes in frequency. We require a circuit which gives an effective resistance independent of frequency, as otherwise the circuit may become self-oscillatory for even a slight fluctuation in the supply frequency, and when this occurs the dynamometer reading can no longer be interpreted as before.

Considering one harmonic only, in other words dealing with a sinusoidal current, we can obtain a mathematical expression for the effective resistance of the oscillatory circuit to the nth harmonic to which it is tuned, in terms of the constants of the circuit and valve used. We can also find the effective impedance to the xth harmonic current and hence determine the increase in the nth harmonic relative to the xth harmonic, which gives the decrease in the effective ratio r/L for the oscillatory circuit.

If the valve is worked on the middle portion only of its characteristic, and the variations in grid and anode voltage are limited so that only the straight portion is worked on, then

$$\frac{\partial i_a}{\partial v_g} = \text{constant} = g; \quad \text{and} \quad \frac{\partial i_a}{\partial v_a} = \text{constant} = a;$$

where i_a = current entering valve at anode,
v_a = voltage of anode above filament,
v_g = voltage of grid above filament.

With this notation it is shown in Appendix 6 that the effective resistance of the oscillatory circuit is reduced from r to $[r - (gM - aL)/C]$ by the use of the valve, where M = mutual inductance between grid coil and choke coil. This is of course the only impedance to the nth harmonic current.

The approximate impedance to the xth harmonic is shown to be $j\dfrac{x^2 - n^2}{x}\omega L$, this impedance being unchanged by the action of the valve.

Thus $\dfrac{I_n'}{I_x'} = \dfrac{E_n}{E_x} \cdot \dfrac{x^2 - n^2}{x} \cdot \dfrac{\omega L}{r - (gM - aL)/C}$ and so is increased by the ratio $\dfrac{r}{r - (gM - aL)/C} = A$, the amplification factor, and is the same as for a circuit with no valve amplification but with an effective resistance $r - (gM - aL)/C$.

(*c*) *Details of apparatus used.*—The full diagram of connections for the whole apparatus used in the tests made with this method has already been given in Fig. 20. As already pointed out, the apparatus will not be described in great detail as it has still to be modified in several respects. The chief difference from the previous method is in the oscillatory circuit and in the method of measuring the resonating current. The saturated transformer and supply to the neon lamps was essentially unchanged.

The inductance in the oscillatory circuit was divided between two equal coils, one of these being used as the fixed coil of the dynamometer while the other was used for coupling purposes with the neon-lamp circuit. Each coil was designed to have an r/L of 50, and was wound with an average of about 150 turns per layer of single-strand enamel-insulated wire, the exact number of turns per layer being adjusted to give an even distribution of current at all frequencies between the layers when these were connected in parallel. The considerations affecting the design of these coils were exactly as for the case of the original coil used, which case has already been fully dealt with in Section 5(*c*) of this paper. The design details of one of the coils used in the present method are given in Appendix 3. The linear dimensions of the coils were rather less than half those of the original coil used.

Each coil was divided permanently into four equal sections, each consisting of 10 layers connected in parallel. By means of plug connections these sections could be connected as desired, in series, series-parallel, or parallel, giving inductances of 0·0983, 0·0239, 0·0058 henry respectively.

The primary of the coupling with the neon-lamp circuit consisted of 14 layers wound on the outside of one of the main inductance coils, each layer consisting of 145 turns of enamelled wire with an approximate inductance of 0·006 henry. Connections from the ends of each layer were brought out to valve-holders, so that the neon-lamp current could be sent through any desired number of layers by plugging into two suitable valve-leg sockets.

The main condenser was of 10 μF in steps of 2 μF, which enabled the circuit to be tuned if desired to the 3rd harmonic of any a.c. supply with a frequency greater than 35. Together with a 1 μF condenser the tuning was done on a Tinsley variable condenser giving a range from 0·01 μF to 1 μF on a single-dial switch.

To keep the damping factor of the oscillatory circuit as low as possible, that main inductance not used as a coupling with the neon-lamp circuit was used as the fixed coil of the dynamometer by suspending the pressure coil in it. To secure the necessary sensitivity and stability the suspension ligaments passed through a hole in the top of the coil to an outside support. The deflection was found by the use of a reflecting system with a scale 1 m from the moving coil. The pressure coil consisted of 450 turns and had a resistance of 140 ohms, an inductance of 0·0161 henry, and a time period of approximately 2 seconds.

The grid coupling was a coil which could be rotated at the end of the dynamometer main inductance so that its mutual inductance with the oscillatory circuit could be varied. As no current is taken by the grid if the anode voltage is sufficiently high, the field of the dynamometer will not be affected. It is advisable to couple the grid with the dynamometer inductance rather than with the neon-lamp inductance, as in the latter the flux contains larger undesired harmonics than does the resonating current itself, owing to the effect of the neon-lamp current. In particular, the fundamental in the neon-lamp current is not inappreciable and so its amplification should be avoided. The grid coupling coil had a mean diameter of 6 in., con-

sisted of about 5 000 turns of fine wire, and had an inductance of about 1 henry. For an amplification of 4 with the 3rd harmonic of a 50-cycle supply, the angle between the axes of the coils had to be about 15°, while for the same amplification of the 21st harmonic it had to be increased to about 80° owing to the reduced mutual inductance required.

For most of the tests carried out with this method the resonating voltages across the fixed coil of the dynamometer were obtained by the use of the same electrostatic voltmeter and potential divider as were employed in all the previous methods. As an electrostatic voltmeter could not form part of the final apparatus it was replaced in several of the tests by a Moullin thermionic-valve voltmeter * which was found to be quite satisfactory for the purpose. The form

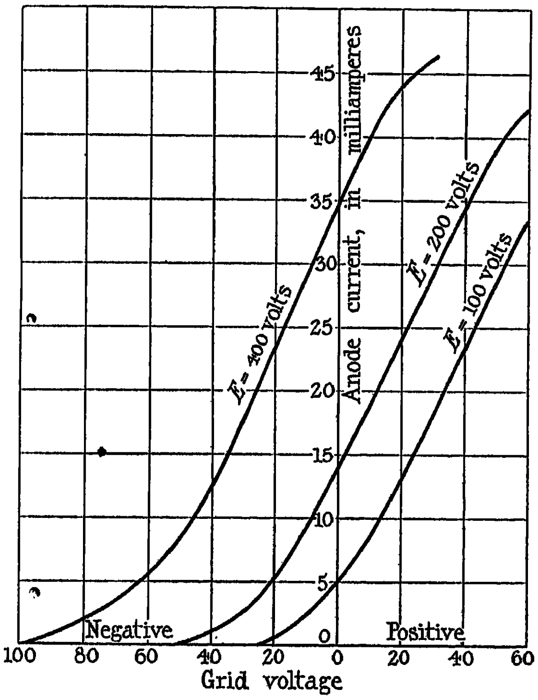

FIG. 21.—Grid voltage/anode current characteristics of the Marconi "LS2" valve used in the tests.

of this voltmeter found most suitable was that in which the a.c. voltage to be measured, and which is applied to the grid, is rectified by means of the grid potential anode-current characteristic, and measured by a d.c. milliameter in the anode circuit. No high-tension battery is required for the anode, which is connected through the ammeter to the positive end of the filament. This voltmeter has of course to be calibrated for the particular valve used, which in this case was a Marconi "R" type valve. This type of voltmeter is not independent of the wave-form, but as the voltage across the swinging circuit is very nearly sinusoidal no appreciable error is introduced. Experiments were made to compare the readings when an electrostatic voltmeter was used and when the Moullin voltmeter was used, the wave-form of the voltage in the moving coil being widely different, and no difference was detected.

Several types of valves were used for amplifying the oscillatory current, but of those tried the Marconi "LS2" valve was found to be the most suitable. This valve was worked with 5·2 volts on the filament, while for the anode circuit the ordinary d.c. supply at 220 volts was used, although a higher voltage would have given better results had it been available.

The characteristics of the valve used are shown in Fig. 21 for anode voltages of 100, 200 and 400 respectively.

(*d*) *Experimental methods.*—Before an actual analysis could be carried out, the transformer and neon-lamp circuits had first to be adjusted so that the desired wave-form of E.M.F. was induced in the oscillatory circuit. This was done as a preliminary test by passing the neon-lamp current through an oscillograph and adjusting the circuit conditions until the duration of neon-lamp current in each half-cycle had the appropriate value. The suitability of the E.M.F. wave obtained for given circuit conditions could also have been judged by calculating harmonics in this E.M.F. wave from the magnitudes of the various resonating voltages.

In the final commercial form of the apparatus there will be no need for a preliminary test of this description, as the transformer and neon-lamp circuits will be so designed that the desired conditions can be obtained by an adjustment of the primary current.

For the apparatus used, the current taken from the a.c. supply was about 10 amperes, although this figure could be greatly reduced by a suitable design of the saturated transformer.

Initially there was no rheostat resistance in the supply circuit, the impedance being almost entirely choke-coil reactance.

The neon-lamp current was passed through the desired numbers of layers of the coupling with the oscillatory circuit by plugging into valve-leg sockets as already explained. As it was desirable, for reasons already given in Section 6(*i*), to know whether the maximum mutual inductance obtainable between the neon-lamp and oscillatory circuits caused too great a reaction between these circuits, a special test was performed. The number of layers of the primary of this coupling through which the neon-lamp current was passed was varied, and the corresponding resonating current found, with the circuit tuned to a given harmonic. The resonating current was found to be proportional to the number of layers of the coil through which the neon-lamp current was passed, that is, to the mutual inductance with the oscillatory circuit up to the maximum mutual inductance obtained with all 14 primary layers in series. The result showed that it was not necessary to limit the coupling to prevent excessive reaction between the circuits. However, in the analysis tests afterwards carried out it was found advisable to pass the neon-lamp current through only two layers of the primary of this coupling, since when a larger coupling was employed the unamplified oscillating current obtained was too large to allow the

* E. B. MOULLIN: "A Direct-Reading Thermionic Voltmeter, and its Applications," *Journal I.E.E.*, 1923, vol. 61, p. 295.

desired amplification to be obtained by the valve as then used.

For the complete analysis of a wave-form, the harmonics are most conveniently worked through in order, starting with the 3rd, for which the approximate capacity required can be calculated. The phase of the current in the supply to the transformer is changed until a maximum reading of the dynamometer is obtained, the oscillatory circuit having been tuned to the desired harmonic. This phase change is effected by inserting resistance in the supply circuit to the transformer and at the same time reducing the reactance of the choke coil to maintain the current constant. In the final apparatus, in order to avoid complication, these adjustments can no doubt be made together by some suitable device, such as a small phase-changing transformer. Owing to the small variation in phase required for the higher harmonics it is only necessary to vary the resistance above about the 9th harmonic. Readings are taken of the maximum dynamometer deflection d'_n, the corresponding resonating voltage v'_n, and the voltage e' of the a.c. supply. The neon-lamp coupling is then disconnected, the valve filament lighted, and the grid coupling adjusted so that the circuit is almost—but not quite—oscillating. The neon-lamp coupling is then remade, the oscillatory circuit again tuned up (the tuning now being much sharper), the phase of the current readjusted if necessary and a further set of readings taken of all three instruments. In the tests made, an amplification of 4 times was obtained without difficulty for all the harmonics, although it could not be greatly exceeded with the valve used.

If d''_n, v''_n and e'' are the respective instrument readings with the amplified current, the readings of both voltmeters being given as R.M.S. values, then

$$d' = ki_n\frac{v'_n}{n\omega L_1},$$ where i_n is the R.M.S. current of nth harmonic in the pressure coil, and k is the d.c. calibration constant of the dynamometer.

$$d'' = ki_n\frac{e''}{e'}\cdot\frac{v''_n}{n\omega L_1}$$

$$\therefore \frac{e'}{e''}d'' - d' = \frac{ki_n}{n\omega L_1}(v''_n - v'_n)$$

$$\therefore \quad i_n = \frac{n\omega L_1}{k}\cdot\frac{\left(\frac{e'}{e''}d'' - d'\right)}{v''_n - v'_n}$$

But $i_n = e_n n\omega C_p$ (approx.), where e_n is the harmonic being found in the E.M.F. wave, and C_p = the capacity in series with the pressure coil.

$$\therefore \quad e_n = \frac{L_1}{kC_p}\cdot\frac{\left(\frac{e'}{e''}d'' - d'\right)}{v''_n - v'_n}$$

$$= K\cdot\frac{\left(\frac{e'}{e''}d'' - d'\right)}{v''_n - v'_n},$$ where $K = \frac{L_1}{kC_p}$ and so depends on the range of inductance used, and on the capacity of the condenser used in series with the pressure coil.

In general the a.c. supply voltage will not change between the two sets of readings, in which case $e'/e'' = 1$.

Since when using a series condenser in the pressure-coil circuit the final result, e_n, is independent of frequency, a change in frequency between the two sets of readings will not affect the accuracy of the result. Thus it is not necessary to know the frequency in order to calculate the magnitude of a harmonic, and so a frequency meter is not essential.

The dynamometer sensitivity was such that, in general, reasonably large deflections could be obtained for a series capacity of only 0·2 or 0·1 μF. In any case it was desirable to use the 0·1 μF condenser for the higher harmonics in order to reduce the error due to the impedance of the pressure-coil circuit being taken as $1/n\omega C_p$, that is, of course, if this error, which is dealt with in Section 7(*e*)(vi) of the paper, is comparable with the error of reading.

One of the advantages of taking two sets of readings and using their difference is that any zero error which there may be is thereby eliminated.

It is desirable that the valve used for amplifying shall not be worked too far beyond the straight portion of its characteristic. A range of grid voltage corresponding to about 0·8 of the anode saturation current is shown in Section 7(*e*)(ii) of the paper not to be excessive. This may be ensured either by calculating the limiting resonating voltage in terms of the limiting grid voltage and the constants of the valve and oscillatory circuit, or by keeping the resonating voltage less than about 80 per cent of the value when the circuit is just oscillating and at the same time working the valve at the middle part of its characteristic, or by working the valve rather below its mid-point and including in the anode circuit a d.c. milliameter, whose indication will begin to increase when the range of grid voltage passes beyond the straight portion of the characteristic.

It might be thought that a considerable increase could be effected in the oscillatory current by using the synchronizing property of coupled valve generators,* since by this property the oscillations in a self-oscillatory circuit can be kept exactly "in step" with an induced E.M.F. whose frequency does not differ from the natural frequency of the oscillatory circuit by an amount greater than that given by

$$\frac{\delta\omega}{\omega} = \frac{1}{\sqrt{2}}\cdot\frac{e_0}{A_0}$$

where e_0 = E.M.F. impressed from outside,
and A_0 = natural amplitude of voltage across oscillatory circuit.

This property cannot be made use of, however, since in the range $p - \delta p$ to $p + \delta p$ for the impressed E.M.F. there is a change in phase of the current in the oscillatory circuit relative to that of the impressed E.M.F. from $-\frac{1}{2}\pi$ to $+\frac{1}{2}\pi$, so that any slight fluctuations in the supply frequency would cause such

* E. V. Appleton: *Proceedings of the Cambridge Philosophical Society*, 1922, vol. 21.

excessive variations in the dynamometer reading that this would be valueless.

The error due to the mutual-inductance effect between the fixed and moving coils of the dynamometer was found to be so small that it was not worth correcting for, as the increase in the deflection due to this cause was less than the error of the reading.

The positions of the iron-cored choke coil in the transformer supply and the neon-lamp coupling, relative to the dynamometer coil, were adjusted for the tests made so that the influence on the deflection of the latter due to stray fields was negligible.

The theory, which forecasted that only the resonating harmonic of the oscillatory current would be amplified, was justified by the test-results obtained, which showed that when the harmonic in the wave being analysed was negligible there was no sensible change in the dynamometer deflection, although this deflection itself might be quite appreciable if the neighbouring harmonics were large. Also the same value for the harmonic was obtained for widely different couplings and resonating voltages.

(*e*) *A theoretical consideration of the various sources of error.*

(i) *Error in dynamometer reading due to the analysing current not being sinusoidal.*—By taking two sets of readings for each harmonic, one before and one after amplification, and calculating the magnitude of the harmonic from the differences of these readings, the dynamometer error is reduced as shown in Appendix 7 to $\frac{3}{8}r/(A\omega L)$ of the value it would have were the harmonic calculated from the single set of readings obtained with the amplified current.

Actually the maximum error is smaller than $[r^2/(40A\omega L)]\psi_n$, where ψ_n is the maximum value of the error in the original single-reading method for an r/L of 15. Thus taking $r/L = 100$, and $A = 4$, tests having shown the latter to be a reasonable figure,

$$\text{max. error} < 0\cdot2\,\psi_n$$

For most waves likely to be analysed, the maximum possible error must therefore be less than 0·1 per cent of the fundamental, which means that the average error likely to be obtained in practice will not exceed about 0·025 per cent of the fundamental, and so in general will be negligible compared with the errors of reading.

For the actual oscillatory circuit used in the tests made with this apparatus, the ratio r/L was considerably increased for the higher harmonics owing to large losses in the main condenser due to inferior dielectric.

For harmonics below the 7th the ratio r/L was probably not greater than 100, and so the maximum error would not have exceeded the figure given above. It was estimated that at the frequency of the 23rd harmonic the ratio r/L might have been as large as 300, which might have led to an average error of about 0·15 per cent of the fundamental. This source of trouble will be removed by a careful design of the condensers used.

(ii) *Error due to interfering harmonics in the analysing current produced by the valve when the latter is worked beyond the straight portion of its characteristic.*—If the valve is worked beyond the straight portion of its characteristic, a sinusoidal voltage applied to the grid will result in an anode current with the tops of its wave flattened, and so this current, and therefore the current in the oscillatory circuit, will contain harmonics of an order other than n.

It is shown in Appendix 8 that if the range of variation of the anode current is limited to about 80 per cent of the saturation current, and the valve is worked from the mid-point of its characteristic, then the only appreciable interfering harmonic induced in the oscillatory circuit will be one of order $3n$. Further, it is shown that due to this cause

$$\text{increase in } \frac{I'_{3n}}{I'_n} < \frac{rhV_g^2}{32n\omega Lg}$$

where V_g = max. value of grid voltage measured from mid-point of characteristic,

and g and h are coefficients determined by the equation

$$i_a = gv_g + hv_g^3 + av_a + bv_a^3$$

which gives a good approximation to the characteristic for a restricted variation of grid voltage, i_a, v_g and v_a being measured from the mid-point of the characteristic.

It is clear from Appendix 6 that this harmonic will not be amplified further by the action of the valve, and is therefore the only harmonic that need be considered for the error in this case.

For the valve used, namely a Marconi "LS2" valve, h/g was of the order of 5×10^{-5} if the valve was worked at the mid-point of its characteristic.

In the tests carried out with this method the valve was worked considerably below the mid-point of its characteristic, as a d.c. supply of only 220 volts was available for use in the anode circuit. Due to this the interfering harmonic was not greater than the value calculated using the ratio h/g as given by the lower portion of the characteristic. This value of h/g was 2×10^{-4}, while the corresponding value of V_g was 30 volts.

The addition to the error as a fraction of the fundamental owing to the presence in the oscillatory circuit of this extra $3n$th harmonic is

$$\frac{I_{3n}}{I_1}\cdot\frac{I'_{3n}}{I'_n}\cos\theta_{3n}$$

(from the general series for the dynamometer error)

$$\leqslant \frac{I_{3n}}{I_1}\cdot\frac{I'_{3n}}{I'_n}$$

This additional error will be greatest when determining the 3rd harmonic, in which case it will be $< 0\cdot0006 I_9/I_1$ for $\omega = 314$ and $r/L = 100$, and since in general we have

$$\frac{I_9}{I_1} < \tfrac{1}{9}$$

the addition to the error will be less than 0·01 per cent of the fundamental under these conditions. This is negligible compared with errors of reading and calibration.

(iii) *Error due to the voltmeter across the main inductance recording the R.M.S. value of the mixed*

wave and not the value of the resonating harmonic only, as assumed.—This is perhaps the chief source of error in this method, owing to the large ratio r/L which is not decreased by amplification for the first set of readings taken for each harmonic.

This error is shown in Appendix 9 to be given by

$$\frac{\delta I_n}{I_n} = \frac{1}{2A} \cdot \left(\frac{r''}{n\omega L}\right)^2 \sum_{x=1}^{x=\infty} \left(\frac{E_x}{E_n} \cdot \frac{x^2}{x^2 - n^2}\right)^2$$

where $\frac{\delta I_n}{I_n}$ = ratio of error to the actual value of the nth harmonic.

The infinite series in the above expression is shown to be convergent for such values of E_x/E_n as would be given by the neon-lamp circuit.

This error is greatest for the 3rd harmonic. For the lower harmonics it is approximately proportional to $1/n^4$, but in all cases it is less than the figure obtained by assuming it to be proportional to $1/n^2$.

Thus for an actual r/L of 100 and an amplification factor of 4, the error will be approximately 10 per cent of the harmonic itself for the 3rd harmonic, 2 per cent for the 5th harmonic, 0·5 per cent for the 7th harmonic, and so on. The error will therefore be negligible except in the case of the 3rd and 5th harmonics, but it should be possible to apply a correction in these cases so that the resulting error is not greater than 1 per cent.

For the oscillatory circuit used, r/L was found to have the approximate values 67, 83 and 96 respectively for the 3rd, 5th and 7th harmonics of a 50-cycle supply. Thus the error for the practical results obtained would be of the order of 4·5 per cent, 1·4 per cent and 0·40 per cent respectively for the 3rd, 5th and 7th harmonics.

If the oscillatory current is measured by means of an ammeter, the error for the lower harmonics is considerably reduced, being now

$$\frac{\delta I_n}{I_n} = \frac{1}{2A} \left(\frac{r''}{n\omega L}\right)^2 \sum_{x=1}^{x=\infty} \left(\frac{E_x}{E_n} \cdot \frac{nx}{x^2 - n^2}\right)^2$$

from which, for $r/L = 100$ and $A = 4$, the error would be 1·3 per cent, 0·8 per cent and 0·4 per cent for the 3rd, 5th and 7th harmonics respectively, and less for all higher harmonics. Thus if an ammeter were used to measure the oscillatory current, and r/L for the circuit did not exceed 100, this error would be negligible for all harmonics.

(iv) *Error due to the reading of the voltmeter across the a.c. supply being taken as due to the fundamental alone.*—Since the voltmeter across the supply being analysed records the R.M.S. value of the fundamental, together with all the harmonics present, a small error may be made by taking this reading as the value of the fundamental alone.

This error, which affects all harmonics in the same ratio, would be only − 1·5 per cent of the harmonic for the Kolben phase voltage as analysed, and, since in general it would be even less than this, it need not be corrected for.

In exceptional cases in which all the harmonics are not small compared with the fundamental, the voltmeter reading can be corrected from the values of the harmonics found to give a close approximation to the true value of the fundamental alone.

(v) *Error due to the impedance of the pressure coil in series with a condenser being taken as $1/(n\omega C_p)$.*

$$\text{Actually } e_n = i_n\sqrt{\left\{r_p^2 + \left(n\omega L_p - \frac{1}{n\omega C_p}\right)^2\right\}}$$

where

e_n and i_n = R.M.S. values of nth harmonics in a.c. voltage and pressure-coil current respectively,

r_p and L_p = resistance and inductance of pressure coil,

and C_p = capacity in series with pressure coil.

$$e_n = \frac{i_n}{n\omega C_p}\sqrt{\left\{1 + n^2\omega^2 C_p^2\left(r_p^2 + n^2\omega^2 L_p^2 - \frac{2L_p}{C_p}\right)\right\}}$$

$$= \frac{i_n}{n\omega C_p}\left\{1 + \tfrac{1}{2}n^2\omega^2 C_p^2\left(r_p^2 + n^2\omega^2 L_p^2 - \frac{2L_p}{C_p}\right)\right\} \text{ (approx.)}$$

Therefore error made in determination of e_n by taking $e_n = i_n/n\omega C_p$ is given by

$$\frac{\text{error}}{e_n} = -\tfrac{1}{2}n^2\omega^2 C_p^2\left(r_p^2 + n^2\omega^2 L^2 - \frac{2L_p}{C_p}\right) \text{ (approx.)}$$

This error increases with the order of the harmonic being found. For the pressure coil used, $r_p = 140$ ohms and $L_p = 0{\cdot}0161$ henry, and so, on substituting these values in the above expression, the error for the 23rd harmonic is given as 7·5 per cent of the harmonic itself for a series capacity of 0·1 μF. This error can be reduced by a suitable design of the pressure coil. Thus it can be reduced to one-half of the above value for the same sensitivity, by rewinding with half the number of turns of wire of double the cross-section.

(vi) *Error due to the mutual-inductance effect between the fixed and moving coils of the dynamometer.*—This error was shown to be negligible for the given dynamometer, exactly as in the case of the dynamometer used in the method dealt with in Section 6 (*g*)(iii).

(vii) *Error due to the grid current affecting the dynamometer reading.*—If the valve cannot be worked so that the grid potential is always negative, a current will flow in the grid coupling coil during part of each cycle and will alter the flux in the fixed coil of the dynamometer if this coil is used for coupling purposes with the grid.

Since the grid current will not flow during the whole cycle, the value of the nth harmonic in this current will be less than u/g of the nth harmonic in the anode current; where u = max. value of $\partial i_g/\partial v_g$, in which i_g = grid current, and $g = \partial i_a/\partial v_g$.

Now ratio of anode current to oscillatory current

= ratio of total admittance of two paths of oscillatory circuit to that of inductive path

$$= \frac{1/(r + jn\omega L) + jn\omega C}{1/(r + jn\omega L)}$$

$$= j\frac{r}{n\omega L} \text{ (approx.)}$$

It can also be shown that the ratio of flux densities produced at the centre of the fixed coil of the dynamo-

meter by the grid coupling coil and the fixed coil itself, respectively, is considerably less than

$$\frac{1}{10}\frac{\text{ampere-turns of coupling coil}}{\text{ampere-turns of fixed coil}}$$

for coils of the same relative dimensions as those used.

Thus the ratio of the flux density produced by the grid coupling to that due to the fixed coil is less than

$$\frac{ur \times 5\,000}{gn\omega L \times 10 \times 640}$$

In general, u/g will be less than $0 \cdot 2$; and so for $n = 3$, for which case it is greatest, the ratio of the two flux densities will be less than 1/30 for an r/L of 200 for the oscillatory circuit.

Since these flux densities differ in phase by approximately 90° the maximum value of the flux density in the fixed coil will only be increased by about $0 \cdot 06$ per cent, and so the error made in the maximum reading of the dynamometer due to this cause will in all cases be negligible.

(*f*) *Summary of errors.*—From the above discussion of the various sources of error it is seen that the only two important errors are due to the reading of the voltmeter across the coil being affected by the interfering harmonics, and to the impedance of the pressure coil differing from the reactance of the series condenser. The former error is only appreciable for the 3rd and 5th harmonics, while the latter only affects the highest harmonics. The former can be reduced by taking both sets of readings with the amplified oscillatory current for both 3rd and 5th harmonics, the amplification factor for the second set being about 25 per cent greater than for the first. By this means the error for the 3rd harmonic can easily be reduced to about $1 \cdot 5$ per cent of that harmonic. As already pointed out, the latter error can also be considerably reduced by redesigning the pressure-coil circuit. With these modifications the total theoretical error should not in any case exceed about 2 per cent of the harmonic being found, for an oscillatory circuit with a total ratio r/L of about 150.

The amplification that can be used with this method may have to be limited for the higher harmonics, if the variation in frequency of the supply being analysed is too great, owing to the corresponding variations that will occur in the magnitude and phase of the oscillatory current relative to the induced E.M.F.

The change in the dynamometer and voltmeter readings for a sudden change in frequency may be obtained as follows. Let the oscillatory circuit be tuned to the nth harmonic of the supply at its initial frequency $\omega/(2\pi)$, and let ϕ = change in phase of nth harmonic current relative to nth harmonic induced E.M.F. caused by a change in frequency given by $\delta\omega/\omega$. Then

$$\phi = \arc\tan\left[\frac{n(\omega+\delta\omega)L - 1/\{n(\omega+\delta\omega)C\}}{r}\right]$$

$$= \arc\tan\left[\frac{n^2\omega^2LC\{1+(2\delta\omega/\omega)+(\delta\omega/\omega)^2\}-1}{rn(\omega+\delta\omega)C}\right]$$

$$= \arc\tan\left(\frac{2n\omega L}{r}\cdot\frac{\delta\omega}{\omega}\right)\text{ (approx., since } n^2\omega^2LC = 1)$$

The oscillatory current and therefore the resonating voltage vary as $\cos\phi$, since impedance $= r/\cos\phi$ and r is fixed

$\therefore$ dynamometer reading varies as $\cos^2\phi$.

Therefore, if ϕ is small,

$$\frac{\text{change in dynamometer reading}}{\text{max. dynamometer reading}} = \sin^2\phi$$

$$= \left(\frac{2n\omega L}{r}\cdot\frac{\delta\omega}{\omega}\right)^2 \text{ approx.}$$

and

$$\frac{\text{change in voltmeter reading}}{\text{max. voltmeter reading}} = \frac{1}{2}\left(\frac{2n\omega L}{r}\cdot\frac{\delta\omega}{\omega}\right)^2 \text{ approx.}$$

Thus the likelihood of frequency variations affecting the readings will be greatest for the higher harmonics.

If actual $r/L = 200$ for $n = 23$, then a sudden change in frequency of $0 \cdot 2$ per cent for this harmonic will cause a change in phase $\phi = \arc\tan 0 \cdot 145$ which will cause decreases of approximately $2 \cdot 0$ per cent and $1 \cdot 0$ per cent in the readings of the dynamometer and voltmeter respectively. However, for an amplification factor of 8, which would mean an effective r''/L of 25, the same change of frequency would cause reductions of approximately 60 per cent and 35 per cent in the readings of the two instruments.

If this change of reading is a measure of the error, the latter can obviously be reduced by using a decreased amplification for the higher harmonics. The neon-lamp coupling could be increased to give a correspondingly larger reading for the unamplified current so that the error of reading is not increased. Thus, with an amplification factor of 2 for the 23rd harmonic the decrease in the dynamometer and voltmeter readings would be $7 \cdot 8$ per cent and $5 \cdot 0$ per cent respectively, for a change in frequency of $0 \cdot 2$ per cent. By using an amplification factor of only 2 an increase will be caused in some of the possible errors that have been dealt with, but it is not anticipated that the total error due to causes other than this fluctuation in frequency will exceed about $0 \cdot 07$ per cent of the fundamental.

It is difficult to predict theoretically the possible error that will arise from a fluctuation in supply frequency, since the latter will not in general be entirely periodic. Also the error will depend on the rate of change of frequency as well as on the limits of its variation. The only fluctuations that will be expected to cause an appreciable error will be those whose frequencies are of the same order as the natural frequency of the moving system of the dynamometer.

The effect of a comparatively high-frequency fluctuation which will naturally be small, will be to cause the dynamometer and voltmeter to give mean readings less than the true readings. Thus for a high-frequency variation in frequency, of amplitude $0 \cdot 1$ per cent, giving a total variation of $0 \cdot 2$ per cent, the maximum readings of the dynamometer and voltmeter that can be obtained will be less than the true maxima by $3 \cdot 9$ per cent and $2 \cdot 5$ per cent respectively for an amplification factor of 4, for the 23rd harmonic.

The fluctuations in speed of low-speed gas- or steam-

engine-driven alternators will be of this type, since the unbalanced torque causing the disturbance will have a frequency at least that of rotation of the crank shaft; this will not in general be less than about 5 per second.

For all very low-frequency variations and slow changes in frequency it will usually be possible to tune the oscillatory circuit so that the resonating current passes through its maximum value. Provided the change is not too rapid, the maximum values of the dynamometer and voltmeter readings will be the true values required.

For the tests performed it was not found necessary to reduce the amplification much for the higher harmonics, although some of the machines analysed were known to have very unsteady speeds. The limits of speed variation within which this method of analysis can be successfully employed were not found, but, as already pointed out, where the frequency fluctuation is large the effect of this fluctuation, which is greatest for the higher harmonics, can be considerably reduced by using less amplification.

(*g*) *Test-results.*—The effect of the valve in reducing the effective resistance of the oscillatory circuit is clearly shown in the oscillograms (Fig. 22) of the resonating voltage before and after amplification. These were obtained as before by connecting the element of the oscillograph direct to a small search coil, which was then brought near to the main inductance. These oscillograms show that the amplitude of the current is increased and that the damping factor as measured by the coefficient of decay of the oscillations is considerably reduced, the current being represented in each half-cycle by an equation of the form

$$i = e^{-rt/(2L)} A \sin n'\omega t$$

where n' differs very little from the order of the harmonic to which the circuit is tuned.

The results of an analysis obtained by this method of the line voltage of the three-phase Kolben alternator are given in Table 5.

In the following table v' and v'' are the voltages across the fixed coil of the dynamometer before and after amplification respectively, while d' and d'' are the corresponding maximum dynamometer deflections.

TABLE 5.

Analysis of Line Voltage of Three-phase Kolben Alternator at 34·5 cycles per second, 170 *volts.*

Order of harmonic n	Resonating voltage		Dynamometer deflection		Ratio of harmonic to fundamental
	v'	v''	d'	d''	
	volts	volts	cm	cm	per cent
3	3·5	10·0	0·95	0·8	0·11
5	2·85	14·3	2·6	15·0	5·46
7	5·3	21·5	1·4	2·5	0·35
9	2·6	15·4	0·6	0·4	0·08
11	9·4	26·0	− 0·5	1·4	0·57
13	4·1	12·6	4·95	15·45	6·35
15	2·5	15·0	0·0	0·4	0·16
17	2·5	18·2	1·4	4·3	0·22
19	2·6	17·5	0·4	6·4	0·51
21	2·4	18·0	− 0·2	0·37	0·43
23	6·4	22·0	2·95	10·4	2·40

The figures obtained for the analysis cannot be compared with the previous figures obtained for the same wave-form, as the machine was running under different conditions of excitation on the two occasions. However, although the absolute accuracy of the method was not verified, the above results show that harmonics known to be very small are in every case indicated as almost negligible, as in the case of the 3rd, 9th and 15th harmonics in the above wave-form. The results show that for these small harmonics the dynamometer reading is not increased appreciably when the analysing current is amplified, which indicates that in general no appreciable error is caused by the dynamometer reading being affected by the change in magnitude and phase of the

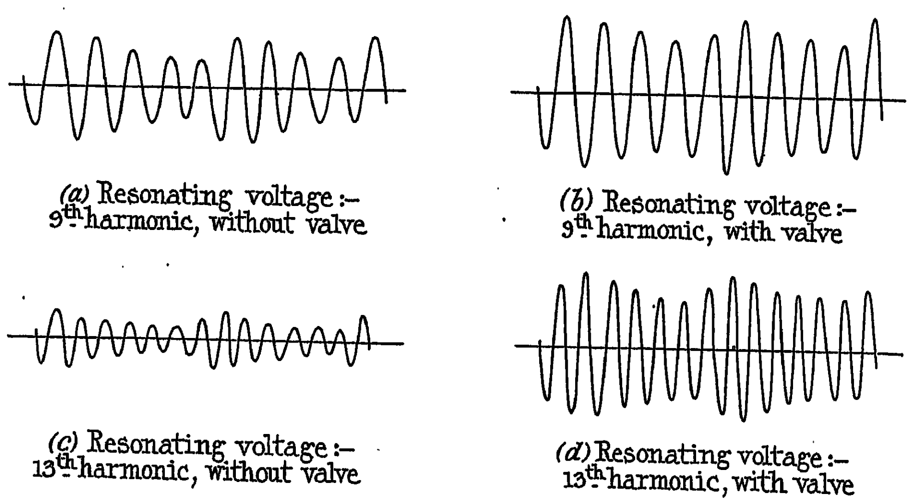

FIG. 22.—Oscillograms showing effect of amplification on the wave-form of the resonating voltage.

interfering harmonics in the analysing current due to the action of the valve, by the extra interfering harmonics induced in the oscillatory circuit by the valve, or by the current taken by the grid coupling of the valve. This is, of course, in accordance with the results of the theoretical investigation of these errors dealt with in Section 6. The average amplification of about 4 in the above results was obtained without difficulty.

In addition to the above test a special "sine wave" alternator was analysed. All the harmonics in the E.M.F. wave of this machine except the 3rd, 5th and 7th were found to be negligible, these latter being of the order of 0·5 per cent.

A test was also carried out on a 20-kW d.c. generator which had been converted into a two-phase alternator for iron-testing purposes. This was found to have a 4 per cent 3rd and a 0·9 per cent 5th harmonic, while all the other harmonics were less than 0·05 per cent.

8. The Possibility of Obtaining the Analysing Current from a Valve Generator without the Neon-Lamp Coupling.

(*a*) *General consideration.*—If the frequency of the wave-form to be analysed were absolutely constant it would be a simple matter to obtain the required analysing sinusoidal current from a valve generator, as the frequency of the latter can be adjusted to any desired value. With this method the oscillatory circuit would be so tuned that a beat period of several seconds was obtained with the harmonic being found, and thus with a suitably designed moving coil the maximum deflection of this would correspond to the instant when the two currents of the frequency of the desired harmonic are in phase, in which case the magnitude of the harmonic could be calculated from this deflection as before.

The time period of the beat must be at least three or four times the natural period of vibration of the moving coil, and so in carrying out the analysis of a 50-cycle wave to the 23rd harmonic this method would be limited to waves in which the maximum fluctuation in frequency did not exceed about 0·02 per cent of the fundamental frequency, or if the change in frequency were comparatively slow it might be limited to cases in which the rate of change of frequency did not exceed about 0·02 per cent per second.

In the neon-lamp method about 10 times this fluctuation can be allowed, and so it is seen that the application of the self-oscillatory method is limited in comparison with that of the neon-lamp method, which may be used in all cases except where the frequency is very unsteady. It will, however, be shown that in those cases in which the self-oscillatory method can be used it is much simpler and probably gives rather more accurate results than the neon-lamp method.

The chief considerations with regard to this method, as affecting the design of the circuits and possible errors, will now be briefly dealt with.

(*b*) *The circuit used and method of analysis.*—The valve circuit used in the last method can be employed, the connections being shown in Fig. 23, with the exception that the neon-lamp supply circuit is entirely dispensed with. The dynamometer can be essentially as before with a capacity in series with the pressure coil, while the resonating current can also be found as before from the voltage across the fixed coil of the dynamometer. Alternatively, the dynamometer and voltmeter may be replaced by a separate portable dynamometer and an ammeter, if this can be done without increasing too much the ratio r/L for the circuit. If an ammeter is used to measure the resonating current it will be advisable to replace the capacity in series with the pressure coil by a non-inductive resistance, so that the calculation of the harmonics does not involve an exact knowledge of the frequency.

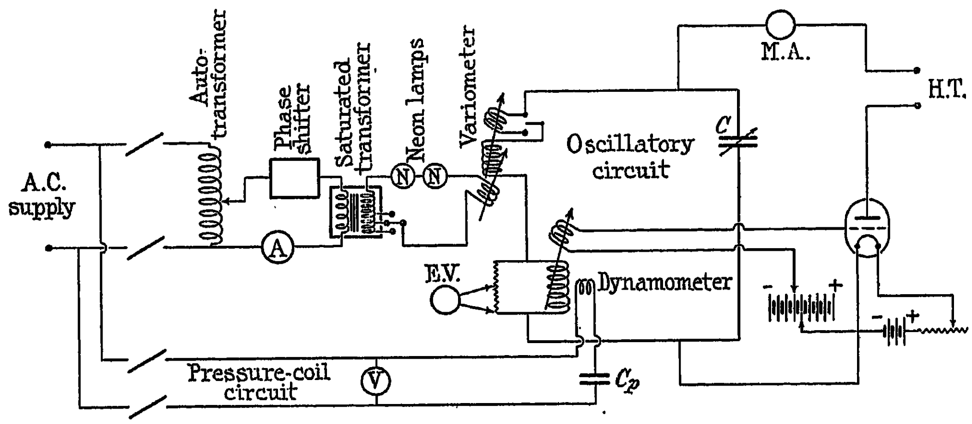

FIG. 23.—Circuit for complete method of analysis.
M.A. = d.c. milliammeter. E.V. = electrostatic voltmeter.

The very fine tuning essential for this method can be obtained by using a capacity variable in steps of 0·01 μF, and covering the intermediate range by means of a small variometer in series with the oscillatory circuit. This variometer must have a ratio of r/L comparable with that of the main inductance. An alternative method is to place a small piece of iron in the vicinity of the main inductance and alter the inductance by varying its position. This works quite well in practice.

To make a complete analysis of a wave-form, the capacity is set at approximately the amount required for the 3rd harmonic, and the circuit is then tuned until

a beat period of at least 4 or 5 seconds is obtained with this harmonic. The maximum reading of the dynamometer is taken, and also the corresponding readings of the voltmeter across the fixed coil of the dynamometer and voltmeter measuring the supply voltage. This is repeated for the other harmonics.

If the readings of the dynamometer and voltmeters are d_n, v_n and e, respectively, for the nth harmonic

then $d_n = ki_n i'_n$ (where k is the d.c. calibration constant)

$= ke_n n\omega C_p \frac{v_n}{n\omega L}$ (where e_n is the desired nth harmonic in E.M.F. wave)

$= k\frac{C_p}{L}e_n v_n$

Therefore $$e_n = \frac{L}{kC_p} \cdot \frac{d_n}{v_n}$$

from which the percentage of the harmonic [$= (100e_n/e)$ per cent] can be calculated.

From Fig. 24, which shows the relation between δ and β for various values of λ, it is seen that by making $\lambda = 0 \cdot 707$ the beat frequency can be as much as 40 per cent of the natural frequency of the moving system before the error exceeds 1 per cent of the reading. Thus for a natural period of 1 sec. for the moving system the beat period can be as small as $2 \cdot 5$ secs. without causing appreciable error.

The practical adjustment of the damping factor to the above figure will in general be a matter of trial and error. If oil damping is used the damping factor can be varied by adding oil of greater or less viscosity as required until the number of oscillations made before the amplitude falls to a given fraction of its initial value when a d.c. current through the coil is switched off, has the theoretical value.

(ii) *The error in the dynamometer reading due to the interfering harmonics in the oscillatory circuit.*—For a self-oscillatory circuit the saturation current of the valve is reached, and so, since the valve must be worked

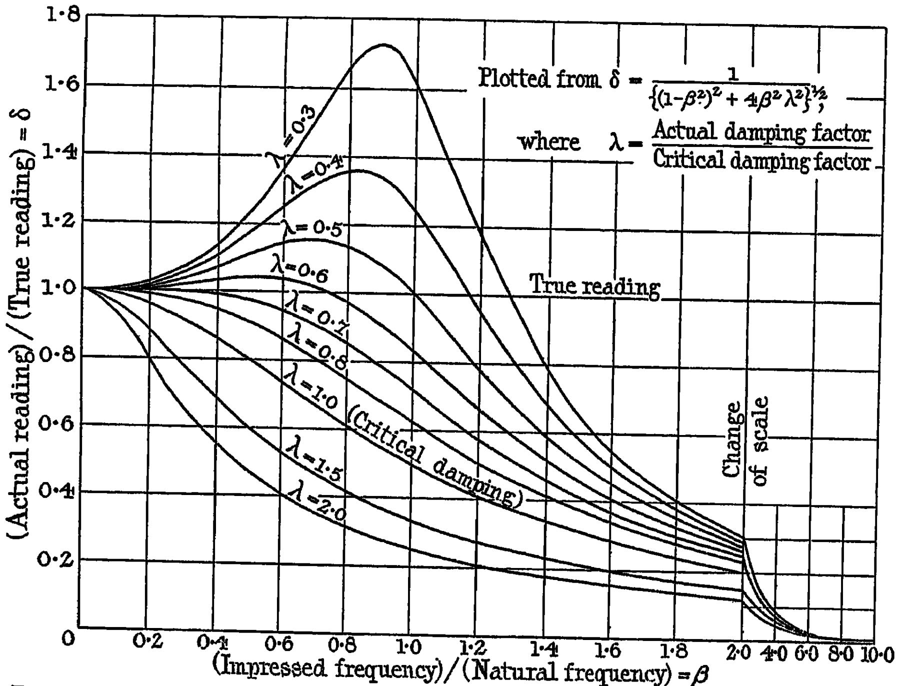

FIG. 24.—Curves showing effect of damping on maximum deflection of dynamometer.

(c) *The various sources of error.*

(i) *The error in the dynamometer reading due to the effects of inertia and damping on the moving system.*—This will be the chief source of error in this method of analysis, although it can be rendered inappreciable by a careful design of the moving system.

It is shown in Appendix 10 that

$$\frac{\text{actual max. reading}}{\text{true max. reading}} = \frac{1}{\sqrt{\{(1-\beta^2)^2 + 4\beta^2\lambda^2\}}} = \delta$$

where β = ratio of impressed to natural frequency of moving system,

and λ = ratio of actual damping factor to critical damping factor.

beyond the straight part of its characteristic, interfering harmonics are induced in the anode current and therefore in the oscillatory current. If the valve is worked from the middle of the characteristic the only appreciable harmonics will be those of odd orders.

It is shown in Appendix 11 that the only appreciable part of this error is due to the combined effect of all the pairs of harmonics of the same order in the currents in the two coils of the dynamometer. The maximum value of this error is shown to be less than $0 \cdot 0016 r/L$ per cent of the true reading, although the actual figure may be very much less than this, as it is unlikely that the deflections due to all the separate harmonics in the torque will have their maximum values at the same

instant that the true reading is a maximum. Also, the above error is for the analysis of a rectangular E.M.F. wave, for which it is considerably greater than for most E.M.F. waves likely to be analysed.

It thus appears that the ratio r/L of the oscillatory circuit might be made as large as 2 000 before the error is increased to 1 per cent of the reading. This would mean that a dynamometer and ammeter both of portable type could probably be employed, although it may not be advisable to replace the Moullin voltmeter by an ammeter, as the indication of the latter would have to be independent of frequency at the frequency of the higher harmonics.

(iii) *The error due to the voltmeter across the main inductance recording the R.M.S. value of the mixed wave and not the value of the resonating harmonic only.*

$$\text{Reading of voltmeter} = \frac{1}{\sqrt{2}}\sqrt{(V_n^2 + \Sigma V_{yn}^2)}$$

$$\text{Required value} = \frac{V_n}{\sqrt{2}}$$

$$\therefore \frac{\text{error}}{\text{reading}} = \frac{1}{2}\sum_{y=3}^{y=\infty}\left(\frac{V_{yn}}{V_n}\right)^2 \text{ approx.}$$

$$\text{But} \quad \frac{V_{yn}}{V_n} = \frac{I'_{yn}}{I'_n}\cdot\frac{yn\omega L}{n\omega L}$$

$$= \frac{r}{n\omega L(y^2-1)}$$

on substituting for I'_{yn}/I'_n from Equation (49) (Appendix 11).

$$\therefore \frac{\text{error}}{\text{reading}} = \frac{r^2}{2n^2\omega^2L^2}\sum_{y=3}^{y=\infty}\frac{1}{(y^2-1)^2}$$

$$< \frac{r^2}{2n^2\omega^2L^2}\left\{\frac{1}{64} + \frac{1}{2}\int_3^\infty \frac{d_y}{(y^2-1)^2}\right\}$$

$$< \frac{0{\cdot}012r^2}{n^2\omega^2L^2}$$

This error will be greatest for $n = 3$, for which case

$$\frac{\text{error}}{\text{reading}} < 1{\cdot}36 \times 10^{-3}\frac{r^2}{L^2}$$

Thus this error will not exceed 1 per cent of the reading if r/L for the oscillatory circuit is less than 860.

If an ammeter is used to measure the oscillatory current the error will be much less, as indicated in the last method of analysis.

(iv) *The error due to the resonating current being calculated from the reactance and not the impedance of the main inductance.*—This error can easily be shown to be

$$\frac{1}{2}\cdot\frac{r_1^2}{n^2\omega^2L_1^2} \text{ (approx.) of the harmonic being found.}$$

This error is greatest for the 3rd harmonic, and therefore for the error in this case not to exceed 1 per cent of the reading, the ratio r_1/L_1 for the main inductance must not exceed 130.

(v) *Error due to the reading of the voltmeter across the a.c. supply being taken as due to the fundamental only.*—This error is as dealt with for the previous method in Section 7(*e*)(iv), where it is shown to be negligible for all ordinary E.M.F. waves likely to be met with.

(vi) *Error due to the impedance of the pressure-coil circuit being taken as the reactance of the series condenser.*—This error is as dealt with for the previous method in Section 7(*e*)(v), where it is shown that it can be made sufficiently small by a suitable design of the pressure-coil circuit.

If an ammeter is used to measure the oscillatory current, and the capacity in series with the pressure coil is replaced by a non-inductive resistance, then the error made by taking the impedance of the pressure-coil circuit as its resistance is in general reduced to a negligible quantity.

(vii) *Error due to mutual-inductance effect between the fixed and moving coils of the dynamometer.*—This is as dealt with in Section 6(*g*)(iii). It will in general be possible to design a pressure coil so that the error due to this effect will not exceed 1 per cent of the reading when a series condenser is used.

(viii) *Error due to the grid current of the valve affecting the dynamometer reading.*—This error is shown to be inappreciable in Section 7(*e*)(vii).

9. Conclusions.

Where the frequency of the a.c. supply being analysed is sufficiently steady to permit its use, the self-oscillatory method has been shown to be capable of giving very accurate results. As the ratio r/L for the oscillatory circuit can be made as large as 1 000 without the error exceeding about 2 per cent of the harmonic being found for the larger harmonics, the whole apparatus can be made very compact and only portable instruments need be employed.

As this method cannot be of general application, however, owing to the limit imposed by frequency variations, the most useful method to meet general requirements will be a combination of this method with the neon-lamp method. The valve used will in the one case supply the necessary oscillatory current, and in the other amplify the current induced by the neon-lamp circuit. This combination of the two methods can be very simply effected, since it is only necessary to modify the apparatus of the neon-lamp method with valve amplification to the extent of ensuring that the damping of the moving system of the dynamometer is properly adjusted, and to provide means of that very fine tuning which is essential to the self-oscillatory method.

The latter feature can be arranged for by using a variometer for the final stage of the tuning, this consisting of a small coil connected in series with the main inductance used for the neon-lamp coupling, and capable of being rotated in it at the opposite end to the coil carrying the neon-lamp current.

The ratio r/L for the oscillatory circuit cannot be as large as for the self-oscillatory method alone, as the requirements of the neon-lamp method will limit it to between 150 and 200. For this figure it should be possible to analyse E.M.F. waves to within 2 per cent of the harmonic itself when using the neon-lamp method, and to within less than 1 per cent of the harmonic itself when

using the self-oscillatory form of apparatus. If the harmonics to be found are small, the accuracy will, of course, be limited by the experimental error in reading the dynamometer.

An attempt should always be made to carry out the analysis with the self-oscillatory method, owing to its greater simplicity and accuracy, but if the fluctuations in frequency are too great then the neon-lamp method can be used.

The complete diagram of connections has already been given in Fig. 23, and the chief features of the complete apparatus required are outlined below.

Neon-lamp circuit.

Auto-transformer. This takes about 2 amperes from the a.c. supply.

Phase-shifter. This should if possible be of a type which requires only one adjustment to be made. If a choke coil is used the iron circuit of this should be closed, so that the external field produced is small. Failing this it may be necessary to enclose it in a thin sheet-iron box for screening purposes so that the dynamometer is not affected.

Ammeter. Ordinary commercial type.

Saturated transformer. This should have 3 tappings on the secondary for use with frequencies of 25, 50 and 100, respectively.

Neon lamps. Two of these only will be required, connected "back to back."

Coupling with oscillatory circuit. Coil of about 1 000 turns that can be rotated inside one end of the smaller inductance of the oscillatory circuit.

To ensure that the desired E.M.F. wave is always induced in the oscillatory circuit, the primary current of the saturated transformer is always adjusted to have a specified value by means of tappings on the auto-transformer across the a.c. supply.

Oscillatory circuit.

Capacity. This should give ranges from $0 \cdot 5$ μF to $10 \cdot 0$ μF in steps of $0 \cdot 5$ μF, and from $0 \cdot 01$ μF to $0 \cdot 5$ μF in steps of $0 \cdot 01$ μF. These two ranges can be controlled by two dial switches, and will provide sufficiently fine tuning for the neon-lamp method.

Main inductance. This is also the fixed coil of dynamometer. It can be designed to have a ratio $r/L = 75$ and to give 4 ranges of inductance with plug connections. The external diameter of such a coil would be about 25 cm.

Dynamometer pressure coil. This is suspended inside the main inductance. The pressure coil and the condenser used in series with it must be so designed that the error due to the mutual-inductance effect, and that due to the impedance of the circuit being taken as the reactance of the series condenser, are both sufficiently small for the higher harmonics. The damping factor must be adjusted to be $0 \cdot 71$ of the critical damping factor. The deflection is most conveniently observed by reflecting a spot of light on a scale at a distance of about 1 m from the coil.

Voltmeter across a.c. supply. This can be a portable instrument of the ordinary commercial type.

Voltmeter across fixed coil of dynamometer. The most suitable instrument is a Moullin thermionic valve voltmeter, in conjunction with a suitable series resistance.

Coupling with neon-lamp circuit. The coil used for this purpose can be much smaller than the main inductance coil. It can be so designed that $L_2 = \frac{1}{4}L_1$ and $r_2/L_2 = 200$, so that the contribution to the total r/L of the oscillatory circuit by the two inductance coils will be 100. This coil should also have 4 ranges of inductance as for the main coil. Its external diameter would be about 18 cm.

Fine-tuning variometer. This should consist of a coil which can be rotated in the above coil, at the opposite end to the neon-lamp current coupling coil. It will require to be wound with about 1/30th of the number of turns in series on the above coil for the largest range of inductance. This will give a total variation in frequency corresponding to a change in capacity of $2 \cdot 0$ per cent on the greatest or first range of inductance, 8 per cent on the second and 10 per cent on the third. This variometer coil can, by changing a plug connection, be connected in series with the coil in which it rotates. It will increase the r/L of the oscillatory circuit by about 10, 40 and 100 respectively, for the three ranges of inductance, but as already shown this will not affect the accuracy of the self-oscillatory method for which method alone it is used.

It may be advisable to screen the dynamometer from the above combination of coils by the use of a thin sheet-iron container round the latter.

Valve circuit.

Three-electrode valve. This must be of a standard type with a saturation current of not less than about 40 mA.

Grid coupling. A coil that can be rotated at one end of the fixed coil of the dynamometer.

Filament d.c. voltmeter. Commercial type.

Low-tension supply for filament. 6-volt accumulator.

Filament rheostat.

Grid potential battery. Dry battery in steps of 3 volts up to about 36 volts.

High-tension supply for anode circuit. In most cases a 400-volt d.c. supply will be available. This is preferable but, failing it, a 200-volt supply will suffice.

D.C. milliammeter in anode circuit. This is not absolutely essential, although its indications are very useful.

In conclusion a list will now be given of the necessary operations to be carried out for the complete analysis of an E.M.F. wave-form.

Procedure to be followed for the analysis of an E.M.F. wave-form.

Preliminary.

Connect high-voltage d.c. supply in anode circuit.

Connect a.c. supply to be analysed to terminals of apparatus.

Adjust filament voltage to normal value.

Adjust grid voltage to give mid-point of characteristic, when milliammeter will record one-half the saturation current.

The self-oscillatory method.

Connect inductance coils of oscillatory circuit to give maximum range.

Connect fine-tuning variometer in series with circuit by changing plug connection.

Set capacity at approximate value required for 3rd harmonic as read from graph.

Increase grid coupling until circuit oscillates.

Tune circuit until period of beat with 3rd harmonic is greater than 3 secs., and preferably as large as possible.

Observe (i) maximum deflection of dynamometer, d.
(ii) corresponding resonating voltage, v.
(iii) corresponding supply voltage, e.

Repeat for higher harmonics in order, changing inductance to a lower range when capacity is reduced to about 1 μF.

Calculate each harmonic $= Kd/(ev) \times 100$ per cent of fundamental, where $K =$ constant for given range of inductance used.

If the fluctuation in frequency is too great for steady readings to be obtained with the self-oscillatory method, then use the neon-lamp method as follows:—

The neon-lamp method.

Connect neon-lamp circuit to appropriate tapping on secondary of saturated transformer according to frequency of a.c. supply.

Adjust auto-transformer to give specified current through primary of saturated transformer.

Disconnect fine-tuning variometer from oscillatory circuit.

Connect inductance coils to give maximum range.

Set capacity at approximate value required for 3rd harmonic.

Tune circuit to 3rd harmonic.

Adjust neon-lamp coupling to give a resonating voltage within the specified limits.

Switch off neon-lamp supply.

Switch on filament supply to valve.

Adjust grid coupling so that the circuit is almost but not quite self-oscillatory.

Switch on neon-lamp supply.

Retune oscillatory circuit.

Readjust grid coupling to give amplification of about 6.

Adjust phase-shifter to give maximum dynamometer reading.

Take readings of—
(i) maximum dynamometer deflection, d'.
(ii) resonating voltage, v'.
(iii) a.c. supply voltage, e'.

Readjust grid coupling to increase amplification further by about 25 per cent.

Retune and readjust phase if necessary.

Take readings of instruments as before, d'', v'' and e'' respectively.

Repeat above operations for the 5th harmonic. Above the 5th harmonic, the first set of readings can be taken before the oscillatory current is amplified, the phase-shifter being first adjusted to give a maximum dynamometer reading. In this case only one set of readings is necessary with the amplified current. In each case,

$$\text{harmonic} = K\frac{(d''/e'') - (d'/e')}{v'' - v'} \times 100 \text{ per cent of the}$$

fundamental, where $K =$ same constant as for the self-oscillatory method.

Finally, although only the case of the analysis of E.M.F. waves has been discussed in the paper, the method advocated can obviously be applied to the analysis of all forms of periodic voltage and current waves, since it is always possible to pass through the moving coil of the dynamometer a current whose harmonics bear a known relation to those of the wave-form in question.

The authors are greatly indebted to Mr. C. P. Lockton, who did much useful experimental work in the later stages, and to Messrs. Metropolitan-Vickers Electrical Co., Ltd., for the manufacture of the inductance coils and for the loan of apparatus.

APPENDIX 1.

To Find I'_n/I'_x and V_n/V_x for Circuit 1.

Circuit 1.—The circuit has already been given in Fig. 1.

Let $L, r_1 =$ self-induction and resistance of choke coil.

$C =$ capacity of condenser.

R_1 and $R =$ non-inductive resistances of the order of 50 000 ohms and 200 000 ohms respectively.

$$e = \sum_1^\infty E_n \sin n\omega t = \text{E.M.F. applied to AB.}$$

$$v = \sum_1^\infty V_n \sin (n\omega t - \phi_n) = \text{E.M.F. across DE.}$$

$i_t =$ current in AD.

$$i = \sum_1^\infty I'_n \sin (n\omega t - \phi'_n) = \text{current in choke coil.}$$

$i_c =$ current in condenser.

$i_r =$ current in R.

Consider the effect of one harmonic of E.M.F. alone. Treating symbolically we obtain

$$i_t = V_n\left[\frac{1}{r_1 + jn\omega L} + jn\omega C + \frac{1}{R}\right]$$

$$= V_n\left[\frac{1}{R} + \frac{1 - n^2\omega^2LC + jr_1n\omega C}{r_1 + jn\omega L}\right]$$

and $$E_n = R_1 i_t + V_n$$

$$\therefore V_n = E_n\Big/\left[1 + R_1\left\{\frac{1}{R} + \frac{1 - n^2\omega^2LC + jr_1n\omega C}{r_1 + jn\omega L}\right\}\right] \quad (7)$$

If now we tune the circuit to the frequency of the nth harmonic, i.e. make $n^2\omega^2LC = 1$, we have

$$V_n = E_n\Big/\left[1 + R_1\left\{\frac{1}{R} + \frac{r_1C}{L}\right\}\right] \text{neglecting } r_1 \text{ in comparison with } n\omega L$$

$$= E_n\Big/\left[1 + \frac{R_1rC}{L}\right] \quad \ldots \ldots \quad (8)$$

where $$r = r_1 + \frac{L}{CR}.$$

We have also

$$\frac{V_n}{V_x} = \frac{E_n}{E_x} \cdot \frac{1 + R_1[(1/R) + (1 - x^2\omega^2LC + jxr_1\omega C)/(r_1 + jx\omega L)]}{1 + (R_1 rC/L)}$$
$$= \frac{E_n}{E_x} \cdot \frac{1 + R_1[\{(1/R) + r_1C/L\} - jR_1(1 - x^2/n^2)/x\omega L]}{1 + (R_1 rC/L)}$$

to same order of approximation and since $x^2\omega^2LC = x^2/n^2$. Thus

$$\frac{V_n}{V_x} = \frac{E_n}{E_x} \cdot \frac{1 + (R_1 rC/L) - (jR_1\omega C)\,(n^2 - x^2)/x}{1 + (R_1 rC/L)}$$
$$= \frac{E_n}{E_x}\left[1 - j\frac{n^2 - x^2}{x} \cdot \frac{R_1\omega C}{1 + (R_1 rC/L)}\right] \quad . \quad . \quad (9)$$
$$= -j\frac{E_n}{E_x} \cdot \frac{n^2 - x^2}{x} \cdot \frac{R_1\omega C}{1 + (R_1 rC/L)} \text{ (approx.)} \quad (10)$$

since in general the real part will be small compared with the imaginary part.

Now $$I'_n = \frac{V_n}{r_1 + jn\omega L} = \frac{V_n}{jn\omega L} \text{ (approx.)}$$
so that

$$\frac{I'_n}{I'_x} = -j\frac{E_n}{E_x} \cdot \frac{n^2 - x^2}{x} \cdot \frac{x}{n} \cdot \frac{R_1\omega C}{1 + (R_1 rC/L)}$$
$$= -j\frac{E_n}{E_x} \cdot \frac{n^2 - x^2}{n} \cdot \frac{R_1\omega C}{1 + (R_1 rC/L)} \quad . \quad . \quad (11)$$

As R_1Cr/L becomes large compared with unity, we have as a further approximation

$$\frac{I'_n}{I'_x} = -j\frac{E_n}{E_x} \cdot \frac{n^2 - x^2}{n} \cdot \frac{\omega L}{r} \quad . \quad . \quad . \quad (12)$$

and $$\frac{|I'_n|}{|I'_x|} = \frac{E_n}{E_x} \cdot \frac{n^2 - x^2}{n} \cdot \frac{\omega L}{r}.$$

We are chiefly concerned with the ratios of the amplitudes and not with the phases of the various quantities.

APPENDIX 2.

The Probable Error Introduced by an Imperfect Auxiliary Wave.

Standard method.—We have, from Section 5(*b*),

$$\psi = \sum_{x=3}^{x=\infty} \frac{I_{xn}}{I_1} \frac{I'_{xn}}{I'_n} \cos \theta_{xn}$$

and from Equation (11),

$$\frac{I'_{xn}}{I'_n} \leqslant \frac{E_{xn}}{E_n} \cdot \frac{n}{n^2x^2 - n^2} \cdot \frac{r}{\omega L} \cdot \frac{1 + (R_1 rC/L)}{R_1 rC/L}$$
$$\leqslant \frac{4}{3} \cdot \frac{E_{xn}}{E_n} \cdot \frac{n}{n^2x^2 - n^2} \cdot \frac{r}{\omega L},$$

provided we make R_1 sufficiently great.

Also from Equation (5*a*), using the first commutator,

$$\frac{E_{xn}}{E_n} \leqslant \frac{1}{x}$$

so that $$\frac{I'_{xn}}{I'_n} \leqslant \frac{4}{3} \cdot \frac{r}{n\omega L} \cdot \frac{1}{x(x^2 - 1)}$$

$$\therefore \psi \leqslant \sum_{x=3}^{x=\infty} \frac{I_{xn}}{I_1} \cdot \frac{4}{3} \cdot \frac{r}{n\omega L} \cdot \frac{1}{x(x^2 - 1)}$$
$$\leqslant \frac{4}{3}\frac{r}{n\omega L}\left[\frac{I_{xn}}{I_1}\right]_{max.} \sum_{x=3}^{x=\infty} \frac{1}{x(x^2 - 1)}.$$

Since the summation is for odd values of x only,

$$\psi \leqslant \frac{1}{15n}\left[\frac{I_{xn}}{I_1}\right]_{max.} \frac{3}{8}\left\{\frac{\pi^2}{8} - 1\right\}$$

and substituting $r/L = 15$, $\omega = 314$, and since also $n \geqslant 3$ in all cases,

$$\psi \leqslant \frac{1}{500}\left[\frac{I_{xn}}{I_1}\right]_{max.} \quad . \quad . \quad . \quad . \quad (13)$$

APPENDIX 3.

Design of Fixed Coil.

The conditions to be fulfilled in the design of the fixed-coil system are :—

(1) The ratio r_1/L must be not greater than some fixed figure when measured with direct current.
(2) The ratio of effective resistance to the resistance measured with direct current must be as small as possible at 1 000 cycles per second, i.e. the eddy-current loss must be small.
(3) It must be possible to obtain values of self-induction as low as 0·005 henry when all the layers are connected in parallel.

Maxwell's approximate formula for the self-induction of a coil of rectangular section is

$$L = 4\pi n^2 a\left(\log_e \frac{8a}{R} - 2\right) \times 10^{-9} \text{ henry} \quad . \quad (15)$$

where n = number of turns,
a = mean radius of coil,
and R = geometric mean distance of the transverse section of the coil from itself.

If the section be $(b \times c)$cm², then

$$R = 0{\cdot}2235(b + c) \text{ approx.} \quad . \quad . \quad (16)$$

Maxwell shows that the coil of maximum self-induction for a given length of wire, and therefore for a given resistance, is given by

$$\log_e \frac{8a}{R} = \frac{7}{2}$$

or $a = 0{\cdot}921\ (b + c)$ on substitution from Equation (16) . (17)

Then Equation (15) becomes

$$L = 6\pi n^2 a \times 10^{-9} \text{ henry}.$$

Now the resistance of the coil to direct current is given by

$$r_1 = \frac{2\pi a n \times 1\cdot 7 \times 10^{-6}}{\text{wire section}} \text{ ohm}$$

and $n \times$ (wire section) $= bc \times \alpha$, where α is the space factor.

Hence $$r_1 = \frac{2\pi a n^2 \times 1\cdot 7 \times 10^{-6}}{bc \times \alpha}$$

so that $$\frac{L}{r_1} = \frac{3\,bc\alpha \times 10^{-9}}{1\cdot 7 \times 10^{-6}} = 1\cdot 77\,bc\alpha \times 10^{-3}.$$

Thus, since $bc\alpha$ is the net copper section, it is clear that if the coil be made according to Maxwell's rule the ratio L/r_1 varies directly as the copper section and therefore depends only on the weight of copper put into the coil.

The weight of copper required varies as $a \times bc \times \alpha$, i.e. as $bc(b + c)$ from Equation (17).

Hence, since bc is fixed by the ratio L/r_1, it is clear that the most economical coil is one with a square section if we have only to consider the d.c. resistance. Since, however, the eddy-current loss will depend on the shape of the coil for a given number of ampere-turns in the coil, we have to consider the effect of varying the ratio of axial length to winding depth, i.e. b/c.

We have to consider the eddy-current loss at frequencies of the order of 1 000. It is clear in the first place that the skin effect will be negligible at these frequencies, and that we can therefore calculate the eddy-current loss in the wire by the formula given by Howe:*

$$W_e = \frac{\pi^2}{8} B^2 f^2 \times d^2 \times \frac{10^{-16}}{\rho} \text{ watt/cm}^3$$

where f is the frequency, d the diameter of wire, ρ the specific resistance in ohms, and B the maximum value of the flux density at the point considered.

B can be found approximately from the dimensions of the coil for a given number of ampere-turns in the coil, and it is clear that if this number be fixed the average value of B will decrease as the coil is lengthened axially. Thus the eddy-current loss will decrease with c/b; on the other hand for a fixed volume of copper, on changing the dimensions to conform to Maxwell's rule, the ratio L/r_1 will decrease. There is thus a definite ratio of c/b which will give a minimum loss for a particular frequency. This may be obtained by a process of trial and error. In the first coil constructed c/b was made equal to 0·25 and the calculated ratio of eddy-current loss to direct-current loss was 0·45 at 1 100 cycles per second.

A further factor to be considered is the distribution of current amongst the various layers when they are connected in parallel. To avoid extra loss we have clearly to arrange for equal distribution of current. This will obtain approximately if the mutual inductance between any *one layer* and the rest of the coil is constant for the various layers. This can be arranged by reducing the number of turns per layer as the diameter of the coil increases. The calculation to determine the exact number of turns is rather laborious and only the outline of the method of calculation will be given.

The mutual inductance between any layer and the rest of the coil may be obtained by summing the values of mutual inductance between this layer and each of the other layers. Maxwell's formula for the mutual inductance of two coaxial solenoids of radii c_1, c_2 and length l is

$$M = 4\pi n_1 n_2 c_2^2 (l - 2c_1 d)$$

where $$d = \frac{1}{2}\frac{(c_1 + l - r)}{c_1} - \frac{1}{16}\frac{c_2^2}{c_1^2}\left(1 - \frac{c_1^3}{r_3}\right) + \cdots$$

where $r = \sqrt{(l_1^2 + c_1^2)}$ and n_1, n_2 are the numbers of turns in the two coils. M may be calculated for c_1 fixed and various values of c_2 corresponding to several layers throughout the coil, assuming equal numbers of turns. A few values only need be calculated; the remainder can be obtained by interpolation. By the use of a graphical method the summation for the total mutual inductance can then be easily carried out. This is repeated for other values of c_1 and then by interpolation the mutual inductance between the whole coil and any layer may be found. It will appear that

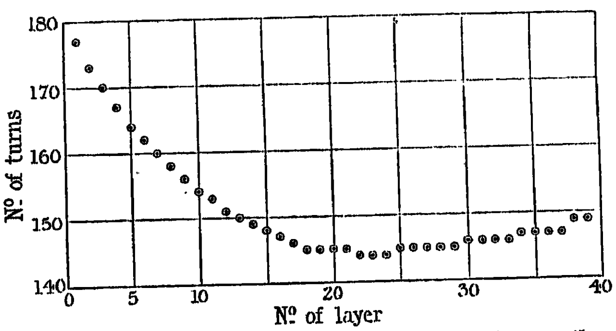

FIG. 25.—Turns per layer on dynamometer fixed coil.

for an equal number of turns in each layer the mutual inductance increases by about 20 per cent in passing from the inner layers to the centre, and then decreases slightly for the outer layers. The corrected number of turns for each layer to make these mutual inductances equal is then found. This gives a first approximation to the correct number of turns. Using these new figures for the turns per layer the calculation should be repeated to get a closer approximation, since the relative contribution of the outer layers of the coil will be reduced. This correction can be effected quite simply graphically and the second approximation should give close enough results in practice.

This method of calculation was adopted for both types of coils constructed, and the figures showing the variation in the turns per layer are given in Fig. 25 for the second coil.

Details of dynamometer used with methods 3 and 4.

(i) *Fixed coil.*

Mean radius: 11·7 cm.
Axial length: 7·7 cm.
Winding depth: 2·35 cm.

* *Proceedings of the Royal Society*, A, 1916-17, vol. 93, p. 468.

Turns per layer: 177 for inner layer, varying uniformly to 145 for centre layer and 148 for outer layer.
No. of layers: 40.
Wire: No. 26 S.W.G.
Self-induction—all layers in parallel: 0·0058 henry.
Resistance—all layers in parallel: 0·314 ohm.
Ratio r_1/L with direct current: 54.

(ii) *Moving coil.*
Winding: 450 turns of No. 32 S.W.G. wire.
Resistance: 140 ohms.
Self-induction: 0·016 henry.
Period: 2 secs.
Weight: 35 g.
Dimensions: $15 \times 1\cdot5 \times 1\cdot0$ cm³.
Suspension: bifilar.

APPENDIX 4.

Consideration of Possible Sources of Error in the Readings of the Instruments.

(i) *Reading of the electrostatic voltmeter.*—The torque on the moving system of the electrostatic voltmeter is proportional to the sum of the squares of the amplitudes of the various harmonics of E.M.F. across the oscillatory circuit. Thus the deflection d on a uniform scale is given by

$$d = K(V_1^2 + V_3^2 + \ldots V_n^2 + \ldots)$$

Thus the computed value V_n of the resonating voltage from this deflection will be

$$V_n' = V_n\left[1 + \left(\frac{V_1}{V_n}\right)^2 + \left(\frac{V_3}{V_n}\right)^2 + \ldots \left(\frac{V_x}{V_n}\right)^2 + \ldots\right]^{\frac{1}{2}}$$

The proportional error is given by

$$\frac{V_n' - V_n}{V_n} = \delta$$

and $$\delta = \left[1 + \left(\frac{V_1}{V_n}\right)^2 + \left(\frac{V_3}{V_n}\right)^2 + \ldots\right]^{\frac{1}{2}} - 1 \quad . \quad (18)$$

For the standard method all the values of V_x except for $V_{(2r+1)n}$ are zero, and

$$\frac{V_{xn}}{V_n} \leqslant \frac{E_{xn}}{E_n}\cdot\frac{r}{\omega L}\cdot\frac{xn}{n^2 - n^2x^2}\cdot\frac{4}{3} \text{ [from Equation (12)]}$$
$$\leqslant \frac{4}{3}\cdot\frac{r}{n\omega L}\cdot\frac{1}{1 - x^2}$$

Thus

$$\delta \leqslant \left[1 + \frac{16}{9}\cdot\frac{r^2}{n^2\omega^2L^2}\sum_{r=1}^{r=\infty}\left\{\frac{1}{1 - (2r+1)^2}\right\}^2\right]^{\frac{1}{2}} - 1$$

and for $r/L = 15$ and $\omega = 314$,

$$\delta \leqslant \left[1 + \frac{1}{5\,000n^2}\right]^{\frac{1}{2}} - 1 = \frac{1}{10^4n^2} \text{ (approx.)}$$

δ is thus negligible for all values of n.

(ii) *The effect of the mutual induction between fixed and moving coil circuits.*—We have to calculate the E.M.F. induced in the moving coil by the fixed-coil flux for a given angular position of the former.

Let $(\frac{1}{2}\pi + \theta)$ be the angle between the magnetic axes of the fixed and moving coils; A the effective area of the moving coil; R, L, the resistance and self-induction of the moving-coil circuit; n the number of turns in the moving coil and H the amplitude of the magnetic force due to the fixed coil.

Then it may easily be shown that the torque due to mutual induction is

$$\frac{1}{4}(AHn)^2\frac{\omega^2L}{R^2 + \omega^2L^2}\sin 2\theta \times 10^{-9} \text{ dyne-cm.}$$

If we substitute

$H = 15\sqrt{2}$, $\omega = 1\,150 \times 6\cdot28$, $n = 200$,
$L = 6 \times 10^{-3}$ henry, $R = 1\,000$ ohms, $A = 24$ cm²,
mean torque $= 0\cdot7 \sin 2\theta$ dyne-cm.

The maximum value of $\sin 2\theta$ with the scale used was 0·25. The torque due to a 1 per cent harmonic with the same value of H is 7·2 dyne-cm.

Thus the torque due to mutual induction is 2·4 per cent of the deflection due to a 1 per cent harmonic. The error due to this will be negligible.

(iii) *The effect on the constant of the instrument of a variation with frequency of the distribution of current in the fixed coil.*—This point was tested experimentally by changing the distribution of a constant direct current in the fixed coil whilst keeping a constant direct current in the moving coil. The maximum variation in the constant was so small as to be negligible.

APPENDIX 5.

To Find the Maximum Error in the Dynamometer Reading Due to all Harmonics of Order Greater than x_0.

We require the closest possible approximation to

$$\frac{r}{\omega L}\sum_{x=x_0+2}^{x=\infty}\frac{I_x}{I_1}\cdot\frac{E_x}{E_n}\cdot\frac{x}{x^2 - n^2}$$

as an upper limit.

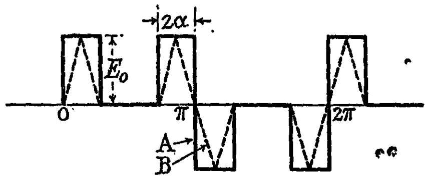

Fig. 26.—Limiting forms of the E.M.F. wave induced in the oscillatory circuit.

For most wave-forms likely to be analysed we shall have

$$\frac{I_x}{I_1} \leqslant \frac{1}{x}$$

The actual wave-form of the E.M.F. induced in the oscillatory circuit is intermediate between the wave-forms A and B in Fig. 26 and so we may expect its

harmonics to be intermediate between the corresponding harmonics in A and B.

The xth harmonic in A is

$$A_x = \frac{8E_0}{\pi} \cdot \frac{\sin^2 xa}{x}$$

and the xth harmonic in B is

$$B_x = \frac{8E_0}{\pi} \cdot \frac{\sin xa(1 - \cos xa)}{x^2 a}$$

$$|A_x| = \left|\frac{8E_0}{\pi} \cdot \frac{\sin^2 xa}{x}\right|$$

$$\leqslant \frac{8E_0}{\pi} \cdot \frac{1}{x} \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

Also $$|B_x| = \left|\frac{8E_0}{\pi} \cdot \frac{\sin xa(1 - \cos xa)}{x^2 a}\right|$$

$$\leqslant \left|\frac{8E_0}{\pi} \cdot \frac{1}{x} \cdot \frac{1 - \cos xa}{xa}\right|$$

But for the maximum value of $\frac{1 - \cos xa}{xa}$ we have $xa^2 \sin xa - a(1 - \cos xa) = 0$, that is $(1 - \cos xa) = xa \sin xa$.

$$\therefore |B_x| \leqslant \left|\frac{8E_0}{\pi} \cdot \frac{1}{x} \cdot \frac{xa \sin xa}{xa}\right|$$

$$\leqslant \frac{8E_0}{\pi} \cdot \frac{1}{x} \cdot \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (19)$$

But $|E_x|$ is less than the greater of $|A_x|$ and $|B_x|$

$$\therefore |E_x| \leqslant \frac{8E_0}{\pi} \cdot \frac{1}{x} \cdot \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (20)$$

Also $|B_n| \leqslant |A_n|$ for all integral values of $n \leqslant n_0$ where n_0 is given by

$$1 - \cos n_0 a = n_0 a \sin n_0 a$$

from which $\quad n_0 a = 2 \cdot 32$ radians (approx.) $= 133°$

The most suitable E.M.F. wave for induction in the oscillatory circuit is one for which $a = 6°$ (approx.), for which the maximum harmonic is about the 11th or 13th.

For $a = 6°$, $n_0 = 22 \cdot 1$ and we shall make no appreciable error in taking $|E_n| \geqslant |B_n|$ providing we do not require n to be greater than 23.

Using the above inequalities we have

Max. error due to terms of order $> x_0$

$$\psi_2 = \frac{r}{\omega L} \sum_{x=x_0+2}^{x=\infty} \frac{I_x}{I_1} \cdot \frac{E_x}{E_n} \cdot \frac{x}{x^2 - n^2}$$

$$= \frac{r}{\omega L} \cdot \frac{n^2 a}{\sin na(1 - \cos na)} \sum_{x=x_0+2}^{x=\infty} \frac{1}{x(x^2 - n^2)}$$

Since $x_0 > n$, $1/\{x(x^2 - n^2)\}$ is positive and decreasing through the whole range of x given by $x_0 + 2 \leqslant x \leqslant \infty$

$$\therefore \psi_2 \leqslant \frac{r}{\omega L} \cdot \frac{n^2 a}{\sin na(1 - \cos na)} \frac{1}{2} \int_{x_0}^{\infty} \frac{dx}{x(x^2 - n^2)}$$

$$= \frac{r}{\omega L} \cdot \frac{n^2 a}{2 \sin na(1 - \cos na)} \cdot \frac{1}{2n^2} \log_e \frac{x_0^2}{x_0^2 - n^2}$$

$$< \frac{r}{\omega L} \cdot \frac{0 \cdot 577a}{\sin na(1 - \cos na)} \log_{10} \frac{1}{1 - (n/x_0)^2} \quad . \quad (21)$$

APPENDIX 6.

To Find I_n''/I_x'' for the Given Combination of Oscillatory and Valve Circuits.

The directions taken as positive in the various parts of the circuit shown in Fig. 27 are indicated by arrows. At each mutual inductance the separate inductances must be so arranged that a positive current in each circuit produces a flux in the same direction.

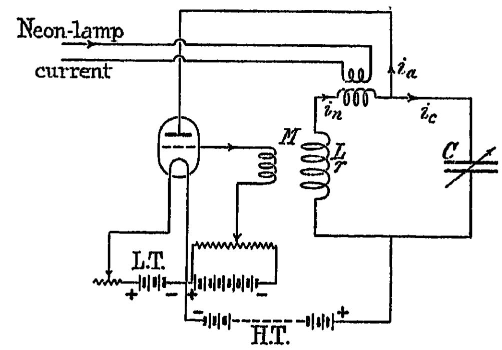

Fig. 27.—Valve circuit used to amplify resonating current.

Considering one harmonic only and making use of the operator D for d/dt, we have

e_n = E.M.F. of nth harmonic induced in oscillatory circuit by neon-lamp current

$$= E_n \sin n\omega t$$

$$= LDi_n + ri_n + \frac{1}{C}\int i_c dt \,. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

where i_n = current of nth harmonic through main inductance

$$= I_n'' \sin (n\omega t - \phi_n')$$

From (22) $e_n = (LD + r)i_n + \dfrac{i_c}{CD}$ (since with the notation employed $\int i_c dt$ may be replaced by $\dfrac{1}{D} i_c$)

$$= \left(LD + r + \frac{1}{CD}\right)i_n - \frac{i_a}{CD} \quad . \quad . \quad (23)$$

since $\quad i_c = i_n - i_a$

For the valve we have, with the notation of Section 7(*b*),

$$Di_a = aDv_a + gDv_g$$
$$= aD(\text{const.} - (LD + r)i_n + e_n) + gD(\text{const.} + MDi_n)$$
$$= \{(gM - aL)D^2 - arD\}i_n + aDe_n$$
$$\therefore i_a = \{(gM - aL)D - ar\}i_n + ae_n$$

and substituting for i_a in (23) we have

$$\left(1 + \frac{a}{CD}\right)e_n = \left\{LD + \left(r - \frac{gM - aL}{C}\right) + \frac{1 + ar}{CD}\right\}i_n \quad (24)$$

To find the particular integral of this differential equation which corresponds to the final steady conditions, we may replace D in it by $jn\omega$, the result then being given in symbolic notation. Thus

$$e_n = \left\{r - \frac{gM - aL}{C} + j\left(n\omega L - \frac{1 + ar}{n\omega C}\right)\right\}i_n \text{ (approx.)} \quad (25)$$

since $a/(Cn\omega)$ is negligible compared with 1.

The effective resistance is at once seen to be, $r'' = r - (gM - aL)/C$ which, being independent of frequency, is the same for all the harmonics.

For maximum current the oscillatory circuit is tuned so that $n^2\omega^2LC = 1 + ar$, when Equation (25) reduces to

$$i_n = \frac{e_n}{r - (gM - aL)/C} \quad . \quad . \quad . \quad (26)$$

Again, considering the xth harmonic only,

$$e_x = \left\{LD + \left(r - \frac{gM - aL}{C}\right) + \frac{1 + ar}{CD}\right\} i_x \text{ (approx.)}$$

from which on replacing D by $jx\omega$ we obtain

$$i_x = \frac{e_x}{r - (gM - aL)/C + j\{x\omega L - (1 + ar)/x\omega C\}}$$
$$= \frac{e_x}{r - (gM - aL)/C + j\omega L(x^2 - n^2)/x}$$
$$= \frac{e_x}{j\omega L(x^2 - n^2)/x} \text{ (approx.)} \quad . \quad . \quad . \quad . \quad . \quad (27)$$

since $r - (gM - aL)/C$ is negligible compared with $\omega L(x^2 - n^2)/x$

$$\therefore \frac{i_n}{i_x} = j\frac{e_n}{e_x} \cdot \frac{x^2 - n^2}{x} \cdot \frac{\omega L}{r - (gM - aL)/C}$$
$$\therefore \frac{I_n''}{I_x''} = \frac{E_n}{E_x} \cdot \frac{x^2 - n^2}{x} \cdot \frac{\omega L}{r - (gM - aL)/C} \quad . \quad (28)$$

By considering the ordinary circuit without valve amplification as a special case of the valve circuit in which the constants g and a are both taken as zero, instead of working it out direct, the necessary calculations can be somewhat reduced.

Thus for this case we have at once, from Equation (28),

$$\frac{I_n'}{I_x'} = \frac{E_n}{E_x} \cdot \frac{x^2 - n^2}{x} \cdot \frac{\omega L}{r} \quad . \quad . \quad . \quad (29)$$

where for the circuit shown in Fig. 8 with two inductance coils in the oscillatory circuit

L = total inductance in oscillatory circuit
$= L_1 + L_2$

and r = total effective resistance of oscillatory circuit.

To find r in terms of r_1 and r_2 the actual resistances of the two coils, and R, the value of the high non-inductive resistance shunting coil 1, we have

$$e_n = (L_1D + r_1)i_n + \left(L_2D + r_2 + \frac{1}{CD}\right)i_c$$
$$= \left\{(L_1 + L_2)D + r_1 + r_2 + \frac{1}{CD}\right\}i_n$$
$$- \left\{L_2D + r_2 + \frac{1}{CD}\right\}i_r \text{ (since } i_c = i_n - i_r)$$

but $i_r = -\dfrac{1}{R}(L_1D + r_1)i_n$

$$\therefore e_n = \left\{\frac{L_1L_2}{R}D^2 + \left(L_1 + L_2 + \frac{L_1r_2 + L_2r_1}{R}\right)D + \left(r_1 + r_2 + \frac{L_1}{CR} + \frac{r_1r_2}{R}\right) + \left(\frac{1}{C} + \frac{r_1}{CR}\right)\frac{1}{D}\right\}i_n$$

which has as its particular integral

$$e_n = \left[r_1 + r_2 - \frac{n^2\omega^2L_1L_2}{R} + \frac{L_1}{CR} + \frac{r_1r_2}{R} + j\left\{n\omega\left(L_1 + L_2 + \frac{L_1r_2 + L_2r_1}{R}\right) - \frac{1}{n\omega C}\left(1 + \frac{r_1}{R}\right)\right\}\right]i_n$$

from which, on using the relation $n^2\omega^2(L_1 + L_2)C = 1$, which is approximately true, and neglecting r_1r_2/R, we see that effective resistance $r = r_1 + r_2 + \dfrac{n^2\omega^2L_1^2}{R}$. (30)

To find E_n/V_n we have

$$V_n = I_n' n\omega L_1 \text{ (approx.)}$$
$$= E_n\frac{n\omega L_1}{r}$$

or

$$E_n = V_n\left(\frac{r_1 + r_2}{n\omega L_1} + \frac{n\omega L_1}{R}\right) \quad . \quad . \quad . \quad (31)$$

To find V_x/V_n for the circuit with valve we have

$$\frac{V_x}{V_n} = \frac{I_x''}{I_n''} \cdot \frac{x}{n}$$
$$= \frac{E_x}{E_n} \cdot \frac{x^2}{x^2 - n^2} \cdot \frac{r''}{n\omega L} \text{ [from (28)]} \quad . \quad . \quad (32)$$

APPENDIX 7.

To Find the Error in the Dynamometer Reading Due to the Auxiliary Current, not being Sinusoidal, the Harmonic being Calculated from the Differences of the Two Sets of Readings.

Let d' = dynamometer reading without amplification.
d'' = dynamometer reading with amplification.
V_n' = resonating voltage (max. value) without amplification.
V_n'' = resonating voltage (max. value) with amplification.
k = d.c. calibration constant of dynamometer.

Assuming that the valve is worked on the straight portion only of its characteristic and that the pressure-coil current does not change in the interval between the readings, then

$$d' = \frac{k}{2}\left(\sum_{x=1}^{x=n-2} I_x I_x' \cos\theta_x + I_n I_n' + \sum_{x=n+2}^{x=\infty} I_x I_x' \cos\theta_x\right)$$

and $$d'' = \frac{k}{2}\left\{\sum_{x=1}^{x=n-2} I_x I_x'' \cos(\theta_x + \mu_x) + I_n I_n'' + \sum_{x=n+2}^{x=\infty} I_x I_x' \cos(\theta_x + \mu_x)\right\}$$

where μ_x = change in phase of xth harmonic current in oscillatory circuit relative to xth harmonic current in the pressure coil, due to the effect of the valve.

$$\therefore d'' - d' = \frac{k}{2}\left[\sum_{n=1}^{x=n-2} I_x\{I_x'' \cos(\theta_x + \mu_x) - I_x' \cos\theta_x\} + I_n(I_n'' - I_n') + \sum_{x=x+2}^{x=\infty} I_x\{I_x'' \cos(\theta_x + \mu_x) - I_x' \cos\theta_x\}\right]$$

With no interfering harmonics in the auxiliary current we should have

$$d'' - d' = \tfrac{1}{2}kI_n(I_n'' - I_n') = \frac{kI_n}{2n\omega L_1}(V_n'' - V_n')$$

$$\therefore \frac{\text{error}}{\text{fundamental}} = \sum_{x=1}^{x=\infty} \frac{I_x}{I_1} \cdot \frac{\{I_x'' \cos(\theta_x + \mu_x) - I_x' \cos\theta_x\}}{I_n'' - I_n'} \quad (33)$$

Let $I_n''/I_n' = A$ = amplification factor.

The only effect of the valve circuit is, as shown in Appendix 7, to reduce the effective resistance of the oscillatory circuit from r to r/A, and to change the effective capacity of the circuit from C to $C/(1 + ar)$. This latter does not, however, affect the reactance component of the impedance to the xth harmonic, for this is

$$x\omega L - \frac{1 + ar}{x\omega C} = \frac{(x^2 - n^2)\omega L}{x} \text{ (since } n^2\omega^2 LC = 1 + ar)$$

$$\therefore \frac{I_x''}{I_x'} = \left[\frac{r^2 + \{\omega L(x^2 - n^2)/x\}^2}{(r/A)^2 + \{\omega L(x^2 - n^2)/x\}^2}\right]^{\frac{1}{2}}$$

$$= \left[1 + \left\{\frac{rx}{\omega L(x^2 - n^2)}\right\}^2\left(1 - \frac{1}{A^2}\right)\right]^{\frac{1}{2}} \text{ (approx.)}$$

$$= 1 + \frac{1}{2}\left(1 - \frac{1}{A^2}\right)\left(\frac{rx}{\omega L(x^2 - n^2)}\right)^2 \text{ (approx.)}$$

If $\gamma_x = \frac{1}{2}\left(1 - \frac{1}{A^2}\right)\left(\frac{rx}{\omega L(x^2 - n^2)}\right)^2$ then $I_x''/I_x' = 1 + \gamma_x$, where γ_x is small,

also μ_x = change in phase of i_x relative to induced E.M.F. e_x

= − (change in phase of impedance vector relative to je_x)

$$= -\left[-\arctan\left\{\frac{rx/A}{\omega L(x^2 - n^2)}\right\} + \arctan\left\{\frac{rx}{\omega L(x^2 - n^2)}\right\}\right]$$

$$= -\frac{\{1 - (1/A)\}rx}{\omega L(x^2 - n^2)} \text{ (approx.)}$$

On substituting for I_x'' and I_n'' in (33) we obtain

$$\frac{\text{error}}{\text{fundamental}} = \sum_{x=1}^{x=\infty} \frac{I_x}{I_1} \cdot \frac{I_x'}{I_n'(A - 1)}\{(1 + \gamma_x)(\cos\theta_x \cos\mu_x - \sin\theta_x \sin\mu_x) - \cos\theta_x\}$$

$$= \sum_{x=1}^{x=\infty} \frac{I_x I_x'}{I_1 I_n'(A - 1)}\{(1 + \gamma_n)(\cos\theta_x - \mu_x \sin\theta_x) - \cos\theta_x\} \text{ (approx.)}$$

$$= \sum_{x=1}^{x=\infty} \frac{I_x I_x'}{I_1 I_n'(A - 1)}(\gamma_x \cos\theta_x - \mu_x \sin\theta_x) \text{ (approx. to 1st order)}$$

$$< \sum_{x=1}^{x=\infty} \frac{I_x I_x'}{I_1 I_n'(A - 1)}(|\gamma_x| + |\mu_x|)$$

$$= \sum_{x=1}^{x=\infty} \frac{I_x I_x'}{I_1 I_n'(A - 1)} \cdot \frac{\{1 - (1/A)\}rx}{\omega L(x^2 - n^2)}\left(1 + \left|\frac{\{1 + (1/A)\}rx}{2\omega L(x^2 - n^2)}\right|\right)$$

$$= \sum_{x=1}^{x=\infty} \frac{I_x I_x'}{I_1 I_n'} \cdot \frac{rx}{A\omega L(x^2 - n^2)} \text{ (approx.)}$$

The ratio of the xth term of this series to the xth term in the series for the error with the single-reading method with no amplification is given by

$$\frac{rx}{A\omega L(x^2 - n^2)} \leqslant \frac{3}{8} \cdot \frac{r}{A\omega L}$$

$\therefore$ Total max. error $\leqslant \frac{3}{8} \cdot \frac{r}{A\omega L}$ times max. error in single-reading method for given r/L, r/L being always taken to mean the effective ratio without amplification.

If maximum error in determination of nth harmonic by single-reading method is ψ_n for an r/L of 15, then maximum error for present method

$$\leqslant \frac{3}{8} \cdot \frac{r}{A\omega L} \cdot \frac{r/L}{15}\psi_n \text{ since error} \propto r/L$$

$$= \frac{r^2}{40A\omega L^2}\psi_n$$

APPENDIX 8.

To Find the Increase in I'_x/I'_n Due to the Valve being worked beyond the Straight Part of its Characteristic.

If the range of variation of the anode current does not exceed about 80 per cent of the saturation current, a good approximation can be made to the grid and anode characteristics by taking

$$i_a = gv_g + hv_g^3 + av_a + bv_a^3$$

where i_a, v_g and v_a are measured from the mid-point of the characteristic from which the valve is worked.

The only appreciable undesired harmonics of order x induced in the oscillatory circuit will be those resulting from the large nth harmonic current in this circuit.

If the resonating current $= I'_n \sin n\omega t$

$$v_g = Mn\omega I'_n \cos n\omega t \quad . \quad . \quad . \quad . \quad (34)$$

also

$$v_a = -Ln\omega I'_n \cos n\omega t \quad . \quad . \quad . \quad (35)$$

$$\begin{aligned}\therefore i_a &= n\omega I'_n(gM - aL)\cos n\omega t \\ &\quad + n^3\omega^3 I'^3_n(hM^3 - bL^3)\cos^3 n\omega t \\ &= n\omega I'_n(gM - aL)\cos n\omega t \\ &\quad + \{n^3\omega^3 I'^3_n(hM^3 - bL^3)\}\tfrac{1}{4}(3\cos n\omega t + \cos 3n\omega t)\end{aligned}$$

The only harmonic in the anode current other than the nth is one of order $3n$, which is of magnitude

$$= \frac{n^3\omega^3 I'^3_n}{4}(hM^3 - bL^3)$$

The proportion of this current passing through the main inductance is in the ratio of the admittance of the inductance to that of the whole oscillatory circuit, that is

$$\frac{-j\{1/(3n\omega L)\}}{-j\{1/(3n\omega L)\} + j3n\omega C} \text{ (approx.)}$$

$$= \frac{1}{1 - 9n^2\omega^2 LC} = -\frac{1}{8}$$

$$\therefore I'_{3n} = \frac{1}{32}\{n^3\omega^3 I'^3_n(hM^3 - bL^3)\}$$

$$\leqslant \frac{1}{32}n^3\omega^3 I'^3_n hM^3$$

$$\therefore \frac{I'_{3n}}{I'_n} \leqslant \frac{1}{32}hn\omega M V_g^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (36)$$

since V_g = max. grid voltage above mean voltage $= Mn\omega I'_n$ [from (34)]

The amplification $A = \dfrac{r}{r - (gM - aL)/C}$ (from Appendix 6)

$$= \frac{r}{r - gM/C} \text{ (approx.)}$$

$$\therefore M = \frac{Cr\{1 - (1/A)\}}{g}$$

$$= \frac{r\{1 - (1/A)\}}{n^2\omega^2 Lg} \quad . \quad . \quad . \quad . \quad (37)$$

$\therefore$ substituting for M in (36) we get

$$\frac{I'_{3n}}{I'_n} \leqslant \frac{rh\{1 - (1/A)\}V_g^2}{32n\omega Lg}$$

$$< \frac{rhV_g^2}{32n\omega Lg} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (38)$$

APPENDIX 9.

To Find the Error Due to the Reading of the Voltmeter Across the Main Inductance being Influenced by the Presence of the Interfering Harmonics in the Oscillatory Current.

The voltmeter across the inductance measures

$$\frac{1}{\sqrt{2}}(V_1^2 + V_3^2 + V_5^2 + \ldots V_n^2 + \ldots)^{\frac{1}{2}}$$

$$= \frac{V_n}{\sqrt{2}}\left[\left(\frac{V_1}{V_n}\right)^2 + \left(\frac{V_3}{V_n}\right)^2 + \ldots + 1 + \left(\frac{V_{n+2}}{V_n}\right)^2 + \ldots\right]^{\frac{1}{2}}$$

The error made by taking this reading as the resonating voltage of the nth harmonic is given by

$$\frac{\text{error}}{\text{true reading}} = \left[1 + \sum_{x=1}^{x=\infty}\left(\frac{V_x}{V_n}\right)^2\right]^{\frac{1}{2}} - 1$$

$$= \frac{1}{2}\sum_{x=1}^{x=\infty}\left(\frac{V_x}{V_n}\right)^2 \text{ (approx.)}$$

$$= \frac{1}{2}\sum_{x=1}^{x=\infty}\left(\frac{E_x}{E_n}\cdot\frac{x^2}{x^2 - n^2}\cdot\frac{r''}{n\omega L}\right)^2 \text{ (on substituting for } V_x/V_n \text{ from Appendix 6)}$$

$$= \frac{1}{2}\left(\frac{r''}{n\omega L}\right)^2\sum_{x=1}^{x=\infty}\left(\frac{E_x}{E_n}\cdot\frac{x^2}{x^2 - n^2}\right)^2 \quad . \quad . \quad (39)$$

To find the error made in the estimation of the nth harmonic of a wave, due to the errors made in the two readings of the resonating voltage before and after amplification, we have

$$d'' - d' = \tfrac{1}{2}kI_n(I''_n - I'_n)$$

$$= \frac{kI_n}{2n\omega L_1}(V''_n - V'_n)$$

$$\therefore I_n = \frac{2(d'' - d')n\omega L_1}{k(V''_n - V'_n)}$$

Now

$$\delta I_n = \frac{\partial I_n}{\partial V''_n}\delta V''_n + \frac{\partial I_n}{\partial V'_n}\delta V'_n$$

where δI_n is the total error in I_n due to errors $\delta V''_n$ and $\delta V'_n$ in V''_n and V'_n respectively.

$$\therefore \delta I_n = \frac{2(d'' - d')n\omega L}{k}\left\{-\frac{\delta V''_n}{(V''_n - V'_n)^2} + \frac{\delta V'_n}{(V''_n - V'_n)^2}\right\}$$

$$= I_n\left\{\frac{\delta V'_n}{V''_n - V'_n} - \frac{\delta V''_n}{V''_n - V'_n}\right\}$$

$$\therefore \frac{\delta I_n}{I_n} = \frac{1}{A - 1}\cdot\frac{\delta V'_n}{V'_n} - \frac{A}{A - 1}\cdot\frac{\delta V''_n}{V''_n} \quad . \quad (40)$$

But the error $\propto \left(\frac{r''}{L}\right)^2$ [from (39)]

$$\propto \left(\frac{1}{A}\right)^2$$

$$\therefore \frac{\delta V_n''}{V_n''} = \frac{\delta V_n'}{V_n'} \cdot \frac{1}{A^2}$$

Substituting for $\frac{\delta V_n''}{V_n''}$ in (40) we have

$$\frac{\delta I_n}{I_n} = \left(\frac{1}{A-1} - \frac{1}{A(A-1)}\right)\frac{\delta V_n'}{V_n'}$$

$$= \frac{1}{A} \cdot \frac{\delta V_n'}{V_n'}$$

$$= \frac{1}{2A}\left(\frac{r''}{n\omega L}\right)^2 \sum_{x=1}^{x=\infty}\left(\frac{E_x}{E_n} \cdot \frac{x^2}{x^2 - n^2}\right)^2 \quad . \quad . \quad (41)$$

The above infinite series can be shown to be convergent for the values of E_x/E_n given by the neon-lamp induced E.M.F. wave, by considering separately the two ranges of x, 1 to x_0, and $x_0 + 2$ to ∞, where x_0 is an odd integer greater than the largest value of n required. All the terms of the first section are finite, while the second section is easily shown to be convergent by comparison with the appropriate infinite integral.

APPENDIX 10.

To Find the Error in the Dynamometer Reading Due to the Beat Frequency being too Near to the Natural Frequency of the Moving System.

The differential equation for the motion of the moving system is

$$(aD^2 + bD + c)\theta$$
$$= T\left\{I_n' \sin\left(n(\omega + \delta\omega)t + \phi_n'\right)\right\}\left\{I_n \sin(n\omega t + \phi_n)\right.$$
$$\left. + \sum_{x=1}^{x=\infty} I_x \sin(x\omega t + \phi_x)\right\} \quad . \quad . \quad . \quad . \quad . \quad (42)$$

assuming that the auxiliary current is sinusoidal and given by

$$I_n' \sin\left\{n(\omega + \delta\omega)t + \phi_n'\right\}$$

where θ = displacement of moving system from its equilibrium position, in radians,
a = moment of inertia of moving system,
b = torque opposing motion, exerted on moving system by damping medium per unit angular velocity,
c = control torque per unit angular displacement,
T = torque on moving system due to unit current in each of fixed and moving coils.

From (42) we have

$$(aD^2 + bD + c)\theta = \frac{TI_n'}{2}\Big[I_n\{\cos(n\delta\omega t + \phi_n' - \phi_n)$$
$$- \cos(\overline{n2\omega + \delta\omega t} + \phi_n' + \phi_n)\}$$
$$+ \sum_{x=1}^{x=\infty} I_x\{\cos[(\overline{n - x\omega} + n\delta\omega)t + \phi_n' - \phi_x]$$
$$- \cos[(\overline{n + x\omega} + n\delta\omega)t + \phi_n' + \phi_x]\}\Big]$$

Considering only that harmonic of the torque given by $\frac{1}{2}TI_nI_n' \cos(n\delta\omega t + \phi_n' - \phi_n)$, which is obviously by far the most important, then

$$(aD^2 + bD + c)\theta = \tfrac{1}{2}TI_nI_n' \cos(n\delta\omega t - \theta_n)$$

where $\theta_n = \phi_n - \phi_n'$.

The particular integral only is required for the solution of this equation, as the reading will not be taken during the initial transition period.

This solution is given by

$$\theta = \frac{1}{\sqrt{\{(c - ap^2)^2 - b^2p^2\}}}\tfrac{1}{2}TI_nI_n'$$
$$\sin\left(pt - \theta_n + \arctan\frac{bp}{c - ap^2}\right)$$

where p is written for $n\delta\omega$.

If time is measured from the instant when $\theta = 0$, we have

$$\theta = \frac{1}{\sqrt{\{(c - ap^2)^2 - b^2p^2\}}}\tfrac{1}{2}TI_nI_n' \sin pt \quad . \quad (43)$$

The above expression is most useful when given in terms of the ratios of actual to critical damping, and impressed to natural frequency.

For critical damping $b_0^2 = 4ac$, where b_0 = critical damping factor.

$\therefore$ if b/b_0 = ratio of actual damping factor to critical damping factor
$= \lambda$

then $$b^2 = 4ac\lambda^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (44)$$

Also if $p_0 = 2\pi$ (natural frequency)

$$p_0^2 = \frac{c}{a} \text{ (approx., if } b \text{ is small)}$$

If $\frac{p}{p_0}$ = ratio of impressed to natural frequency
$= \beta$

then $$p^2 = \frac{c\beta^2}{a} \quad . \quad . \quad . \quad . \quad . \quad . \quad (45)$$

Substituting in (43) from (44) and (45) we have

$$\theta = \frac{1}{\sqrt{\{(c - c\beta^2)^2 + 4c^2\beta^2\lambda^2\}}}\tfrac{1}{2}TI_nI_n' \sin pt$$
$$= \frac{1}{\sqrt{\{(1 - \beta^2)^2 + 4\beta^2\lambda^2\}}} \cdot \frac{TI_nI_n'}{2c} \sin pt \quad . \quad (46)$$

If true reading = max. reading with no damping and inertia effects then true reading $= \frac{TI_n I'_n}{2c}$

$$\therefore \frac{\text{actual reading}}{\text{true reading}} = \frac{1}{\sqrt{\{(1-\beta^2)^2 + 4\beta^2\lambda^2\}}} = \delta$$

The variation of δ with β is shown in Fig. 24 for several values of λ. It is seen that the best damping is that which makes $\lambda = 0{\cdot}707$, as then the beat frequency can be up to 40 per cent of the natural frequency of the moving system without the error exceeding 1 per cent of the maximum reading.

The other harmonics in the torque are given by

$$-\tfrac{1}{2}TI'_n I_n \cos\{n(2\omega+\delta\omega)t + \phi'_n + \phi_n\}$$
$$+\frac{TI'_n}{2}\sum_{x=1}^{x=\infty} I_x[\cos\{(\overline{n-x\omega}+n\delta\omega)t + \phi'_n - \phi_x\}$$
$$-\cos\{(\overline{n+x\omega}+n\delta\omega)t + \phi'_n + \phi_x\}]$$

Then taking $\lambda = 0{\cdot}707$ we have $\delta < 1/\beta^2$ for each harmonic of torque, and since, owing to the arbitrary distribution of phase angles in the above series, the amplitude of resultant deflection is less than the sum of the amplitudes of deflections due to separate harmonics in the torque, we have at once

extra deflection

$$< \frac{TI'_n I_n}{2c}\left\{\frac{p_0^2}{4n^2\omega^2} + \sum_{x=1}^{x=\infty}\frac{I_x p_0^2}{I_n\omega^2}\left(\frac{1}{(n-x)^2}+\frac{1}{(n+x)^2}\right)\right\} \quad . \quad (47)$$

$$\therefore \frac{\text{error}}{\text{fundamental}} < \frac{p_0^2 I_n}{4n^2\omega^2 I_1} + \frac{p_0^2}{\omega^2}\sum_{x=1}^{x=\infty}\frac{I_x}{I_1}\left\{\frac{1}{(x-n)^2} + \frac{1}{(x+n)^2}\right\}$$

The error will in general be less than that which obtains for the analysis of a rectangular wave, and so, taking $I_x/I_1 = 1/x$ and considering the infinite series in two sections as before, it can be shown that

$$\frac{\text{error}}{\text{fundamental}} < \frac{p_0^2}{\omega^2}\left\{\frac{1}{4n^3} + \frac{5}{16}(1+\tfrac{1}{2}\log_e x_0) + \frac{1}{x_0^2-n^2} + \frac{1}{n^2}\log_e\left(1-\frac{n^2}{x_0^2}\right)\right\}$$

The above error is greatest for $n = 3$, for which case, taking natural period of moving system = 1 sec., frequency of wave being analysed = 50 and $x_0 = 31$, we have maximum possible error $< 0{\cdot}034$ per cent of fundamental. The actual error is likely to be much less than this, and so will in general be quite negligible.

APPENDIX 11.

To Find the Error in the Dynamometer Reading Due to the Interfering Harmonics Induced in the Oscillatory Circuit by the Valve.

If the valve is worked at the middle of its characteristic the only appreciable harmonics induced in the oscillatory current will be odd harmonics of the fundamental wave, i.e. referring to the wave being analysed the interfering harmonics in the oscillatory circuit are denoted by I'_{3n}, I'_{5n}, I'_{7n}, etc., or by $\Sigma I'_{yn}$, where y is an odd integer differing from unity.

The torque produced by one of these harmonics in the fixed-coil current reacting with all the harmonics in the moving-coil current is

$$\tfrac{1}{2}TI'_{yn}\sum_{x=1}^{x=\infty} I_x[\cos\{(\overline{yn-x\omega}+yn\delta\omega)t + \phi'_{yn} - \phi_x\}$$
$$-\cos\{(\overline{yn+x\omega}+yn\delta\omega)t + \phi'_{yn} + \phi_x\}]$$

where the range of x includes $x = n$.

The maximum error will be expected from the terms for which $x = yn$, and so these terms will be considered separately.

For a single value of y, i.e. considering only one of the interfering harmonics in the oscillatory current and excluding the term for $x = yn$ from the summation, we obtain from Equation (47), Appendix 10,

$$\frac{\text{error}}{\text{true reading}} < \frac{p_0^2}{\omega^2}\sum_{x=1}^{x=\infty}\frac{I'_{yn}}{I'_n}\cdot\frac{I_x}{I_n}\left\{\frac{1}{(yn-x)^2}+\frac{1}{(yn+x)^2}\right\} \quad . \quad (48)$$

For a self-oscillatory circuit the effective resistance of the circuit is made negative and then the oscillations increase until the saturation current is reached, this being the limiting factor. As a consequence of this the anode current waves are flattened on top and so contain harmonics other than the fundamental.

The anode-current wave will be smooth and without ripples, and so we can expect the harmonics in it to be less than the corresponding harmonics in a rectangular wave.

If Ia_n and Ia_{yn} are the harmonics in the anode current of order n and yn respectively, referred to the wave being analysed as fundamental, and if the oscillatory circuit is tuned to the nth harmonic, then the anode current divides between the two paths of the oscillatory circuit in the ratio of their admittances

$$\frac{I'_{yn}}{Ia_{yn}} = \frac{-j\{1/(yn\omega L)\}}{-j\{1/(yn\omega L)\} + jyn\omega C} \text{ (approx.)}$$
$$= \frac{1}{1-y^2}$$

Also $$\frac{I'_n}{Ia_n} = \frac{-j\{1/(n\omega L)\}}{r/(n^2\omega^2L^2) - j1/(n\omega L) + jn\omega C} \text{ (approx., neglecting } r^2 \text{ compared with } n^2\omega^2L^2\text{)}$$
$$= -j\frac{n\omega L}{r}$$

but $$\frac{Ia_{yn}}{Ia_n} = \frac{1}{y} \text{ for a rectangular wave}$$

$$\therefore \frac{I'_{yn}}{I'_n} = \frac{r}{y(y^2-1)n\omega L} \quad . \quad . \quad . \quad (49)$$

The error will be less for most waves likely to be considered than for the case of the rectangular wave for which, on substituting in Equation (48), we have

$$\frac{\text{error}}{\text{fundamental}}$$
$$< \frac{p_0^2 r}{n\omega^3 Ly(y^2-1)}\left\{F(1) + \tfrac{1}{2}\int_1^{yn-2} F(x)dx + F(yn+2) + \tfrac{1}{2}\int_{yn+2}^{\infty} F(x)dx\right\}$$

where $F(x) = \dfrac{1}{x(yn-x)^2} + \dfrac{1}{x(yn+x)^2}$, the term for $x = yn$ being excluded from the summation.

On evaluating this expression and putting $n = 3$, since the error is greatest for this case, we have

$$\frac{\text{error}}{\text{fundamental}} < \frac{0\cdot 8rp_0^2}{3\omega^3 Ly(y^2-1)}$$

Therefore, considering all possible values of y from 3 to ∞, we obtain

$$\frac{\text{error}}{\text{fundamental}} < \frac{0\cdot 27rp_0^2}{\omega^3 L}\left\{\frac{1}{24} + \sum_{y=5}^{y=\infty}\frac{1}{y(y^2-1)}\right\}$$
$$< \frac{0\cdot 27rp_0^2}{\omega^3 L}\left\{\frac{1}{24} + \tfrac{1}{2}\int_3^{\infty}\frac{dy}{y(y^2-1)}\right\}$$
$$< \frac{0\cdot 02rp_0^2}{\omega^3 L}$$

For $r/L = 200$, $\omega = 314$, and natural period of moving system $= 1$ sec., this error is less than $0\cdot 0006$ per cent of the fundamental, and is thus quite negligible.

Considering now the terms in the series for the torque for which $x = yn$, we have

$$\text{torque} = \tfrac{1}{2}T\sum_{y=3}^{y=\infty} I'_{yn}I_{yn}\{\cos(yn\delta\omega t + \phi'_{yn} - \phi_{yn}) - \cos(yn2\omega + \delta\omega t + \phi'_{yn} + \phi_{yn})\}$$

which gives

$$\frac{\text{error}}{\text{true reading}} < \sum_{y=3}^{y=\infty}\frac{I'_{yn}}{I'_n}\cdot\frac{I_{yn}}{I_n}\left(\frac{p_0^2}{y^2n^2\delta\omega^2} + \frac{p_0^2}{4y^2n^2\omega^2}\right)$$

On substituting for I'_{yn}/I'_n from (49), and taking $I_{yn}/I_n < 1/y$, since the error will in general be less than that for the analysis of a rectangular wave, we have

$$\frac{\text{error}}{\text{true reading}} < \frac{p_0^2 r}{n^3\omega L}\left(\frac{1}{\delta\omega^2} + \frac{1}{4\omega^2}\right)\sum_{y=3}^{y=\infty}\frac{1}{y^4(y^2-1)}$$
$$< \frac{p_0^2 r}{n^3\omega L}\left(\frac{1}{\delta\omega^2} + \frac{1}{4\omega^2}\right)\left\{\frac{1}{648} + \frac{1}{2}\int_3^{\infty}\frac{dy}{y^4(y^2-1)}\right\}$$
$$= \frac{0\cdot 0023p_0^2 r}{n^3\omega L\delta\omega^2}\ \text{(approx.)}$$
$$= \frac{0\cdot 0023r}{n\omega\beta^2 L}\ (\text{since } \beta = n\delta\omega/p_0)$$

Taking $\beta = 0\cdot 4$ and $\omega = 314$, the maximum possible error is less than $0\cdot 0046r/(nL)$ per cent of true reading.

For $n = 3$, for which case it is greatest, the error is less than $0\cdot 0016r/L$ per cent of true reading.

DISCUSSION BEFORE THE INSTITUTION, 6 NOVEMBER, 1924.

Dr. C. V. Drysdale: Anyone who has had actual experience of wave-form analysis will agree with the authors that the old methods of separating out the harmonics from a single wave-trace are tedious and inaccurate, and there can be no question that a direct electrical method of measuring the harmonics is greatly to be preferred. They have certainly shown by their careful theoretical analysis and experimental examples that the method proposed by them is capable of a high degree of accuracy; and the neon-lamp method of obtaining the various frequencies for the analysing wave is certainly most highly ingenious and valuable for many purposes. There are, however, certain directions in which it appears to me that the electrical method could be improved while retaining the fundamental principle employed by the authors. It will be noticed that one of the reasons for their attempts at deriving the high-frequency analysing wave directly from the machine under test is that, on account of the comparatively large periodic time of their dynamometer instrument, it is necessary to maintain the analysing and test waves in synchronism over a moderately long period, and this is difficult to do unless they originate from the same source. If the periodic time of the wattmeter could be reduced to 0·1 second or less, so as still to give the average value of the product of the two components while being able to follow beats of the order of a few periods per second, the whole procedure would be greatly simplified, and it would be possible to obtain the analysing wave from a separate oscillating set and to tune it sufficiently closely to be able to obtain the maximum deflection without the need for holding it in exact phase relation for any considerable length of time. Although for ordinary accurate measurements of power I have always championed the dynamometer wattmeter against its electrostatic and other rivals, this is a case in which the electrostatic or hot-wire form of wattmeter in which the moving element can be made very light and will consequently have a very small periodic time can be used with advantage, with the additional benefit that all difficulties concerning self-inductance or mutual inductance in the wattmeter disappear and that the observing instruments become commercially procurable. The simple form of string electrometer made by the Cambridge and Paul Instrument Co. and other firms is extremely suitable for this purpose, as the moving element is only a thin fibre having a periodic time of only a few hundredths of a second, which time can be varied over a considerable range by adjusting the tension. One of my assistants, Mr. G. F. Partridge, B.Sc., has developed a system of harmonic analysis originated by Mr. B. S. Smith, in which a valve-generated analysing wave is used to polarize the plates of a string electrometer while the string is connected to the source to be analysed.

The frequency of the analysing wave can be varied continuously by the rotation of a variometer, the motion of the string being photographed on a drum rotating with the variometer. Frequencies of 50 periods per sec. and upwards can be produced with ease, and by changing the capacity in the oscillating circuit the frequency can be varied over a very wide range with an approximately constant E.M.F. Fig. A shows the connections of the electrometer, from which it will be seen that the E.M.F. to be analysed is merely applied between the string and the mid-point between the attracting plates or "quadrants," and the analysing E.M.F. is applied across the quadrants themselves, as in the standard connections for electrostatic wattmeters. In the ordinary form of Cambridge string electrometer employed the camera is coupled to the variable oscillator for producing the analysing wave. The variometer is coupled to the rotating drum of the camera and to a motor which enables the two to be run in perfect correspondence at any desired speed. There is therefore a definite oscillating frequency corre-

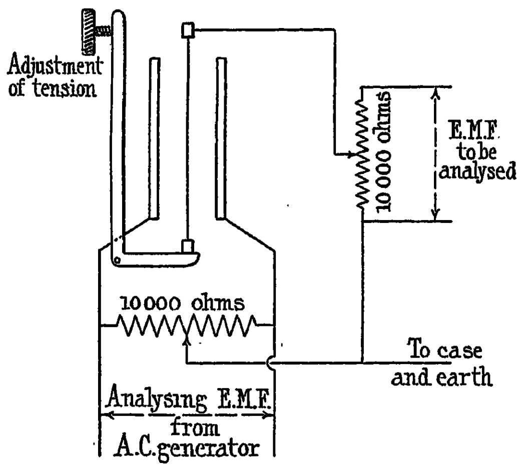

Fig. A.—Method of connecting string electrometer.

sponding to each angular position of the rotating drum, which can be determined initially; and it is possible to arrange the oscillator circuits so that an approximately constant P.D. is maintained between the quadrants or attracting plates throughout the range of frequency, in which case the maximum peaks on the record can be made to give the values of the harmonics directly. Tests made with different speeds of rotation of the variometer have given the same maxima, showing that the electrometer follows the beats accurately even when they are of moderately high frequency. This method has been used very successfully for the harmonic analysis of irregular waves of short duration, and is especially useful in the case of irregular disturbances containing a number of unrelated vibration frequencies. For the majority of practical tests on electrical machines, however, there should be no difficulty in maintaining the frequency sufficiently constant for a short time to be able to read the maximum directly, and this has been found to be easily possible. In this case the whole of the apparatus required is the string electrometer and an ordinary oscillating set with coils of sufficiently high inductance and low resistance to produce oscillations of the comparatively low frequencies required, thus reducing the whole of the gear to apparatus which is already easily obtainable. Care must, of course, be taken to work the valves over a sufficiently low range to avoid the generation of harmonics in the analysing wave, but this is not usually a difficult matter. The authors' method of producing the series of analysing waves from the machine under test by the commutator or neon-lamp method certainly has the advantage of enabling the phase as well as the magnitude of each of the harmonics to be determined, but I have never known a case in which the phase of the harmonics appears to be of great importance, and the authors do not appear to have troubled to obtain it in the tests they have recorded. It therefore appears to me that the electrometer method with a separate oscillating set

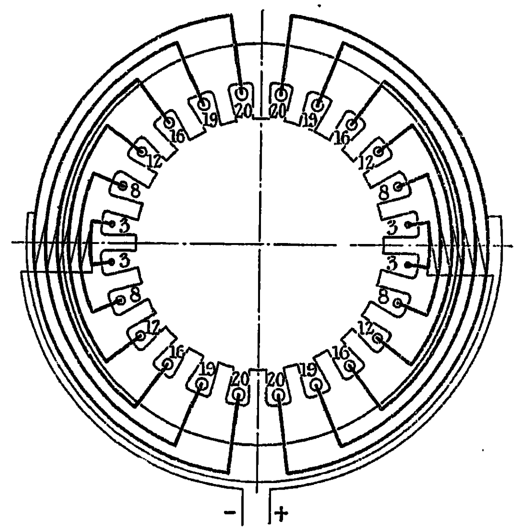

Fig. B.—Winding diagram of sine-wave alternator, showing distribution of turns in slots.

will fulfil all practical requirements; and quite possibly hot-wire elements of the Irwin type would prove almost equally suitable; and either of them could, it appears to me, be adapted to the authors' devices without difficulty.

In this connection there seems to be a great need for an alternator which will give a true sine wave for testing purposes. It occurred to me some years ago that an alternator made up with sinusoidally distributed windings on the lines of my phase-shifting transformers would give a much more perfect wave-form than is usually obtainable. Within the last few weeks a small machine has been made up on these lines. It consists simply of a stator and rotor, like an ordinary induction motor, but with distributed windings on both the stator and rotor, the distribution of turns in the slots being according to a sine law so that the flux is almost perfectly uniform across the whole diameter. The slots are staggered in order to make the effect of the teeth as small as possible, and a soft-iron shroud is inserted in the stator core to reduce this effect still further. Fig. B is a winding diagram and Fig. C an

oscillograph trace of the E.M.F. wave of a small 20-watt machine of this type which can be easily held in the hand, and it will be seen that it is almost per-

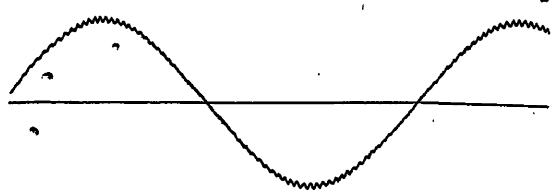

FIG. C.—Oscillograph trace of E.M.F. wave of sine-wave alternator (50 volts, 46 periods per second).

fectly sinusoidal but with a small high-frequency harmonic which corresponds approximately to the sum of the stator and rotor slots ($36 + 24 = 60$). It is probable that with a little further attention to the staggering and shrouding of the rotor these ripples could be practically eliminated; and from experiments made on the phase-shifting transformers it would appear possible to obtain a very perfect sine-wave alternator by this device. The machine shown is only a two-pole one, and consequently is only suitable for frequencies up to about 50 periods per second. A considerably higher frequency could, of course, be obtained by means of a multipolar winding, although it would probably be difficult to utilize such a winding for the frequencies required for the highest harmonics. It is thought, however, that such a machine should be of value as a testing machine for ordinary calibration, etc.

[The author's reply to the discussion will be found on page 117.]

Mersey and North Wales (Liverpool) Centre, at Liverpool, 17 November, 1924.

Prof. E. W. Marchant: Those who have had to do with the analysis of irregular wave-shapes will agree that the apparatus devised by the authors should be of practical value. Over 25 years ago I was working in Prof. Henrici's department at the City and Guilds College, using the beautiful analyser which he had devised for obtaining the amplitude of the different harmonics in a wave-shape drawn out to scale, by readings similar to those which are taken on a planimeter. The method that has to be adopted to find the harmonics to-day, even with the shortened methods of analysis that are now well known, is rather cumbrous, and, of course, when the higher harmonics of the wave have to be found it is open to error, not merely because the oscillograph itself does not record exactly the higher harmonics in the wave, as the authors have pointed out, but also because of the mechanical difficulties in analysing the curves. A slight error in going over a photographic record of the wave-shape may make an appreciable difference in the determination of the value of one of the higher harmonics. It may be well to point out, however, that even with a 20th harmonic on a 50-cycle wave, the high-frequency oscillograph will not be very far out in its record, since the frequency of the harmonic is 1 000 per second, as compared with a natural frequency of 10 000 per second for the vibrator of the oscillograph. If the apparatus described in the paper can be relied upon it will get over these difficulties, because it determines directly the value of the harmonics from the wave itself and, therefore, avoids both the errors inevitable in the recording of waves and also the mechanical errors likely to arise in the estimation of the higher harmonic from the curve, when it has been found. The circuit shown in Fig. 1 is a very useful one and its selectivity is remarkable. It is, of course, exactly the same circuit as is used in so many wireless sets in what is known as the tuned anode arrangement, and those who have had experience with this circuit will realize how selective it may be made. The values of λnx calculated in Table 1 are, I presume, values which have been found without taking account of the fact that the power factor of the condenser is not zero. If one makes correction for the power factor of the condenser, the value of r in Equation (4) will be altered by a considerable amount. If R_1rC/L is nearly unity the effect of this correction is not large, but in some calculations which I have made the value of the coefficient R_1rC/L works out at something a good deal greater than unity, and in such cases the value of r becomes important. For example, in the case of a condenser of 40 μF capacity, working on the 11th harmonic of a 50-cycle wave, assuming a power factor of 0·4 per cent, which is almost as good as can be expected, the effective resistance, i.e. the resistance which must be shunted across the condenser in order to make the circuit equivalent to one containing a condenser with this power factor, would be only 1 800 ohms, and the values of λnx in Table 1 would therefore require considerable correction. With regard to the standard method of analysis described in Section 5, it would seem likely that a good deal of trouble would be experienced in getting the square or trapezoidal wave that should be obtained by means of a commutator. The authors refer to the difficulties met with in connection with the brush gear of their "standard" arrangement when it is using the small currents that are employed with the circuit shown in Fig. 1. Even with these small currents, to judge from the experience that one has had with rubbing contacts of this kind, I think that the possibilities of irregularity are very considerable. There is a great liability to chatter if the commutator surfaces are not absolutely true and, of course, if the motor hunts at all there will be a further difficulty due to phase displacement of the wave. With regard to Fig. 15, I should like to ask what degree of accuracy has been observed in the time of the shutting off and lighting up again of the neon lamps due to the pulses of current which produce the oscillations in the dynamometer circuit. In our experience with these lamps we have found that after a lamp has been burning at a given voltage for some time it will probably take to start it a different pressure from that which was required when the lamp first began to burn, and I should think that there might be a considerable amount of irregularity

in the interval between the switching off of the pulse due to one alternation and the starting of the pulse corresponding to the next. There may also be differences between the two lamps that are arranged back to back. I should have anticipated considerable errors in the readings of the dynamometer, due to this cause. The errors that are likely to occur in this apparatus in determining the amplitude of the various harmonics of a wave have been worked out with great precision, but I am inclined to think that the accuracy that could be obtained in practice is limited. The cases in which an analyser of this kind is likely to be most useful are those in which fairly heavy machinery is employed, where the amount of power available is considerable, and in the case of a turbo-generator or a low-speed water-wheel-driven alternator I think that the slight variations which are inevitable, due to vibration and other causes, would produce a difference of more than 0·1 per cent between the successive waves given by the alternator. It is, of course, of the highest value if this instrument can be relied on to determine within 0·1 per cent or even 1 per cent the values of the harmonics to be found, but I do not think that an analysis of this accuracy will be either possible or necessary in practice. Towards the end of the paper the authors refer to the use to which the apparatus may be put, and state that the method can possibly be applied to the analysis of all forms of periodic voltage and current curves. I should like to know what is the smallest amount of power that is necessary to operate an analyser of this description. If one is attempting to analyse the waves of current that are obtained, for example, from speech in a telephone transmitter or the periodic currents that are flowing along a telephone line due to speech, it is obvious that the amount of power available for the operation of the instrument is limited. For such purposes as the determination of harmonics, which are likely to cause interference with telephone lines, the apparatus should be of the very greatest value, and for this purpose the accuracy necessary need not be very great. All that is needed is an instrument which will find what harmonics are present, and their order of magnitude. For such purposes the instrument described in the paper should be of the highest value.

Dr. F. J. Teago: The value of the proposed new method for analysing complex wave-forms is very great, provided its accuracy is demonstrated. It is not of academic interest only, since improvements in the design and manufacture of electrical apparatus can only be made when the nature and magnitude of the existing trouble are known. The difficulty is that there is no standard to which the various methods of analysing complex waves may be referred, and the sole guide in this case is the mathematical reasoning. Taking Equation (3), viz.

$$d_1 = \tfrac{1}{2}k(I_1 I_1' \cos\theta_1 + \ldots + I_n I_n' + \ldots)$$

this deflection has been measured on a dynamometer with the object of determining I_n, and d_1 will be larger than its true value by an amount depending upon the value of the sum of all the terms except the nth. The equation for the analysing current has been given as a complex wave, apparently generated by some form of oscillating circuit, although no mention is made of this in the first part of the paper. One would also suppose that the circuit is such that every term except that containing the nth harmonic is relatively small, otherwise the error in d_1 will be exceedingly large. If, however, the analysing current had been generated by some rotating machine, then it would have contained no harmonic of an order less than the nth, and the magnitude of each harmonic other than the nth would be relatively small, and the equation for d_1 would have been

$$d_1 = \tfrac{1}{2}k(I_n I_n' + I_{n+2} I_{n+2}' \cos\theta_{n+2} + \ldots)$$

and d_1 in this case cannot differ greatly from $\tfrac{1}{2}kI_nI_n'$ (since the products of small terms are negligible) and would be larger than it. In this connection also the ammeter-measured analysing current has probably been multiplied by $\sqrt{2}$. Let this value of the analysing current $= [I_n']$. The maximum value of the nth harmonic must be got from

$$[I_n] = 2d_1/k[I_n']$$

and the question is, what is the relationship between $[I_n]$ the measured maximum value, and I_n the true maximum value of the nth harmonic in the wave under analysis?

If $[I_n']$ has been obtained as suggested above, then, since

$$[I_n'] = \sqrt{(I_1'^2 + I_3'^2 + \ldots + I_n'^2 + \ldots)}$$

we have $$[I_n'] > I_n'$$

and very much greater unless I_n' is the predominant term, so that $[I_n]$ may differ greatly from I_n. If the rotating machine analysing current is considered in relation to the value of $[I_n']$ then

$$[I_n'] = \sqrt{(I_n'^2 + I_{n+2}'^2 + \ldots)}$$

and cannot differ greatly from I_n' but is rather larger than it, so that $[I_n] = 2d_1/k[I_n'] = I_n$, since the errors tend to cancel one another. On the information given in the first part of the paper the problem appears almost hopeless, but this is due to the fact that the Appendix is at the end instead of being in front.

Mr. R. O. Street: In approximating from Equation (4*a*) to Equation (4*b*) it is assumed that R_1rC/L is large compared with unity, and this does not seem consistent with the statement in the next paragraph that it is advisable to make it of the order unity.* Also, in the simplification of Equation (7) the term $r_1/(n\omega L)$ is neglected. The condition of tuning makes $n^2\omega^2LC = 1$, so that we have really neglected $n\omega r_1C$. Thus the higher the harmonic the greater is the error, and not the smaller, as would appear at first sight. Further, in obtaining Equation (10) it is assumed that $R_1\omega C/\{1 + R_1rC/L\}$ is large, and so, in virtue of the previous supposition, $R_1\omega C$ must be very large, say of the order 10 000 for anything approaching a 1 per cent accuracy. Also, $\omega L/r$ must be large, but its actual value is never greater than about 20, and is often much less. I think that in

* This has since been corrected by the authors.

neasuring the degree of accuracy of any harmonic the ırror should be referred to the harmonic itself and not o the fundamental.

Mr. F. Mercer: The third harmonic and perhaps ›thers of a correspondingly low frequency result in a oss of efficiency and therefore command attention from upply engineers, but the higher harmonics of frequencies ›etween 500 and 2 000, i.e. those in the audible range, ıre of concern to telephone engineers and it is becoming ncreasingly desirable that attempts should be made to ›liminate them either in the better design of alternators ›r by the use of filters. Hitherto no satisfactory method ıas been available for measuring the higher harmonics, ınd the authors are to be congratulated in having so ıearly approached a solution. There is one criticism I ›hould like to make in connection with the method of neasurement of current in the oscillatory circuit (Fig. 2). An electrostatic voltmeter is used which measures the voltage in conjunction with a potential divider of total resistance 200 000 ohms. It seems likely that the capacity between the plates of this instrument, even if of the order of 20×10^{-6} μF, may lead to a serious error in calculating the values of harmonics having frequencies of 500 and upwards. I should like to ask the authors whether this point was appreciated and whether a suitable correction was made for it.

Mr. R. B. Burrowes: Referring to the dynamometer, let the analysing current be given by

$$i_2 = I_{n+\epsilon} \sin \{(n + \epsilon)\omega t - \phi'_{n+\epsilon}\}, \text{ where } \epsilon < 1.$$

The product of this and the current under analysis given by

$$i_1 = I_0 + I_1 \sin (\omega t - \phi_1) + \ldots + I_n \sin (n\omega t - \phi_n) + \ldots$$

gives rise to a number of terms the integrals of which do not cancel out over the period of the fundamental, from which it might be supposed at first that the high-frequency impulses which they represent do not cancel out in their effect on the torque. But, as the authors point out, to obtain the effect on the torque we must integrate the impulses, not over the period of the fundamental, but over the period of swing of the moving system, whatever this may be. For example, putting $\epsilon = 0$, the period of the torque is infinite, that is, the torque is steady and therefore also the deflection, the torque being given by $\frac{1}{2}KI'_nI_n \cos (\phi - \phi'_n)$, so that all the harmonically varying impulses cancel out absolutely. By increasing ϵ from 0 up to $0 \cdot 5$ in steps, we can find the effect on the torque of this difference in frequency between the analysing current and the harmonic under analysis. Putting $\epsilon = 0 \cdot 1$, the low-frequency torque due to the harmonic under analysis is given by $\frac{1}{2}KI'_{n+\epsilon} I'_n \cos (0 \cdot 1\omega t + \phi'_n - \phi'_{n+\epsilon})$. That is, if the fundamental has a period of 1/50th second, this torque has a period of $\frac{1}{5}$ second. Superposed on this is a torque of high frequency $(2n + 0 \cdot 1)$ of the fundamental, which therefore almost cancels out over the longer period. The other harmonics which will produce the greatest effort will be those of frequency nearest to that under analysis. So, taking the next higher [the $(n + 1)$th], the low-frequency torque due to this and the analysing current is given by

$$\tfrac{1}{2}KI'_{n+\epsilon}I_{n+1} \cos (0 \cdot 9\omega t + \phi_{n+1} - \phi'_{n+\epsilon}),$$

i.e. it has a period of 1/45th second. Putting $\epsilon = 0 \cdot 5$, the analysing current now produces torques of equal low frequency with both the nth and the $(n + 1)$th harmonics of the current under analysis. The equal periods are double that of the fundamental, i.e. 1/25th sec. The effect of these, whether they add up or to what extent they cancel, will depend on their phase relations as well as on their amplitudes; so that in this case there will be total confusion between two consecutive harmonics, though with only odd harmonics this confusion would be less. These results seem to show that in order to get a torque effect due to only one harmonic ϵ must be less than $0 \cdot 1$, or, as the authors have it, σ must be small compared with ω. Another necessity for having ϵ less than $0 \cdot 1$ is, of course, in order to be able to observe the amplitude of the deflection. For with a fundamental frequency of 50 and $\epsilon = 0 \cdot 1$, the frequency of swing would be 5, i.e. too high to allow the deflections to be read comfortably. With a swing frequency of 1 sec., ϵ must equal 1/50. From this it appears that a very fine gradation of frequency of the analysing current is required in order to produce the torque effect due to one harmonic only. With regard to the error due to these low-frequency swings or beats being nearly equal to that of the moving system, this seems to be fully worked out in Appendix 10. I should like to ask whether the authors are able to obtain deflections of very long-period or even steady deflection, in which case the errors due to damping and resonance vanish.

Messrs. J. D. Cockcroft, R. T. Coe, J. A. Tyacke and Miles Walker (*in reply*): The very interesting instrument described by Dr. Drysdale employs the self-oscillating method described in section (8) of our paper and, in addition, makes use of an electrostatic wattmeter having a very small periodic time of swing. This type of instrument seems admirably suited to give quick readings of the watts, and thus to work well when the frequency is changing slightly, or to be used with a variometer as described by Dr. Drysdale. The periodic time of the swing must not, however, be made too small. The filar must be able to average the power throughout the cycle and not move so quickly as to give instantaneous readings of the watts. The method of producing a sinusoidal field by properly distributing the winding is very effective, as is shown by the successful operation of the phase-shifter. Small tooth-ripples are, however, very difficult to overcome. Even the skewing of the slots does not completely eliminate such ripples, on account of discontinuity of the skewed slot at each end of the stator.

The point raised by Prof. Marchant as to the effect of the power factor of the condenser on the value of r is quite a good one if paper condensers having foil of poor conductivity are employed. We know this to our cost. For a long time the ratio r/L was increased unduly by the poor condensers that were employed. By using mica condensers having good conductivity in the opposing metal surfaces the power factor is so low

as hardly to effect the value of r. For the 11th harmonic of a 50-cycle wave we should employ a condenser of only about $3\mu F$. The exact wave-form of the current obtained from the commutator does not matter much; it affects the wave-form of the analysing current to only a very small degree. The more the corners are taken off the square wave, the smaller is the interference with I'. The variation of the effect does not matter, because we measure the value of I' at the same time as we take the dynamometer reading.

With regard to the variation in the characteristics of the neon lamps, we have not noticed any difference in the two lamps that we used back-to-back. So far as the oscillograph record goes they appear to be identical. It is true that if the lamps had different characteristics there would be a slight difference in the time phase at the beginning of each half-cycle, which would make it impossible to get what should be the maximum reading of the wattmeter. It must be remembered, however, that the reading of the wattmeter would only be multiplied by the cosine of half the angle of variation induced by the lamps, and, as this angle is apparently extremely small (if it exists at all), the value of this cosine would be practically unity.

Prof. Marchant asks what is the smallest amount of power necessary to operate an analyser of this description. By making use of valves the amount of power required can be made excessively small. One of the methods that we have recently devised for providing the analysing current is shown diagrammatically in Fig. D. Instead of using the neon-lamp circuit shown in Fig. 13 the exciting coil M' is fed from the plate of a triode whose grid is excited by a voltage of a frequency corresponding to the frequency of the harmonic to be measured. The positive end of a battery B (about 60 volts) is connected by a contact maker F to the grid of the triode. A resistance R_3 of about 100 000 ohms acts as a grid leak and has one end connected to a roving contact on the battery so that the grid potential can be adjusted. When the contact is made, the grid becomes positive and a current flows in the plate circuit. When the contact is broken, the grid becomes negative and the plate current stops. The contact maker F consists of a minute brush running upon a copper plate which has been engraved and enamelled with a hard-wearing enamel so as to represent in concentric rings a number of concentric commutators having a number of bars as follows:—6, 10, 14, 18, 22, 26, 30, 34, 38, 42, etc. The disc is attached to a 2-pole synchronous motor so that on a 50-cycle circuit it runs at 3 000 r.p.m. In the 6-bar commutator three of the bars are of bright copper and the other three are of non-conducting enamel, so that at one revolution of the commutator the grid receives excitation having a frequency equal to that of the 3rd harmonic. The other concentric rings give excitation for the 5th, 7th, 9th, etc., harmonics as required. In order to take off the square corners of the wave-form of the voltage supplied to the grid, the coil L_4 is connected in series with the grid, and a condenser C_4 of very small capacity is connected across the resistance R_3. It will be seen that with this apparatus the only energy required to be taken from the circuit is that required to drive the synchronous motor, and need not be more than $\frac{1}{2}$ ampere at 100 volts (or 50 watts). If this power is not available from the circuit the voltage of which is required to be analysed, it would be possible to supply it by a combination of triode valves and relay, the grid of the first valve being connected to the circuit in question. With the analysing current provided by the excitation illustrated in Fig. D the wattmeter shown at the meeting will give a full-scale deflection when a current of 10mA flows through the moving coil. It would, of course, be possible to supply this current from the plate of a valve whose grid was connected to the supply, so that the total power would be only that required to energize the grids of two valves.

A complete reply to the points raised by Dr. Teago will be found in the Appendixes to the paper.

Mr. Street is quite right in his objection to the statement (in the advance copies of the paper) that $R_1 rC/L$ is of the order of unity. This has been corrected on page 74 and now reads "is of the order of three." In the values of λ_{nx} worked out in Table 1 this quantity $(R_1 rC/L)$ was made equal to 3. In neglecting $r_1/n\omega L$ in simplifying Equation (7), Appendix 1, it must be

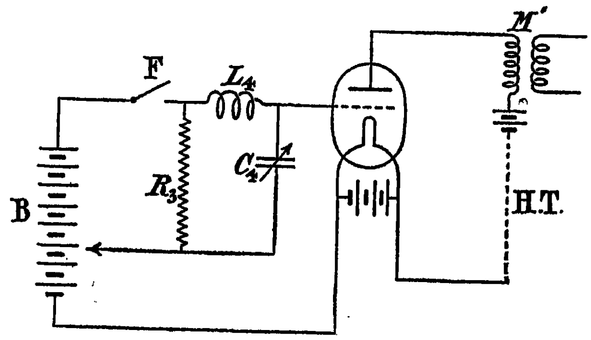

FIG. D.

remembered that r_1/L is a fixed ratio, so that the error varies as $1/n$. Mr. Street does not take into account the fact that r_1 and C are decreased with increasing n. In approximating from (9) to (10), if Rr_1C/L is made equal to three, the imaginary part of (9) is never less than 40 times the real part, so that in adding vectorially to get the ratio of the amplitudes, the real part is quite negligible.

Mr. Mercer is quite right in pointing out that where the capacity of the electrostatic voltmeter affects the voltage applied to it when obtained from a potential divider, it is necessary to make a suitable correction. The correction required in the case of the instrument employed by us is less than 1/10th of 1 per cent. In calculating this it must be remembered that the current taken by the electrostatic voltmeter is at right angles in phase to the current flowing in the potentiometer resistance, and therefore a current of a few micro-amperes when added at right angles to a few milli-amperes makes practically no difference in the virtual value of the voltage on the instrument.

Mr. Burrowes's remarks about the torques of different frequencies apply only to the method using the valve

generator. It should be remembered, however, that, as shown in Appendix 10, the response of a low-frequency moving system such as the dynamometer coil to a torque of relatively high frequency varies inversely as the square of the torque frequency, so that these higher harmonics of torque produce no appreciable effect. The magnitude of the error introduced is worked out in Appendix 10.

SOUTH MIDLAND CENTRE: CHAIRMAN'S ADDRESS

By W. Lawson, Member.

(Extract * *from Address delivered at* Birmingham, *22nd October,* 1924.)

The normal routine and details of daily toil are rarely of general interest, but in almost all our occupations we touch the fringe of a variety of matters and problems which, though outside the prescribed limits of our work, specially entice our interest or insistently induce reflection in those directions compatible with personal bent and predilections.

Such ideas as I shall endeavour to put before you are therefore of the order of by-products of those activities in which I have been concerned as a supply meter engineer, as management secretary of a Whitley works committee in a large supply undertaking and as a member of the Institution.

It has been said that the right way to study history is to start with the parish and radiate back to Egypt and Mesopotamia, and though history is not my theme the plan of this address is analogous in so far as my remarks will concern, first our Centre, then the Institution, and afterwards the electrical industry.

If one is satisfied by merely statistical evidence, it is easy to claim that this Centre is in a flourishing condition. It is, for instance, gratifying to know that our present membership (including the East Midland Sub-Centre) numbers 936 as against 421 in the year 1913. Such figures spell progress but they do not reveal the more obscure and more vital factors representing the amount of interest taken by each individual member in the affairs of the Centre and its future development, and what his conception is of the part to be played by it in furthering the prestige and influence of the whole Institution.

It would appear that we are approaching the flood-tide of electrical development in this country, and the interchange of information and ideas which is our main purpose is becoming of increasing necessity. It is extremely desirable that more papers should be forthcoming from amongst our own members so that all available special knowledge and talent should be disclosed. In this respect much good would result from the establishment of co-operation between the various Centres and Sub-Centres and by bringing them into closer touch. I suggest that it would be feasible for Local Centres to obtain from their own members, papers for informal reading at their own and adjacent Centres and Sub-Centres, and adopt a system of interchange of such papers. The papers, together with discussions thereon, could be submitted to the Papers Committee, who would decide whether or not they should be published in the *Journal*. This would create a certain amount of competition for the honour of publication, and help to assist in the framing of more varied programmes.

It is all a question of whether we are content as a body to function mechanically on set lines or wish to intensify our interests and extract the last ounce from every privilege of membership.

The welfare of the Students' Sections is a matter of prime consideration, and senior members should associate themselves as far as they are able in the various functions held by the Students, and in addition to render, when possible, individual advice and counsel. In no better way can we ensure that in the future the Institution will contain an ever increasing number of men eager to serve it.

There is one matter to which I should like to refer on which statistics are not flattering to this Centre; and it concerns not only ourselves but the whole Institution. It is one which calls for the sympathy and support of every member: I mean the Benevolent Fund. You have all received an appeal from our Hon. Treasurer of the Fund, Mr. W. J. Anderson, who is anxious to appear in that capacity as something more than a mere figure-head. It is obvious, however, that he cannot effect much without your co-operation and I implore that you will do this, not solely by subscribing but in persuading others to do likewise. Last March the then President issued a circular to all members of the Institution in which he stated that from total of 11 500 members a sum of £636 10s. in donations and subscriptions was received. This works out at an average for the year of 1s. 1¼d. per member. Viewed in this way I think you will agree that it is an insignificant sum.

The Institution is of the order of Societies that function centrifugally, and we can claim that it does a large amount of work unostentatiously and in co-operation with other bodies for objects to which it lends its support. Let us not fail in kindliness to those of our

* The technical part of the address (not included in this extract) described the handling of three special problems in metering.

own members who have fallen on evil times. We have been criticized as a body for our inability to advance the material interests of our members, and in spite of all modern tendencies we have, through sheer weight of tradition, resisted the temptation to become protective in character. If we are frank we must admit that under existing conditions this can be a handicap in individual cases but, in promoting the advancement of electrical engineering science, the Institution does indirectly foster the interests of the electrical engineer. But that does not denote any question of the reality of its ethic of "service" implied in its constitution.

It would be absurd to suppose that its members are not influenced by prevailing currents of feeling and ideas, and that it is sterilized of all forms of self-interest, so it does well to remember and preserve its best traditions. Very rightly then does it cherish the memories and aim to do justice to the fame of men of exalted character and outstanding genius, such as Faraday, the founder of the science, and Kelvin, and foster genius from the romantic age of early discovery to the maturer period of practical application.

Kelvin, the centenary of whose birth was recently celebrated, was a man of extraordinary versatility who worked in the whole field of physical science, but is it too much to claim that his greatest contribution to the service of mankind was through his work as an electrical engineer? In this connection one feels that it would have been fitting had the Kelvin Centenary been marked by a public celebration in every Centre, organized in the name of the Institution. I mention this, not by way of retrospective criticism, because it is well known that in the crush of other work and events with which the Institution was deeply engaged it was impossible to arrange for a more extensive celebration: the point I wish to bring out was that the lives of these men symbolize the underlying spirit of the Institution, and we should be mindful of this.

I think it is a matter of general agreement that the Institution should be better known amongst all thinking sections of the public, who, if they are aware of its existence, merely regard it as a body responsible for keeping a register of qualified electrical engineers. We ourselves are apt to forget the great work accomplished by the Institution in the past. It is no exaggeration to say that it was the sheet anchor of electrical engineering and the chief source of inspiration to those engaged therein for a long period when lighting and power development was struggling against archaic legislation.

It would appear that the time is ripe for someone to write the history of the Institution of Electrical Engineers. There is a wealth of material waiting for such a volume, and what a gallery of portraits of pioneers in the most fascinating period of discovery and invention in history would be contained within its pages!

Intrinsically the Institution is richly endowed with possibilities of impressing its character on the minds of those who will take a leading part in the period of reconstruction which ultimately must follow this difficult and distracting time of industrial rehabilitation.

Within its confines are men in divers positions, leading and subordinate, engaged in administrative, managerial, and business, as well as technical affairs, all more or less in direct contact with industrial problems. It is to such as these, trained to methodical investigation, and, moreover, capable of practical judgment, that we should look for some contribution to their solution. Evolved through a century of discord and misunderstanding of fundamental causes, the problems cannot be treated successfully by mere palliatives. The political atmosphere with which they have been surrounded must be removed and they must be dealt with on social and economic lines by those actually engaged in the industries. It is a matter of practical rather than theoretical consideration.

As an educational body, I believe it is within the scope of the Institution to take its part in this connection. Amongst the list of subjects that can be taken for the Associate Membership Examination is "Works management," and I suggest that to this might be added "Economics and industrial organization." A student destined to fill an important position in either the supply or manufacturing side of the industry would be infinitely better equipped for his future work and advancement if he possessed a knowledge of the design and objects of such machinery as exists for the adjustment of the differences and relationships between employers and employees. He should know something of the history and development of trade associations from the Hanseatic League to the B.E.A.M.A., and also of the origin and history of trade unions. He would, when the time came to take a hand in these matters, be properly fitted for it. Such knowledge, so far from creating in him the perilous fervour of the industrial propagandist, would induce a wholesome interest in industrial affairs.

I think it was Mr. Wordingham who said that the Institution ramifies and is bound up with the electrical industry. It cannot, therefore, hold aloof from those problems of human organization which are the concern of and affect a large proportion of its members. To these let it, if it can, be a source of instruction and guidance as undoubtedly it can be a source of inspiration.

The sixth year following the close of the European war has been of unique interest to every sort of worker in the electrical industry. The coming into power of the first Labour Government, the British Empire Exhibition, the World Power Conference, the wages dispute in the electrical industry—all these constitute a recital almost dramatic in form, and the relative prosperity of the electrical industry can at least give us one pleasurable thrill of self-satisfaction. The general outlook, however, is far from encouraging; trade depression persists and unemployment remains an unsolved problem. It is now almost universally accepted that these are the war's inevitable after-effects and must be endured. But in spite of this the deplorable fact remains that our industries have not settled down to a united effort to get to grips with their difficulties. Industrial peace still remains a dream apparently beyond realization, and no industry, prosperous or dying, can claim entire freedom from the possibility of interruption by strike or lock-out. The materialism which possesses the national soul, and the extraordinary spread of the spirit of combination permeating all classes of the community, are the

principal factors in a fierce movement towards fostering sectional rather than public interests. In the conflicts between trade unions and employers' associations the evil effects of the movement gain their chief publicity. But an equally serious, if a less conspicuous, resultant, is the multiplicity of trade organizations that are too prone to extract from the community such rewards for their services as accord with their own valuation. In the Articles of Association of even the most predatory of societies, doubtless there will be found aims and objects of altruistic design. It is the suppression of the better part of their purpose that constitutes the leading modern error of many such societies. Self-interest cannot be eliminated from human nature or from human institutions, but it can be directed to useful and beneficent ends. Indiscriminately exercised, it induces violent reactions and opposition and leads to recurring dislocations, in the adjustment of which the factor of satisfaction is a negligible quantity. One cannot help thinking that herein lies one of the greatest and most urgent problems of our day.

Another matter of grave concern is that eternal kink in the relationships between employers and employees which is still as pronounced as ever. It is the business and public duty of both to straighten this out. It originated with the introduction of the factory system and the inevitable estrangement between the two partners in production. The working class never forgave it and it became a rooted memory which, in process of time, has developed into a collective attitude. It is a psychological phenomenon which, like political antipathies, tends to persist long after the fundamental causes have been removed. Those who wait for the demise of the capitalist system, as well as those who look to the time when the forces of labour will have been spent, are merely shirking the problem. The solution must be sought at the point of origin, namely, the factory or its equivalent. Many devices have been tried, from cold scientific management to sheer benevolence. Doubtless, Arcadian conditions of employment could be instituted by rate aid or subsidy on the benevolent plan, but this would not be the act of a model employer, neither would it create the model employee. Of the recommendations in the Whitley Report, probably the most valuable was that for the formation of works committees fully representative of management and employees, for here was suggested a simple and practical means of getting down to the bed-rock of the problem. Their aim—and this is what really matters—is to establish goodwill between employer and employee. Perhaps I can express this better by saying that free discussion and frank expression of the mind of both will help to remove those obstacles which create misunderstanding and intercept the natural flow of goodwill.

Works committees can and do materially promote the comfort of the worker, and the benefits derived from them are cumulative and permanent. They should form an integral part of works organization and should be backed by all the administrative machinery to carry out their recommendations efficiently and promptly. The electrical industry has grown to a stature to be counted amongst the great industries of the world, and it is certainly the most modern. It is therefore demanded of it that it should aim at being the best organized industrially. The recent threat of a general stoppage in the electric supply industry was a reminder that we have not yet reached security in this respect. It is a matter of deep concern to every one of us, and the fact that it appears to be beyond our control does not relieve us of the responsibility of giving thought to it. The fetish of collective action, and its narrow limitations to the securing of rewards for services, has resulted in a partial suppression of the sense of personal duty and responsibility, neglect of individual values and loss of faith in individual opinion. We are all in danger of developing into the type of person who has been described as "knowing the price of everything and the value of nothing."

I have spoken of the prosperity of the electrical industry—I think a better word would be "advancement." Advancement does not necessarily denote prosperity; it has always to be paid for, and the era of high wages and large profits can hardly be said to have arrived. The early half of the nineteenth century was, through the introduction of steam power, a period of enormous advancement in manufacturing, but it was anything but a prosperous one to the worker. Moreover, we are faced with severe competition, and competition always means cut prices from older interests. That this is becoming more intense is evident by the campaign in the Press, designed to single out and advertise the weak spots in our armour. We are aware that we have more fields to conquer and that we cannot always compete with raw and semi-raw fuels but, confident in the knowledge that our product in use is the most convenient, adaptable and healthful, and therefore the most scientific, we have nothing to fear.

The question of the nationalization of the electric supply industry has recently appeared on the political horizon. We are all familiar with nationalization in actual working, but at the present time the question is confused with so many crude theories of ownership, of the means of production and industrial control, that it cannot be said that public opinion is ripe for legislation of this character. In any case no industry can be said to be ready for nationalization until it is prepared as a whole to accept all the obligations of national service.

NORTH-EASTERN CENTRE: CHAIRMAN'S ADDRESS

By W. T. MACCALL, Member.

"ITEMS OF INTEREST, AND INSTRUCTION."

(ABSTRACT *of Address delivered at* NEWCASTLE, *27th October,* 1924.)

(I). GENERAL.

ELECTION OF COUNCIL.

Owing to well-known objections to the former method of election of the Council of the Institution a new scheme is in operation, but it has its drawbacks. Members will be more reluctant than in the past to make independent nominations, as is evidenced by the fact that last session was the only one of the last five or more in which no such nomination was made. The apparent reasons are, first, that such nominations seem now more like a vote of censure on the Council, and, secondly, that the probability of the election of an independent candidate is smaller than before. The dangers are that election to the Council will be restricted to those members who are known to the Council, and that ordinary members, having merely a formal part in the election, will lose interest in the composition of the Council. This will lead to dissatisfaction and possibly to loss of membership.

An improvement would be to retain the present method of nomination and to change the method of election to that of proportional representation by the single transferable vote. This would enable any section consisting of about one-sixth of the voters to secure the election of a particular member, and would ensure the fairest possible result in any contested election. Further, it would increase the number of voters. At present many are deterred from voting because they do not know a sufficient number of the candidates. Under proportional representation the voter may limit the expression of his preferences to the candidates he knows well; and this neither wastes his vote nor gives him any advantage over a voter who expresses a wider choice.

Those not acquainted with proportional representation may suppose that it is very complicated; but this is not the case. The method of counting the votes is certainly a little more complicated than the present system, but anyone can easily understand and carry out the counting after a quarter of an hour's instruction.

POWER SUPPLY.

A somewhat disquieting event of the past few months is that electrical power supply has become politically popular. This is to the good if it leads to more rapid development; but I trust that electrical power in reality, like foreign policy in theory, will remain outside party strife. Otherwise, electrical development will be retarded while politicians wrangle about some subject which should be left to electrical engineers.

Among events of particular interest to this Centre was the permission granted by the Electricity Commissioners to the Newcastle Electric Supply Co. to earth their system at several points. This was done after tests by engineers of the Post Office and of the power company in co-operation had shown that no harmful effects followed, provided that the earthed points were on the primary windings of transformers with delta-connected secondaries.

The raising of the line pressure for underground networks from 22 kV to 33 kV is being tackled by British mains engineers with little guidance from outside sources. The present methods of jointing appear scarcely adequate for the increased stress. It is evident that either now, or before the next rise in pressure is carried out, a radical improvement is essential in either the materials or the art of jointing.

The manufacture of the cables presents no special difficulty, nor is the pressure yet high enough to make intersheaths or similar schemes commercially advantageous; but it cannot be far in the future before methods of this type will require very serious consideration. It is therefore very unfortunate that our knowledge as to the conditions determining the breakdown pressure of a cable is extremely uncertain. It would be easy to devise experiments which would throw considerable light on this obscure region at a cost which would be small in comparison with its importance. I suggest that the Institution should co-operate with the cable makers and set up a Committee on the lines of the Buried Cables Research Committee, to investigate the criterion determining breakdown in high-pressure cables. The main points suggested for investigation are:—

(i) Is the criterion of breakdown in cables

(*a*) the maximum dielectric stress (voltage gradient);
(*b*) the dielectric stress at a radius $0 \cdot 368$ ($= 1/\epsilon$) of the outer radius of the insulation;
(*c*) the loss due to dielectric hysteresis;
(*d*) a combination of two of these;
(*e*) some other cause?

(ii) If the cause is found to be (*c*), (*d*) or (*e*) above, do the methods of construction and laying of cables which assist the dissipation of heat increase the breakdown voltage as well as the carrying capacity of the cables?

It can be shown mathematically, by making certain reasonable assumptions, that the dielectric-leakage loss on reaching a certain point will increase without limit and so must cause breakdown; and further that, whereas the heat conductivity of the dielectric largely

affects this critical point, alteration in the facilities for dissipating heat outside the dielectric affect the critical point only indirectly, and probably to a very small degree. But the assumptions, however reasonable, are insufficient as a basis for design until checked by experiment, as is shown by Preece's so-called "law" for fuses, which is based on mathematical proof from reasonable assumptions, but is inaccurate in fact. And the alternative rule for fuses ($I \propto d^{5/4}$) proved mathematically by Dr. Alexander Russell, though closer to the facts in many cases, requires considerable modification to bring it into good accord. Mathematical reasoning, on the other hand, does provide a basis for experiments designed either to confirm or to confute the assumptions on which it is based.

Has not the development of power supply arrived at the stage for the general use of the terms "megawatt" and the "megawatt-hour"? Magnetic flux is sometimes stated in megalines, and all are familiar with the megohm; then surely it is better to speak of turbo-alternators as of 20 megawatts (or MW) than as of 20 000 kilowatts (or kW), and of a daily output as, say, 583 megawatt-hours (MWh), rather than as 583 000 kilowatt-hours (kWh). Apart from the saving of time and space, there is a further advantage in the fact that it lessens the temptation of stating the latter quantity as, say, 583 172 kWh, although anyone at all familiar with metering knows that the last three figures are meaningless.

Ex-Enemy Candidates for Membership.

Another suggestion—about the present reception of which I have greater doubts, though not as to its ultimate consideration—is that the time has arrived for the withdrawal of the prohibition of membership of the Institution in the case of all citizens of ex-enemy states. I do not suggest that all such should be admitted on their electrical engineering qualifications without any regard to their nationality, but that it should be within the discretion of the Council to recommend them for election in suitable cases. In favour of this step I urge that "one cannot indict a nation," and however strongly one holds that some Germans, Austrians, Bulgarians or Turks were guilty of the terrible suffering and loss due to the war, it is un-English to penalize all members of those nations for all time. In this connection, it is relevant to point out that many who were citizens of the ex-enemy nations are no longer so, owing to changes in the frontiers. Of two electrical engineers living a few miles apart and of exactly similar antecedents one may, owing to a frontier intervening, be eligible for membership and the other ineligible under the present rule.

Tariff Dependent on Power Factor.

Arnò proposed a tariff for the encouragement of high power factors by charging on the "complex load" (defined as two-thirds of the kilowatt-hours plus one-third of the kilovolt-ampere-hours). By adjustment of the phase difference in an energy meter this "complex load" can be measured with reasonable accuracy over a fair range of power factors. My suggestion is that this method be used, since it requires no addition to the usual meters, but that the term "complex load" be omitted in the statement of the tariff. It would still have its use in deciding on the phase difference. The tariff could then be stated as in the following example:—

Charge at a power factor of 0·7 to be *n* pence per kWh.
Bonus for power factor of 0·8 to be 4 per cent.
Bonus for power factor of 0·9 to be 9 per cent.
Bonus for power factor of unity to be 15 per cent.
Penalty for power factor of 0·6 to be 5 per cent.
Penalty for power factor of 0·5 to be 11 per cent.

All these bonuses and penalties would require no calculation beyond multiplying the reading by *n* pence, the meter automatically changing its registration according to the power factor. The values of the percentages could be altered by changing the phase difference in the meter. The standard power factor at which the meter registers true kilowatt-hours could be altered by changing its gearing. The testing of the meters would be rather more difficult than with the standard pattern, but not seriously so.

The main obstacle appears to be the doubt as to the legality of basing charges on the reading of a meter of this type. The Electricity (Supply) Act of 1922, however, enables supply authorities to apply for sanction to be given to other methods of charging than those now allowed.

(II). INSTRUCTION.

Definitions.

This section might be termed "Education," but "Instruction" has been preferred as being wider in some ways though narrower in others. The Education Committee of the British Electrical and Allied Manufacturers' Association in their Report published in 1920 define "education" as "individual development through intellectual, moral, and physical instruction," and say that "the word 'training' is limited in sense strictly to practical instruction in the shops." "Instruction" therefore covers both education and training.

It is of some importance to define the terms used. The word "training" is used in a wider sense than the B.E.A.M.A. Committee's definition; in fact it covers even more than "instruction," by the inclusion of such things as the parts of collegiate life outside definite instruction. If I do not adhere to the meaning stated, I shall err in good company. For in the B.E.A.M.A. Report two lines below the definition of "training" this word is used in its wider, more general, sense.

The diversity of the methods of instruction in actual operation is due in a large measure to the diverse results desired in the finished product. The B.E.A.M.A. Committee's Report divides apprentices into four classes, viz.:—

(*a*) Trade apprentices, who will become skilled workmen, foremen, etc.;
(*b*) Engineering apprentices, who are trained for the drawing office, test-room, etc.;
(*d*) Student apprentices, who are trained for senior positions in the drawing office, etc.; and
(*d*) Research apprentices.

These definitions should be borne in mind in connection with quotations from this Report, which is a very valuable piece of work, but would have been even more so if the Committee had included a full-time technical (as distinct from university) teacher.

Preliminary Training.

Up to about 11 years old the choice lies between the (public) elementary school and a private school. I consider that for engineers the greater advantages are with the former. These consist in making the acquaintance of boys of a great variety of types, and in the (usually) more efficient "instruction"; while those of the private school are the socially higher class of the boys, and the (doubtfully) better "education." There is much to be said for the general Scotch and American practice of common elementary schools for all classes.

received a college training, the figures for England being:—

Year	Men	Women	Total
	Per cent	Per cent	Per cent
1913–14	74	54	60½
1919–20	75½	62	66
1921–22	78	65½	69

At the age of about 11 years the majority of the private school pupils will pass to a secondary school (see Fig. 1). This will also receive pupils from the elementary school, some by means of scholarships (known as "free places"), others paying the ordinary fees. The bulk of the elementary school pupils will continue therein until 14 years of age or a little over.

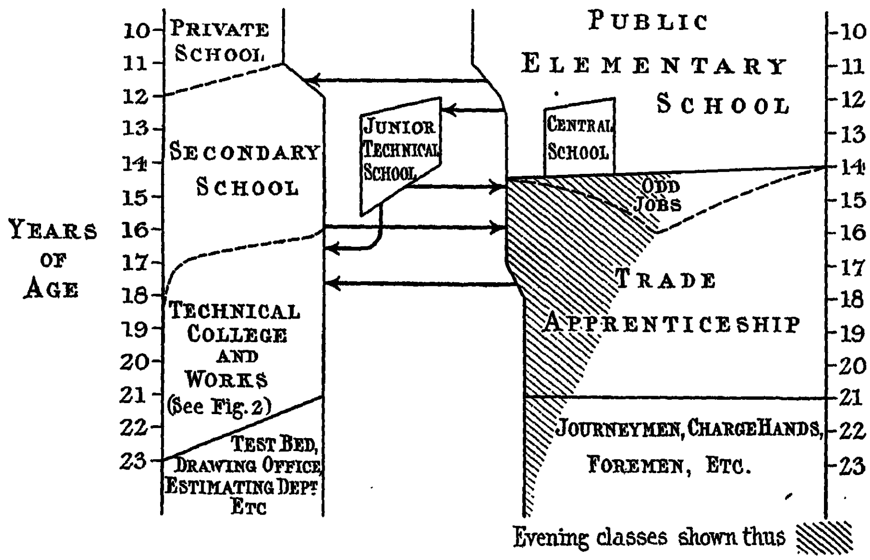

Fig. 1.

As regards trade apprentices, the following quotation from the B.E.A.M.A. Report gives the main point; others occur incidentally. "The general education of trade apprentices should consist in an equilibrium between intellectual studies and practical activities (including organized games) so arranged as to encourage the growth of civic and social ideals. It should not be specialized with respect to practical studies, trades or hobbies, but should be directed towards the development of human beings of character and intelligence. In choosing subjects . . . those might be selected which will enable a sound foundation to be laid for subsequent vocational training."

The Report refers also to the insufficient training of teachers. This is being gradually improved, the percentage of certificated teachers out of the total of about 150 000 in public elementary schools in England having increased from 68 per cent in 1913–14 to 71 per cent in 1919–20, and to 72½ per cent in 1921–2. Moreover, an increasing percentage of these certificated teachers has

Fig. 1 does not attempt to show the percentage taking secondary education, but the following figures for all boys will give a probable percentage for budding electrical engineers. In 1922, in England, there were 543 149 boys between the ages of 12 and 14 in elementary schools, and about 129 000 between the ages of 12 and 16 in secondary schools. There was therefore about 11 per cent of the total in secondary schools. Of those leaving the elementary school at 14 years of age most will start their trade apprenticeship at once or after a period as errand boys, etc. Their other source of training will be in evening and correspondence classes. A few will have a longer schooling through transferring at about the age of 12 to a junior technical school, and still fewer by entering a secondary school.

There are great differences of opinion as to what the work of the junior technical school should be, and also large differences in the actual work of existing schools. For the moment it is sufficient to say that a junior technical school is not a trade school, and is something

between that and a secondary school with a technical bias.

The junior technical school course lasts two or three years. On its conclusion the majority of pupils will become apprenticed and complete their training in evening classes. The expectation (which is confirmed by experience) is that the pupils of the school will, before the end of apprenticeship, usually outstrip those from elementary schools. The former will thus qualify for positions requiring greater technical knowledge or entailing more responsibility. The best of the junior technical school pupils should be able to obtain and to profit by training of a higher type.

Nearly all the secondary school pupils take some form of higher training, but a few become apprentices and receive only evening-class instruction. On the other hand, a few of those apprenticed soon after leaving an elementary school will succeed later in obtaining higher training inclusive of day classes.

These various courses are indicated by the arrows in Fig. 1. There are, however, two main streams, viz. :—

(a) Elementary school followed by (trade) apprenticeship accompanied by evening classes;

(b) Secondary school followed by technical training, at least partially in day classes.

Higher Training.

Methods of day-class training may be divided into two main groups :—

(I) Those in which the whole of the academic instruction is given continuously (apart from vacations), the course covering three years normally;

(II) "Sandwich" systems, in which the academic and workshop parts of the instruction occur alternately.

Fig. 2, I (a), (b), (c), shows the subdivisions of group I according to when the three years' academic course is taken. I (c) combines most of the advantages of the other two, and so is superior to either of them. This opinion was supported by the Institution of Civil Engineers and by the B.E.A.M.A. Committee. They say: 'It is becoming increasingly customary for boys to have a year's experience of a suitable training course in a Works before proceeding to a university. This enables each boy to find out where his interests lie, and it establishes a connection between the youth and the Works which may subsequently be mutually advantageous. After such a period the college course is followed much more intelligently."

The sandwich systems also have three subdivisions [see Fig. 2 II (a), (b), (c)] according as the length of the continuous period of academic instruction is :—

(a) a year; (b) five or six months; (c) a few hours.

(a) This is the Faraday House scheme, a four years' course with the first and third years in works, and the second and fourth years at college. The students have usually stayed longer at school so as to cover the mathematics, physics, etc., of the more usual courses.

(b) In this there is a preliminary year or more in works, followed by four (sometimes less) years of which part is spent at college, the rest in works. Examples are the Sunderland Technical College with four 6-month periods (October to March); Rutherford College, Newcastle-upon-Tyne, with three or four 5-month periods; Sheffield University, with 2-year and 3-year courses; and for railway engineers, Darlington Technical College (5 months); and for mining engineers, Treforest School of Mines (6 months).

(c) In this from 3 hours to 12 hours (normally 8 hours) per week are spent in day classes, combined with evening classes on two or three evenings a week. This type of course is often carried out in works schools, but also in technical schools, e.g. the Woolwich Arsenal Trade Lads scheme. It is usually of the trade-apprenticeship type, i.e. a modified evening course rather than a sandwich day-course.

Another course which may be considered to belong to this group is that in which the college supplies all the practical instruction, as well as the technical part, and possesses workshops run on commercial lines. This system is attractive at first sight but has many draw-

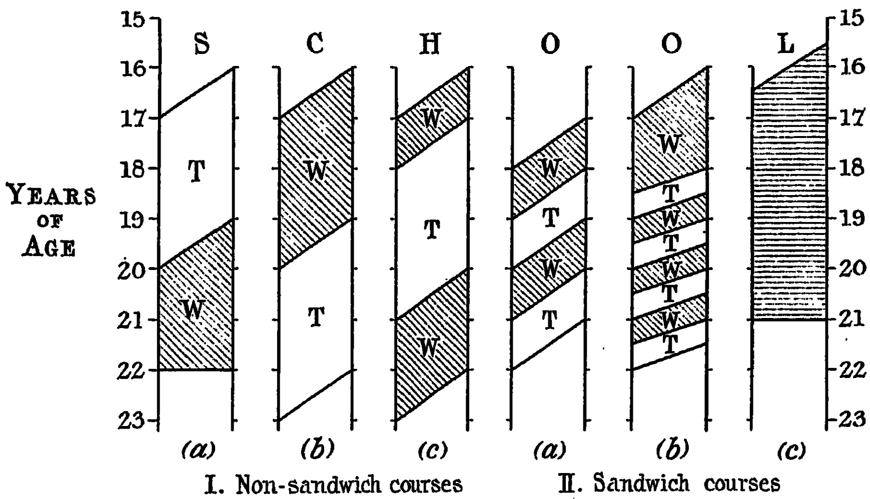

Fig. 2.—Courses of technical instruction. T = technical college; W = works.

backs, e.g. the difficulty of keeping equipment up-to-date and the working really commercial; and the natural objection of the owners of works to the subsidized competition of the college.

The advantages of the sandwich system are that the alternation of the two types of training increases the value of each of them. The workshop training makes the college work more interesting to average students. On the other hand the college instruction shows the reasons for many workshop practices. The disadvantages for the students lie in the tendency to attempt too much in the time available. The best length for these periods depends partly on the capacity of the students, partly on the rapidity with which they can adapt themselves to the changes in the type of instruction (college and workshop), and partly on the suitability of the periods for the workshop organization. As far as the first two are concerned, my preference is for type II (*b*).

Just as there is excessive leakage in a transformer if the windings are not sandwiched, so there is a loss of benefit in a course in which the whole of the college instruction is concentrated into three successive years. Sandwiching diminishes magnetic leakage, and similarly improves the course of instruction by making closer the interaction between the academic and workshop portions (I refrain from particularizing as to which of these two corresponds to the "primary" and which to the 'secondary" of the transformer). Again, the greater the extent of the sandwiching the greater the reduction of magnetic leakage, but if this is carried too far there is excessive loss of winding space and increase of cost due to the additional insulation needed. This corresponds to the loss occurring in courses of instruction in which sandwiching is carried too far, due to the time needed for adaptation when changing from one type to the other (college to workshop and vice versa). Whether six months is the optimum length for college periods is a matter of opinion, but I have little doubt that it is close to the best value.

That technical teachers are in favour of the sandwich system is shown by the unanimous passing at the 1924 Annual Conference of the Association of Teachers in Technical Institutions of the following resolution: "That this Conference, considering the need for extended technical training in the development of industrial processes, desires to express its conviction that immediate steps should be taken to develop and extend sandwich systems of training for boys preparing for industrial careers, and urges local education authorities and Industrial Organizations to co-operate in providing the facilities required for joint technical and industrial training."

Curriculum.

Early training is almost necessarily general, specialization amounting only to the difference between the classical and "modern" sides of a public school. Even when greater specialization is possible it would not be desirable to make the training of engineers different from that of non-engineers at this stage.

The case of Oundle School is not really an exception to this statement. In its equipment are included metal and wood workshops, an engineering laboratory with gas, oil and steam engines and a turbine, pattern-makers' shop, forge, foundry, and a metallurgical laboratory. It contains, however, in addition a biological laboratory, two farms, one purely experimental of over 30 acres, the other of about 100 acres, and gardens, and also the usual laboratories. This equipment was not obtained for the purpose of producing skilled engineers or biologists or farmers, but to give each boy the fullest opportunity for development.

A very brief summary (largely in his own words) follows of the aims of F. W. Sanderson who established Oundle in its present form.

Boys at about 15 begin science with an informal, mainly experimental, course to learn "to do things and to take pleasure in this." First, applied mechanics; later, chemistry, biology, or geology. Next year, pure physics and mechanics are introduced similarly, and then a more regular course of applied science. In heat the steam and gas engines form the basis of instruction.

In the workshops Sanderson insisted that boys come to school "not to learn but to do." They were to be "the home of creativeness." Their primary object was to give the boys the opportunity to do constructive work for the community, not exercises devised for instruction. The operations inculcate accuracy and attention, in place of teaching these by courses of practical measurement. The workshops and laboratories are open to the boys out of school hours.

"Applied science is complex and apparently difficult, yet it has romance and mystery which appeal to youth." Moreover, "it is in direct contact with the ordinary life of the day." Again, "Science teaching must be alive, changing, moving forward. It should not have about it the atmosphere of certainty and finality."

And in his last lecture, at the end of which he died suddenly: "It is not difficult to see that a modern school is not created by abandoning ancient studies. Far from it. Nor by converting it into a technical school. If these alone are the changes made, the soil will remain much as it was. . . . A modern school is a school in which the spirit which we call the spirit of science permeates and changes all its methods, aims, and relative values. Such a school will endeavour to make the fullest use of all branches of knowledge and of all the faculties of all its members. It will have constantly in mind the welfare and development of all its workers; and its aim will be to do service for the community.

"The school will therefore have . . . a wealth of plant, apparatus, and opportunities for community work. . . . The usual school studies are really the tools, and class-rooms the tool-making shops, all directed towards the main purpose of the creative factory. It will soon be evident that methods of teaching are of very slight importance compared with the overwhelming urge to create and to do service and to master the necessary tools and their use. . . . We must send out workers imbued with the determination to seek and investigate truth—truth that will make them free—and to take great care that in the search for truth they will never take part in or sympathize with those methods by which the edge of truth is blunted."

There is the ideal; but let us consider the present state of things.

Most students entering an electrical engineering course from secondary schools have had an education including (i) a general English course; (ii) Latin, and possibly some Greek; (iii) French or German, possibly both; (iv) mathematics; (v) mechanics; (vi) geometrical drawing, and sometimes engineering drawing, but not design; (vii) chemistry; (viii) physics; (ix) manual training, usually woodwork; (x) physical training, including organized games.

The above is a bare skeleton on which may be built courses differing as widely as the members of the human race. Similarly the actual courses in British schools, though they have some family likeness, differ somewhat as the varied members of the British race. This variation lies partly in the relative amounts of time given to the different subjects, and partly in the spirit and standpoint of their treatment.

The B.E.A.M.A. Committee's recommendation on this point for engineering apprentices is merely "that boys who propose to enter the engineering industry should give special attention to the study of mathematics and science." This will be provided by any secondary school, and does not require a specifically engineering type of instruction; as is emphasized by the Committee in saying "Education obtained in those schools providing an engineering side cannot be accepted in lieu either of the practical training of the works or of higher technical training." And later, "The best foundation for any grade of industrial life is sound general education, entirely free from specialization in any form."

There will be no difference of opinion as to many of the subjects to be included in day courses, though there may be as to the amount of time to be given to them. These include (*a*) mathematics; (*b*) engineering drawing and design; (*c*) applied mechanics, merging into strength of materials, and structures; (*d*) physics, merging into electrical engineering, with the possible addition of heat engines; (*e*) chemistry, with an engineering bias.

These subjects with laboratory work occur in all electrical engineering courses, but the time given to them varies largely. Taking three B.Sc. courses at random the relative times are:—

Group.	Course A.	Course B.	Course C.
Mathematics and mechanics	$18\frac{1}{2}$	23	$27\frac{1}{4}$
Mechanical engineering	$20\frac{1}{2}$	20	25
Electrical engineering	30	31	24
Physics	9	$6\frac{1}{2}$	$9\frac{1}{4}$
Chemistry	5	$9\frac{1}{2}$	3
Languages	7	nil	$1\frac{1}{2}$

The figures are not percentages but total 90 for each course, corresponding to three sessions with 30 hours' work per week.

It would be easy to draw up a complete course including nothing but the subjects (*a*) to (*e*), which would give a reasonably varied training. Actual courses, however, include other subjects, e.g. hydraulics, German, estimating (or other commercial subject), industrial management, etc. Everyone agrees that a knowledge of these other subjects is useful; but the following facts must be considered:—

(1) Instruction, including laboratory and drawing classes, lasts for about 30 hours a week for three or four years.

(2) "Electrical engineering" alone, apart from design, is really several subjects, not one.

(3) Students are human.

What can be done to overcome these obstacles to the inclusion of additional subjects?

(1) (*a*) "Increase the hours per week." This would be worse than the ill which it attempts to cure. Students reading for the Cambridge Mathematical Tripos say "Five + one = six; but six + one = five"; i.e. not more than six hours per day can be employed usefully in study. In an engineering course with its greater variety owing to laboratory work, etc., this allowance may be increased, but the same principle holds.

(*b*) "Increase the number of years in the course." More can be said in favour of this, but a longer course would increase the number debarred from a full-time course by lack of means. This can be mitigated by scholarships and by reducing the length of the works training. If this is organized with the aim of giving real training rather than of obtaining cheap labour, and if the student is keen to profit by his opportunities, this reduction can be made without losing the value of the works training. The B.E.A.M.A. Report recommends the reduction of this to two years for student apprentices who are graduates.

(*c*) "Cut down the time given to some of the present subjects." The usual complaint is that the present time available is insufficient for thorough treatment, and many consider that it would be better to concentrate on a smaller number of subjects. In some cases time for extra subjects could be obtained by allowing a greater variety of choice in the last year of the course. This must entail increased expense, which the result may not justify. It is perhaps worth pointing out that in any reasonable course of design considerable reference to costs will be included, and this may be amplified instead of attempting separate classes in costing.

Some of those who recommend these extra subjects are thinking too exclusively, it seems to me, of their own particular branch, and not of electrical engineering as a whole. I am not saying that any or all of the above subjects should be excluded, but am merely pointing out that their inclusion must be paid for, and that, as in most engineering problems, it is a question of so balancing advantages as to arrive at the best solution.

Mr. Dempster Smith, Head of the Department of Industrial Administration in the Manchester School of Technology, said (1924): "A careful examination of the course of study usually provided in technical colleges of university standing leads to the conclusion that nothing can be cut out without detracting from the training." And he suggests an additional year for "a liberal introduction to this most interesting subject (viz. industrial administration) which the student can develop while receiving his practical training."

The second obstacle, viz. the multiplicity of the branches of electrical engineering, introduces similar considerations. It can be dealt with partially by increased specialization. But a student by no means always knows into what branch he will go: and when

he thinks he knows, the future often falsifies his expectations.

The third obstacle, that students are human, could be overcome by replacing them by Robots. But these would not require any education, so this possibility need not be considered. On the contrary, I endorse strongly the statement of the B.E.A.M.A. Report that "It is desirable that all engineering students . . . should enter into the full collegiate life, as the experience thereby gained is of real advantage in an industrial career."

Suggestions for Improvement.

Education up to 12 years old appears to be developing on sound lines; but from 12 to 15 years of age there seems to be need for a great extension of junior technical schools. In 1921–2 there were in England only 86 of these, with a total attendance of 10 302 boys; and only 34 schools had 3-year courses. Their work is supplemented by "central schools," which, however, are merely elementary schools confined to the higher classes and are not technical.

Most of the 2-year junior technical school courses should be extended to 3 years, and these might be continued longer, up to 16 years old. Alternatively, the year 15–16 might be a part-time course so as to make less abrupt the transition from school to works. The junior technical schools should be allowed to have courses suitable for boys preparing for matriculation. Even when a secondary school exists in the same district, most elementary scholars will be unable to attend it unless they win scholarships when 12 years old. Those who develop late ought to be given in the third year of their junior technical school course another opportunity of obtaining higher education.

The chief defect in secondary education also seems to be that there is inadequate provision for the numbers who desire it and would profit thereby.

The main principle of these suggestions is to increase the lateral fluidity indicated by the arrows in Fig. 1. To quote the B.E.A.M.A. Report again, "Greater facilities must be afforded for selecting and training that limited percentage which will be engaged in directing the work of others, or in prosecuting work of a highly technical character. The ability to carry out such work is not confined to one section of the population."

Anything which widens the area of choice is good, e.g. (*a*) increased provision of secondary education and of "free places," supplemented by maintenance allowances; and (*b*) further scholarships to higher technical institutions from secondary and from junior technical schools, the latter being contingent on the suggested permission to junior technical schools to give matriculation work.

These may be summed up as "more, and more varied scholarships (including maintenance) at every stage, culminating in research scholarships"; but with the corollary "greater precautions to prevent the waste of costly instruction on unsuitable students."

For the workshop training is needed a further extension of the practice of many manufacturers in affording suitable courses in works, including in this the extension of the sandwich system. Even if the provisions of the Education Act (1918) for courses of type II (*c*) is brought into general operation, the need will still exist for more sandwich courses of the higher type.

TEES-SIDE SUB-CENTRE: CHAIRMAN'S ADDRESS

By A. M. Paton, B.A., B.Sc., Member.

"THE PROFESSIONAL STATUS OF THE ENGINEER."

(Abstract *of Address delivered at* Middlesbrough, *13th November*, 1924.)

On such an occasion as this, it is the custom for your Chairman to deliver a short address on a matter or matters of general interest, without dipping too deeply into technical matters. New developments on Tees-side, with which I am principally concerned, do not, I regret to say, constitute a promising subject for an address. Bad times are responsible for the holding-up of a considerable amount of projected new work. Directors and managers are occupied with the problem of keeping their existing plants loaded, and have postponed contemplated extensions until better times arrive. Lest, however, we may be inclined to take too short a view of the present position, I may be excused for mentioning some encouraging words spoken by an eminent man of this district at a function at which I happened to be present. They were to this effect: "The best thing that manufacturers on Tees-side can do under present conditions is to keep their heads: the natural advantages of Tees-side must tell in the long run." We all hope that it may be true.

In the circumstances, I propose to say a few words on a subject which affects each one of us, and which is particularly in our minds at the present time, namely, the professional status of the engineer in Great Britain.

As a preface to my remarks, I would put the fol-

lowing words, which I came across recently in an American technical journal:—

"It is difficult to appreciate the cycle through which engineering has passed in the last two decades. Twenty years ago it was a profession more or less mysterious to the general public. Its work was associated largely in their minds with the building of bridges and viaducts. Its members were not known professionally to the average citizen. The functions of the mechanical engineer could not be described by the average man. The combustion engineer was unknown. The electrical engineer was an inventor, the most renowned amongst them being termed a wizard. To-day the men of this calling present as a whole the most definite profession in public life. They are recognized as the men in whose hands the material advancement of the race rests. They have gained a leading, if not the leading, place in the list of professions."

The last part of this extract is the part which to me is the most striking. If it truly represents the status of the professional engineer in America, as I believe it does, I think that we must recognize that engineers are more honoured there than they are in this country. Later, I shall have a few words to say as to their actual status.

I propose now to examine briefly the status of the engineer in this country, to contrast it with the status in America and Canada, and to offer some reasons for that status and also some suggestions for helping to raise it to the status which I maintain it ought to occupy. By way of introduction to the subject, we may first consider the meaning of the word "engineer." The word was originally a military term, like "charioteer," "musketeer," etc., and denoted one who managed military engines or artillery. Later it has come to denote one who manages or has to do with the construction or use of engines or machinery, or a person skilled in the practice of engineering, that is, the construction or use of engines or machinery, or the art of executing such works as are the objects of civil and military architecture, in which machinery is extensively employed.

It appears, then, that the title "engineer" has always denoted a person with superior knowledge or skill, primarily in military works, but latterly also in civil—in contrast to military—works. We electrical engineers are concerned with the civil side of engineering only, hence all my remarks this evening are confined to civil—in contrast to military—engineering.

The original and classic definition of a civil engineer occurs in the Royal Charter of Incorporation of the Institution of Civil Engineers, granted in 1828, that institution being the first and only professional engineering institution in existence at that time. As the definition may not be familiar to some of you, it is worth noting . . . "the profession of a civil engineer, being the art of directing the great sources of power in nature for the use and convenience of man." It is curious that this definition might have been framed for the electrical engineer—then of course undreamed of—so aptly does it describe his present functions.

Notwithstanding the enormous development in engineering which has taken place during the last half-century, and the corresponding increase in scientific knowledge which the engineer has had to acquire as part of his equipment for his profession, the title "engineer" has in this country never become a term of art in the legal sense; that is to say, any person may describe himself as, or practise as, an engineer whatever his qualifications or experience. It is therefore not surprising that the title is of no repute in this country. [Mr. Paton read a few cuttings from recent newspapers in order to illustrate the current abuse of the title "engineer."]

We may well ask ourselves whether there is not something amiss in a community which classes men, obviously of the worst type, as members of the same profession as ourselves and others who have spent years in acquiring the necessary knowledge and experience. There can be only one answer to that question. The next question then follows: How long is the community going to allow such a state of things to continue? I hold, and it is the object of my remarks this evening to show, that we engineers in the true sense of the word must not be content until the title "engineer," or at any rate some simple modification such as "registered engineer" or "professional engineer," is so established by law that the community will regard it in the same way as they now regard the titles "registered medical practitioner," "solicitor," etc.

Next let us see what has been done in the desired direction. On the broadest lines which I have suggested as being desirable I do not know of anything having been even attempted, and it is only since the war that less ambitious attempts have been made. These have succeeded as far as they have gone. The first steps of the kind were taken in 1919 by the Institution of Civil Engineers, who proposed to introduce a Bill in Parliament reserving the title "civil engineer" to its corporate members and others coming within the scope of that title as defined in the charters of the Institution, and interpreted in their broadest sense. Under that Bill all "civil engineers" would have been registered, and only those so registered would have been entitled to describe themselves as "civil engineers." The objects of the Bill were, however, found to be unattainable, largely, I believe, to the title "civil engineer" being so broad as to affect other Institutions who considered themselves inadequately provided for. The Bill was therefore not proceeded with. In 1922 the same Institution obtained its second supplementary Royal Charter, leading to the establishment of the title "chartered civil engineer" for its corporate members in 1923. Similarly our Institution obtained its Royal Charter in 1921, and the similar title "chartered electrical engineer." As I understand the wording of the bye-laws governing the use of these titles, the title must in every case be preceded by a designation of the class in the Institution to which the user belongs. In other words, it is not in order to use the title "chartered electrical engineer" without the preceding letters M.I.E.E. or A.M.I.E.E., as the case may be. These somewhat

cumbrous titles then may be taken to indicate the present difficulty of establishing such simpler titles as "civil engineer" or "electrical engineer." So far as I am aware, these are the only steps of the kind which have been taken in this country.

The Institution of Mechanical Engineers has not yet proceeded on similar lines, because it is of opinion that the principal advantage of a Charter is one of sentiment, and is balanced by the cost and the difficulty that arises if variation of the constitution or bye-laws should be required. This view appears to support my own, that although the recent achievements constitute a big advance in the right direction they are not to be regarded as final.

Next it is interesting to compare the legal status of chartered engineers (in which term I include chartered civil engineers and chartered electrical engineers, for simplicity) with that of the members of other professions. These professions which are at all comparable with our own appear to me to fall into two classes. The first of these includes the older professions, of which the medical practitioner and the solicitor are typical; and the second the newer professions, of which I regard chartered patent agents, architects and surveyors, accountants and secretaries as typical.

Acts of Parliament provide for the control of the older professions, and for the registration of all persons qualified to practise. In addition, the solicitor has to provide himself annually with a certificate entitling him to practise. These Acts provide fines in the case of any person falsely pretending to be qualified or registered. Thus falsely to pretend is therefore a criminal offence which can immediately be stopped. A qualified but unregistered medical practitioner may practise, but cannot recover by legal process any fees, nor hold an official appointment, nor sign any certificate required by Act of Parliament. To all intents and purposes, therefore, registration is necessary for the purpose of practice.

Chartered engineers are of course not regulated by Act of Parliament, and have not any legal advantage over any other person in respect to the recovery of fees, the holding of official appointments, or on any other material point. Further, it would appear that, if any person were falsely to pretend to be a chartered engineer, that would be a civil and not a criminal offence. To stop this, the Institution concerned would apparently have to apply for an injunction in restraint of the wrongful use of the title reserved to its members. This would be a complicated process in comparison with the simple recovery of a fine instituted by Act of Parliament.

In trying to assess the relative necessity for the legal establishment of the medical and the engineering professions, it might be argued that the medical is the more necessary of the two because the work of a medical man may often affect the life of his patient. This is a very strong argument. To meet it I could only suggest that a mistake on the part of the chartered engineer might have more serious consequences to life than that of the medical man. The former might involve the loss of many lives—take, for instance, a wrongly designed flywheel or bridge—whereas the latter as a rule involves only one life. On the whole, there is no getting away from the fact that medical registration is a very necessary procedure for the protection of the public.

The case of the solicitor differs from that of the medical man and the engineer in that the practice of his profession does not involve any danger to life. On considering the arguments, I have not been able to find one leading to the conclusion that the registration of solicitors is more necessary than that of chartered engineers.

Since registration is a necessary procedure in the control of a profession by Act of Parliament, I may perhaps explain the mechanism of medical registration. This is in the hands of the General Council of Medical Education and Registration established by Act of Parliament in 1858 in order to secure a minimum uniform standard of qualification amongst medical practitioners trained at different places. It consists of representatives elected by the training bodies, the Crown and the medical profession. Any person possessing the necessary qualifications is entitled to be registered by the Council on payment of the prescribed fee. Once a year the Registrar of the Council is required to publish a list of the names on the Register, as those entitled to practise. The Council deals with all cases affecting professional conduct.

We chartered engineers must recognize that the measures which I have outlined have been singularly successful in the case of the medical profession, and the principal factor in guiding that profession into the high position of efficiency and esteem which it now occupies.

Apart from the advantages which members of the older professions enjoy in respect of their practice, they are not required to serve on juries. There seems some ground for this in the case of medical men, but none in the case of solicitors. Legal luminaries so often descant upon the privilege of serving one's country as a juryman that it is surprising the legal profession do not set others the example in this respect. In this matter of public service I am sure that chartered engineers are willing, however inconvenient it may be to them, to do their duty.

The only one of the newer professions on which I have to make any comment as being on a different status from our own is that of patent agent. This profession is established by Act of Parliament on similar lines to the older professions. This case seems to me to create a hopeful precedent for engineers, which I need not trouble to elaborate.

I trust that by the foregoing examples and remarks I have established the case for the ultimate control of our profession by Act of Parliament on similar lines to the others I have cited. That such legislation is not an idle theory, and that without it we are lagging behind other countries, I hope to show by outlining what has been done in Canada and the United States in this respect. [Mr. Paton then read extracts from Acts passed in 1920 in the provinces of Alberta and British Columbia and also similar legislation in the United States to establish the engineering profession.]

I now pass on to suggest a few reasons for the

existing status of the engineer, and to offer a few suggestions to influence us in our efforts to obtain our rightful status. The reasons which I would suggest fall into two groups :—

1. Those without the control of the engineering profession ; and
2. Those within that control.

In the first group I put the following reasons :—

(a) Natural conservatism of the British public.
(b) Ignorance of the Government, the administrative classes, and the general public on scientific matters.
(c) Lack of tradition in the engineering profession.

In the second group I put the following reasons :—

(a) Apathy of the engineering profession.
(b) Lack of unison amongst the engineering profession.
(c) Insufficient participation by the engineering profession in public affairs.

1(a). *Natural conservatism of the British public.*—In endeavouring to account for the existing status of the engineering profession, I have come to the conclusion that the natural conservatism of the British public is one of the factors which have had a retarding effect upon that status. This conservatism acquiesces in the conditions of the past and refuses to adapt itself to new conditions.

I think it unquestionable that the British public has not yet taken the trouble to recognize that there is such a thing as a profession of engineering, and will not do so until compelled by force of circumstances. As an instance of that conservatism, there has in the past been a feeling amongst the leading families in the country that to be connected with trade is *infra dig*. Since engineering cannot be practised apart from trade, that to some extent comes under the same category. There could not, of course, be anything more false or injurious, because trade is the life-blood of the country, and everybody in it is, to a greater or less extent, dependent upon trade. Nevertheless, the feeling which I have indicated has tended to prejudice the status of the engineer by directing a steady flow of recruits from those families into the church, the army and navy, law, medicine and the civil services in preference to engineering. In these circumstances it is not surprising that the status of the engineer is not so high as it ought to be.

Having classed the conservatism of the public as a reason beyond the control of the engineering profession, naturally I can suggest no remedy beyond the lapse of time. I think, however, that each individual engineer can do a little to help matters. In the first place, he can by his personal example show the general public that he is a man of high culture and ideals. In the second place, he can use his influence to induce the best young men, in every sense of the word, to enter his profession.

1(b). *Ignorance of the Government, the administrative classes and the general public on scientific matters.*—Arising to some extent out of the conservatism of the British public, I now come to probably the most vital reason, which is the ignorance of the Government, the administrative classes and the general public on scientific matters. Governments have recently arisen and fallen with such rapidity that it has been difficult to keep track of their individual members. It is, however, a fact that a few years ago there had only been one trained scientific man in the British Cabinet for the previous 100 years.

The administrative officials of the country have been for the most part appointed by examinations in which science has played an almost insignificant part. Consequently the public and other schools of the country have been accustomed to frame their curricula to suit the examinations, almost to the exclusion of scientific subjects. Hence it has come about that recently 34 out of 35 leading public schools had classical men as headmasters, and not one a scientific man. In these circumstances it is only to be expected that the officials and civil servants recruited from these schools have little knowledge of, or sympathy with, scientific matters of any kind, not to mention the scientific profession of engineering. If there were any doubt on this point, which I think there cannot be, reference to the periodical honours lists issued by the Government of the day will show the relative value placed upon the public services of the engineer in comparison with those of the navy, army, administrative, civil and diplomatic services.

Here, again, is a state of affairs which only time and increasing knowledge and appreciation of modern conditions can cure. I think that knowledge must inevitably come quickly, for, if this highly organized and densely populated country is to continue to occupy its present position amongst the nations of the world, it can only do so by conducting all its affairs on a truly scientific basis. Once this fact is thoroughly recognized we may perhaps see the inauguration of a Ministry of Science, leading to a gradual improvement in the status of all scientific workers, including all members of the engineering profession.

Before leaving this point it is gratifying to note that the nation is, in spite of its Governments and officials, becoming more and more scientific from day to day. The advent of the motor cycle and motor car have done a great deal to spread a knowledge of mechanical engineering amongst the general public, and the popular craze for wireless transmission during the last two years has turned everybody into an amateur electrical engineer.

1(c). *Lack of tradition.*—Although real, tradition is a subtle thing, wherefore I shall not say anything about it. I do, however, feel that our profession is of such comparative recent growth that it suffers in status by the lack of the fine traditions of service which obtain in the older professions. In this connection we can but endeavour to initiate and hand down a standard of honour and service fully equal to that obtaining in the older professions.

2(a). *Apathy of the engineering profession.*—I must reluctantly assign the foremost place amongst the reasons within the control of the engineer to his own apathy. Although it is obvious that the individual engineer is powerless to improve his status, and that

this can only be done by combination, there are nevertheless many engineers, some of them in good positions, who neglect, or do not consider it worth their while, to associate themselves professionally with their fellows. Personally, I recently met one such man, who seemed proud of the fact that he had stopped his subscriptions to several engineering institutions as soon as he became prosperous.

As far as I can see, the only bodies in the country which are sufficiently strong and representative to carry any weight in a national matter, such as the further improvement of status, are the three great Institutions in London, of which we are the largest. It is therefore the first duty of every qualified engineer, whatever local institutions he may support, to belong to at least one of these three Institutions. It is incumbent upon members of Institutions, in the words of their undertaking on election, "to advance the objects of the Institution as far as is in their power." It is incumbent upon the Institution as a body to keep in touch with developments in all other countries affecting the status of their engineers, and with public opinion in this country, and to see that this country is not in any way behind others in this respect.

2(*b*). *Lack of unison amongst the engineering profession.*—It is, I think, unfortunate for the status of the engineer that the interests of his profession are in the hands of not one body, but three, not to mention a host of smaller ones. It is, I think, still more unfortunate that in the matter of status each body has seen fit to act, or not to act, as the case may be, independently of the others. This gives the impression to the general public, which is no doubt correct, that we cannot agree amongst ourselves as to the status we want. For that reason I should welcome immediate co-operation between the Institutions in this and all other matters affecting the profession as a whole. It would, I suggest, be a good thing for the profession to form a small "General Engineering Council," consisting of a few members from each Institution, to deal with all matters of the kind.* In the course of time this Council would no doubt expand into a Council fulfilling the same functions, as nearly as may be, as the General Medical Council.

It is interesting to note that combination of the members of the three Institutions would bring into line a body of members approximately half the number now on the medical register, which latter is about 48 000.

2(*c*). *Insufficient participation in public affairs by members of the engineering profession.*—The small extent in which we engineers participate in public affairs is to my mind another reason for our present status. We are, I fear, out of the eyes of the general public, and "out of sight is out of mind." Unfortunately, the average engineer has little time to devote to public affairs after finishing his daily work and his constant struggle to keep himself up-to-date by absorbing a fractional part of the technical literature which is such a feature of these times. Therefore I suggest that large employers should take the long view and allow some of their suitable men time to participate in public affairs. At the last two parliamentary elections we have seen the managing director of one of the largest electrical manufacturing companies standing as a candidate. That precedent is one which I suggest might be extended to employees of good standing, and also to municipal and other public affairs. If this suggestion were adopted, wherever possible, I feel sure that the time so allowed would come back to the employer, with interest.

Under a previous heading I have suggested that it is a necessity for this country to conduct all its affairs on a scientific basis. To carry that out the country requires more engineers in Parliament. To see that they get there is therefore an important duty of the engineering profession, both for the prestige of the profession and the good work they can do for the country.

In conclusion, I should like to explain that I do not advocate change of status for the mere sake of change, nor for the sake of putting our profession on the same legal status I have mentioned; but because I believe that the change would lead to our better standing in the community and an increase in our prosperity.

If I have succeeded in convincing you that we have not reached finality in this matter of our status, my address will have served its purpose.

* ADDENDUM. The Engineering Joint Council (see *Journal I.E.E.*, 1924, vol. 62, p. 533) appears to fulfil many of the functions of the General Engineering Council referred to in this Address.

DIRECTIONS FOR THE STUDY OF UNVARNISHED* TEXTILE FABRICS (INCLUDING CLOTH, TAPE, WEBBING AND YARN).†

[REPORT (REF. A/S11) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

CONTENTS.

* The term "unvarnished" denotes that the fabric has not been varnished or impregnated with insulating compounds, but embraces material which has been subjected to treatments such as those referred to in this Specification.

† The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

PREFACE.

Varnished cloth being a complicated material with many variables affecting the final product, it was considered necessary, with a view to the improvement of this class of insulating material, to attack the problem in detail.

Work on raw fabrics has now reached such a stage that the Association is able to issue directions for the study of suitable types for the manufacture of varnished cloth, and also for the study of the properties of unvarnished tape and webbing, which are employed

in the construction of electrical machinery and apparatus.

In view of the confusion existing in the terminology adopted in the cotton and kindred industries, it was considered desirable to deal with this subject somewhat fully. All the processes likely to be employed in the manufacture of cotton and linen fabrics for electrical purposes have been defined, and some information is given with respect to silk. The last named material, however, has not been dealt with exhaustively and is receiving further consideration, the results of which will be issued in due course.

The Association is indebted to the British Cotton Industry Research Association for valuable assistance.

The Director of the E.R.A. will welcome comments and criticisms from those who have occasion to use this specification.

I. FEATURES TO BE CONSIDERED IN THE EXAMINATION OF MATERIALS.

In order to produce a fabric of the highest quality a careful selection of the fibre is essential, and it should be treated at every stage with a view to the production of the best result. Consideration should therefore be given to the following :—

(*a*) The kind, class, source, grade and staple of the raw material employed (Clauses 1, 2, 3, 4, 40, 47 and 52).
(*b*) The count of yarn (Clauses 6, 29 and 55).
(*c*) Whether the yarn is single or folded, and, if the latter, the number of folds (Clauses 7 and 55).
(*d*) The number of spinning, or spinning and doubling, twists per inch of warp and weft respectively, and whether the twist is right-hand or left-hand (Clauses 30, 45 and 56).
(*e*) The strength of the yarn (Clauses 31, 55 and 56).
(*f*) The type of weave (Clauses 13, 14, 15, 16, 17, 46 and 57).
(*g*) The numbers of warp and weft threads (ends and picks) per inch (Clauses 18, 19, 20, 21 and 32).
(*h*) The weight of the fabric (Clauses 8 and 9).
(*j*) The thickness of the fabric (Clause 33).
(*k*) The amount of the sizing and filling materials and the mineral ash, and the effect of the sizing and filling materials on the electrical and mechanical properties of the fabric * (Clauses 10, 26, 34, 35, 36, 39 and 54).
(*l*) The extent to which the fabric has been scoured and/or bleached (Clauses 22 and 23).
(*m*) The effect of surface treatment, such as singeing, calendering, or beetling, on the fabric (Clause 24).
(*n*) The effect of chemical treatment, such as parchmentizing or mercerizing, on the yarn or fabric (Clause 25).

II. DEFINITIONS.

1. Kind.

The term "kind" refers to the actual fibre used, i.e. cotton, flax (linen) or silk.

* See Ref. L/S2, Tentative Directions for the Determination of the Electric Strength of Solid Dielectrics.

2. Class.

The term "class" refers to the variety of the specified fibre used, e.g. Sea Island Cotton.

3. Grade.

The term "grade" refers to the cleanliness of the fibre with respect to freedom from leaf and other impurities.

4. Staple.

The term "staple" denotes the average length of the bulk of the fibres being assessed.

5. Yarn.

The term "yarn" denotes the spun fibre.

6. Count.

The term "count" or "counts" applied to yarn denotes the relative fineness or coarseness of the yarn.

Note.—The use of the term "count" is sometimes applied to the number of threads per inch of the fabric, but this is incorrect.

(*a*) *Cotton Count.*

The term "cotton count" denotes the number of hanks, each consisting of 840 yards, contained in one pound (453·6 grammes) of yarn.

(*b*) *Linen Count.*

The term "linen count" denotes the number of leas (hanks), each consisting of 300 yards, contained in one pound (453·6 grammes) of yarn.

(*c*) *Raw Silk Count.*

The following systems are in general use :—

(i) *Raw Silk Ounce Count.*

The term "raw silk ounce count" denotes the number of lengths (hanks), each consisting of 1 000 yards, contained in one ounce (28·35 grammes) of raw silk.

(ii) *Raw Silk Dram Count.*

The term "raw silk dram count" denotes the number of drams per 1 000 yards of raw silk (1 dram $= \frac{1}{16}$ ounce $= 1\cdot772$ grammes).

(iii) *Raw Silk Denier Count.*

The term "raw silk denier count" denotes the number of deniers per 4 000 ells (= 520·57 yards) of raw silk.

1 denier = 0·825 grain = 0·0531 gramme.
Deniers per ounce = 533·3.
$\therefore$ 533·3 × 16 × 520·57 = 4 442 000 yards per lb. = denier silk.

(*d*) *Spun Silk Count.*

The term "spun silk count" denotes the number of hanks, each consisting of 840 yards, contained in one pound (453·6 grammes) of yarn (i.e. same as cotton).

(*e*) *Momme Silk.*

The term "momme silk" denotes fine silk fabric. It is generally sold by the weight per square yard, which is expressed in mommes.

NOTE.—The momme is a Japanese weight equivalent to 2·14 drams (1 dram = $\frac{1}{16}$ ounce = 1·772 grammes).

7. FOLDED OR DOUBLED YARN.

The term "folded" or "doubled" yarn denotes a yarn made of two or more threads twisted together.

NOTE.—If threads are composed of two-fold, three-fold, etc., yarns, they are described as 2/20s or 3/16s, etc., according to the count being 20s or 16s, etc.

In counting "doubled" spun silk there is a difference between the method adopted and that employed in the cotton trade, which may be illustrated as follows:—"2/60 cotton yarn" means two 60 count yarns twisted together resulting in a doubled yarn, which would only weigh 30 hanks to the pound (453·6 grammes). In the case of spun silk, however, 2/60 yarn would mean that two 120s count yarns had been doubled together to produce a doubled yarn weighing 60 hanks to the pound (453·6 grammes).

8. WEIGHT OF FABRIC.

The term "weight of fabric" denotes the weight of unit area of the fabric, and is expressed in ounces (avoirdupois) per square yard (grammes per square metre).

NOTE.—The weight in grammes of a piece of fabric 6·76 inches square is equal to the weight in ounces of a square yard.

9. WEIGHT OF TAPE AND WEBBING.

The term "weight of tape" (webbing) denotes the weight of unit length of tape (webbing) and is expressed in ounces (avoirdupois) per 144 yards.

10. SIZING.

The term "sizing" denotes the treatment of the yarn to hold the individual fibres together to enable it to withstand the frictional stress, and to smooth down the projecting fibres so as to reduce friction during weaving.

Size is also added to increase the weight of the yarn so as to produce a cheaper fabric.

In the cotton industry four kinds of sizing are in general use, as follows:—

(*a*) *Pure Sizing.*

The purpose of pure sizing is to enable yarn to weave. Although the sized yarn is increased by 5 per cent to 8 per cent in weight before scouring, very little, if any, additional weight is added to the resultant fabric. The materials used in the size mixtures are pure, and include sago, farina and occasionally flour, without any loading matter whatever. A little tallow or soap is usually put in for softening purposes.

(*b*) *Light Sizing.*

Light sizing is similar to pure sizing, but 6 to 20 per cent by weight is added to the warp yarn.

(*c*) *Medium Sizing.*

Medium sizing adds from 20 to 80 per cent by weight to the yarn. The object of this sizing is to give cheap cloths a good "feel."

(*d*) *Heavy Sizing.*

Heavy sizing adds over 80 per cent additional weight to yarn, and is in general only applied to heavily "filled" fabrics for West African and Eastern markets.

NOTE.—For electrical purposes, (*a*) and (*b*) above are the only sizing treatments permissible, and, in general, pure sizing only should be specified.

11. GASSING.

The term "gassing" denotes the operation by which projecting fibres are removed from the surface of the yarn before weaving.

12. FABRIC.

The term "fabric" denotes the woven yarn and includes cloth, tape and webbing.

13. PLAIN WEAVE.

The term "plain weave" denotes a weave in which both warp and weft threads are over one and under one throughout, and this gives equal bending of the threads.

14. MATT WEAVE.

The term "matt weave" denotes a weave in which one or both series of threads work two or more ends or picks together; such as 2 × 2, 3 × 3 or 4 × 4 ends and picks, and these are known as 2 × 2, 3 × 3 or 4 × 4 matts.

15. TWILL WEAVE.

The term "twill weave" denotes any weave that produces a diagonal line across the fabric. The simplest twill weave is the 2 × 1 or 1 × 2, in which one thread is lifted once and is down twice.

NOTE.—By the use of a twill weave a fabric can be made heavier and more compact than if a plain weave is employed. In most fabrics the warp is twisted harder than the weft.

In 2 × 1 the ends are in excess of the picks.
In 1 × 2 the picks are in excess of the ends.
In 2 × 2 very often the ends equal the picks, but with a heavier weft than warp.

16. SATIN WEAVE.

The term "satin weave" denotes a weave in which no two consecutive warp ends intersect with successive picks.

NOTE.—The satin weave gives a smooth, even face to the fabric and allows one set of threads to be completely covered, the face threads being much greater in number than the other series of threads.

17. DOUBLE TEXTURE.

The term "double texture" denotes a weave in which two plain or other fabrics are woven together at one weaving. The two fabrics, though quite distinct, may change places to form stripes, checks or figures.

18. WARP.

The term "warp" denotes the series of threads placed longitudinally in the loom over any desired width.

19. END.

The term "end" denotes the individual thread of warp yarn, e.g. 90 ends per inch means 90 threads of warp yarn per inch.

20. WEFT OR WOOF.

The term "weft" or "woof" denotes the series of threads passing transversely in the loom, and put into the fabric by means of the shuttle. Weft yarn is usually softer spun than warp yarn, and is frequently spun anti-clockwise.

21. PICK.

The term "pick" denotes the individual thread of weft yarn passing from selvedge to selvedge.

22. SCOURING.

The term "scouring" denotes the operation of washing the fabric after weaving to remove the sizing materials and the natural wax from the fibre.

NOTE.—In varnishing a fabric in the loom state, i.e. before being scoured, there is a possibility of chemical action between the cellulose or varnish and the material used in the size. Such action may materially affect the strength and durability of a fabric as well as the efficiency of the varnish. From the point of view of "proofing" fabrics, experience in textile chemistry has shown that the best results can only be obtained on fabrics that have been freed entirely from extraneous materials. On the other hand, scouring slightly reduces the tensile strength of fabrics.

23. BLEACHING.

The term "bleaching" denotes the series of operations through which a "grey" fabric (i.e. a fabric made from yarn that has not been bleached or dyed) passes to remove the natural colour of the fibre and to obtain a white fabric.

24. SURFACE TREATMENTS.

(*a*) *Singeing or Dressing.**

The term "singeing" or "dressing" denotes the operation by which projecting fibres are removed from the surface of a cloth by burning.

(*b*) *Shearing.*

The term "shearing" denotes the operation in which a cloth is passed over rotating razor blades and shorn.

* In America the term "dressing" is synonymous with "filling" and not with "singeing."

(*c*) *Calendering.*

The term "calendering" denotes the operation of finishing a cloth by passing it between heated rollers under pressure.

NOTE.—The arrangement of rollers varies according to the kind of finish required.

(*d*) *Beetling.*

The term "beetling" denotes a process of cloth finishing in which the finish is produced by winding a cloth upon rollers or cylinders, and subjecting it to a rapid succession of blows from wooden hammers.

NOTE.—The beetle finish may be imitated by means of a special calendering process.

(*e*) *Chesting.*

The term "chesting" denotes a process of cloth finishing in which the finish is produced by calendering a cloth between heavily weighted rollers, and winding the cloth during the process on to one of the calender bowls or rollers.

25. CHEMICAL TREATMENTS.

(*a*) *Parchmentizing.*

The term "parchmentizing" denotes an acid treatment of cotton yarn or fabric to increase the lustre.

(*b*) *Mercerizing.*

The term "mercerizing" denotes a caustic soda treatment of cotton yarn or fabric to increase the lustre.

26. FILLING * (also referred to as Stiffening).

The term "filling" denotes the filling up of the inter stices of the fabric with some chemical compound to produce a smooth surface.

27. REGAIN.

(*a*) When referring to weave, the term "regain" denotes the difference between the length of a fabric and that of a thread when removed from the fabric.

(*b*) When referring to moisture, the term "regain" denotes the percentage to be added to the dry weight of a material in order to obtain the weight of that material under normal humidity conditions.

III. METHODS OF INVESTIGATION.

NOTE.—The rules of the Liverpool Chamber of Commerce provide for the investigation of the features of raw cotton, and the rules of the Manchester Chamber of Commerce provide for the investigation of the features of yarn and fabric.

28. CONDITIONING OF SPECIMENS FOR TEST.

Before the tests specified in Clauses 29, 30, 31, 32, 33, 34, 35, 36 and 37 are carried out, samples of yarn or single sheets of fabric shall be conditioned in a controlled atmosphere for not less than 18 hours. The controlled atmosphere shall have a relative humidity of 75 per cent and a temperature of from 15° C. to 25° C.

* In America the term "dressing" is synonymous with "filling" and not with "singeing."

The yarn or fabric shall be tested as soon as possible after removal from the controlled atmosphere, and in any case before three minutes have elapsed.

The specified relative humidity may be obtained by the use of a solution of calcium chloride in water, specific gravity 1·22 at 20° C. (32 grammes of calcium chloride in 100 grammes of solution). Sulphuric acid shall not be used.

To ensure that the relative humidity of the controlled atmosphere is maintained at the correct value it is necessary either that the temperature be kept very constant or the air must be circulated within the chamber. The surface of the calcium chloride solution should be large per unit volume of air space, as if it is not the rate of attainment of equilibrium is very slow.

The following apparatus has been found satisfactory in maintaining the relative humidity of the controlled atmosphere constant:—

The chamber consists of a cubical box, with sides 24 inches long, the floor of which is nearly covered by a dish containing the solution of calcium chloride of the correct density. The samples of yarn or fabric to be conditioned are placed on a shelf half-way up the box. Air is circulated, by means of a small fan, over the solution up through holes cut at two corners of the shelf, over the samples and down through holes at the opposite corners of the shelf.

The humidity of the air, which may be measured by wet and dry bulb thermometers if the velocity of the air past them is greater than three metres per second, attains a constant value about three minutes after the box has been closed and the fan started, unless the prevailing conditions are extreme. If a humidity near saturation or dryness is required it is necessary that the walls of the box should be non-absorbent.

A solution of calcium chloride in water is satisfactory when a relative humidity above 45 per cent is required, and this solution should be employed in preference to sulphuric acid of which the vapour is liable to be absorbed by the fabric.

The correctness of the strength of the solution should be checked from time to time by humidity readings. As an alternative to wet and dry bulb thermometers, which require a known air velocity, a dew-point thimble may be inserted in the box and used when the fan is not working; with either method a window is necessary to avoid opening the box.

The value of the relative humidity of the air due to the calcium chloride solution given above will not vary 2 per cent over a temperature range of 30 deg. C.

NOTE.—The method of conditioning given above cannot be applied to fabric in rolls, which must be cut up before conditioning.

29. Determination of the Count of Yarn.

The yarn shall be conditioned as specified in Clause 28 before the count is determined.

In order to determine the count of the yarn used in the fabric it is necessary to remove the individual threads. A piece of fabric shall be cut out and sufficient threads of each kind (warp and weft) shall be placed on the scale pan to balance the appropriate weight given below. The number of inches is the count. In the case of two-fold, three-fold yarns, etc., the threads must be separated.

(*a*) *Cotton and Spun Silk.*

In the case of cotton and spun silk, if N is the count the relation may be written thus :—

$$N \times 840 \text{ yards weigh 1 pound } (= 7\,000 \text{ grains} = 453\cdot6 \text{ grammes})$$

$$\therefore N \text{ inches weigh } \frac{7\,000}{840 \times 36} \text{ grains} = 0\cdot231 \text{ grain} = 0\cdot015 \text{ gramme}$$

In other words, the number of inches of a cotton or spun silk yarn which weighs 0·231 grain or 0·015 gramme is the count of that yarn.

(*b*) *Linen.*

In the case of linen, if N is the count the relation may be written thus :—

$$N \times 300 \text{ yards weigh 1 pound } (= 7\,000 \text{ grains} = 453\cdot6 \text{ grammes})$$

$$\therefore N \text{ inches weigh } \frac{7\,000}{300 \times 36} \text{ grains} = 0\cdot646 \text{ grain} = 0\cdot042 \text{ gramme}$$

(*c*) *Raw Silk.*

In the case of raw silk the appropriate values given in Clause 6 shall be adopted.

30. Determination of the Twist of Yarn.

The yarn shall be conditioned as specified in Clause 28 before the twist is determined.

A suitable method for the determination of the twist of yarn is described in " Technical Testing of Yarn and Textile Fabrics," by J. Herzfeld, as follows :—

The apparatus consists of a base plate on which is fixed a frame supporting two small shafts (see Fig. 1).

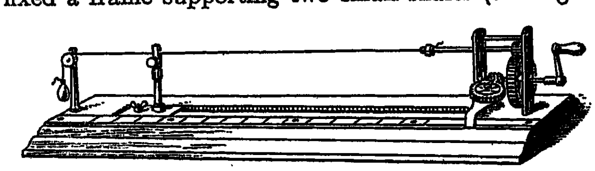

FIG. 1.—Apparatus for the Determination of the Twist of Yarn.

The lower shaft is fitted with a crank, and carries a spur wheel which engages with a pinion on the upper shaft, the gear ratio being 10 to 1. The lower shaft also rotates the graduated plate of a counter by means of worm gearing. The free end of the upper shaft terminates in a catch for holding one end of the yarn under test, which passes through a small split catch and then over a pulley as shown in Fig. 1. The support with the split catch is movable over a distance of 15 inches along a groove in the base plate, and can be fixed in any desired position by means of a thumb-screw, the position being indicated by a graduated scale on the plate.

To determine the twist of a yarn, the zero on the counter is adjusted to coincide with a fixed pointer. The movable support is placed in the position corresponding to the length of the sample of yarn it is desired to test, and one end of the latter is fastened in the catch fixed at the end of the upper shaft. The yarn is passed through the split catch on the top of the movable support, and then over the pulley, the free end being fastened to a small weight, the value of which varies according to the strength of the yarn, being heavier for stout and lighter for weak yarns. The split catch on the movable support is then screwed up, the lower shaft rotated by the crank and the yarn untwisted, the number of twists being recorded by the counter and read off direct. The counter will register either right-handed or left-handed twists.

Other suitable methods for the determination of the twist of yarn are described in the *Journal of the Textile Institute*, March 1922, page 81.

31. Tensile Strength of Yarn.

The yarn shall be conditioned as specified in Clause 28 before the test for tensile strength is carried out.

The tensile strength of yarn shall be determined by means of a single thread tester. A suitable apparatus for carrying out this test (Goodbrand) is described in the *Journal of the Textile Institute*, July 1923, as follows :—

> "The Goodbrand tester is one of the constant traverse pendulum-balance type, the load being applied by a falling weight, the motion of which is regulated by a plunger in an oil dashpot. The load is registered by the motion of a pendulum over a graduated arc, the pendulum being prevented from falling back when the specimen breaks by means of a small ratchet."

Another suitable method for the determination of the strength of yarn is described in "Technical Testing of Yarn and Textile Fabrics," by J. Herzfeld.

Ten breaking tests shall be carried out, and the maximum, minimum, and mean valves of the tensile strength of the yarn shall be stated.

32. Determination of the Number of Warp and Weft Threads per Inch.

The fabric shall be conditioned as specified in Clause 28 before the determination of the number of warp and weft threads per inch.

In the determination of the number of threads per inch it is not satisfactory to count the threads over a fraction of an inch and then multiply by a factor.

The number of threads shall be counted over a complete inch by means of a microscope cloth counting glass.

Note.—A suitable form of instrument for this purpose is supplied by Messrs. J. Casartelli & Son, Manchester.

33. Determination of Thickness of Fabric.

The fabric shall be conditioned as specified in Clause 28 before the thickness is determined.

The thickness of the fabric shall be measured by means of a ratchet micrometer* fitted with an anvil not less than ⅜ inch and not more than ½ inch diameter.

The average thickness of the fabric shall be ascertained as follows :—

A test piece one foot long and the full width of the roll shall be taken sufficiently far from the end to be representative of the bulk of the fabric. Ten measurements of thickness equally spaced diagonally across the test piece shall be made.

The maximum, minimum and mean values of the thickness shall be stated.

34. Tensile Strength of Fabric.

The fabric shall be conditioned as specified in Clause 28 before the test for tensile strength is carried out.

Nine specimens shall be cut in such a manner as to be representative of the bulk of the fabric. Three specimens shall be cut in the direction of the warp, three in the direction of the weft and three on the bias at an angle of 45°. No two specimens cut in the same direction shall contain the same longitudinal threads.

The specimens shall be not less than 2¼ inches wide, and the threads frayed out from each side to reduce the width of 2 inches. The specimens shall be placed evenly in the jaws of the testing machine so that the unstretched length of the fabric between the jaws is not less than 7 inches. The load shall be applied at a uniform rate, and the time taken to reach the breaking load from the commencement of the application of the load shall be one minute. If the specimen breaks unevenly, or in or at the jaws, due to incorrect clamping, a duplicate test shall be made on another test piece including the same threads. The maximum, minimum and mean values of the three tests warp way, of the three tests weft way and of the three tests on the bias respectively shall be stated.

Tests shall be carried out at the following temperatures :—

20° C., 60° C., 90° C. and 120° C.

Note.—When testing at the high temperatures the specimen should be surrounded by a heated cylinder to maintain the required temperature.

35. Tearing Strength of Fabric.

The fabric shall be conditioned as specified in Clause 28 before the test for tearing strength is carried out.

The tearing strength test shall be carried out by means of the apparatus shown in Fig. 2 as follows :—

The resistance to tearing shall be proved by the load required to tear a tongue 2 inches wide, commencing from holes $\frac{1}{32}$ inch diameter punched out of the fabric.

The size of each separate specimen tested shall be 12 inches by 6 inches.

(*a*) Three tests shall be made with the tear in the direction of the warp of the fabric.

(*b*) Three tests shall be made with the tear in the direction of the weft of the fabric.

* The permissible limits of the torque of the ratchet stop are under consideration.

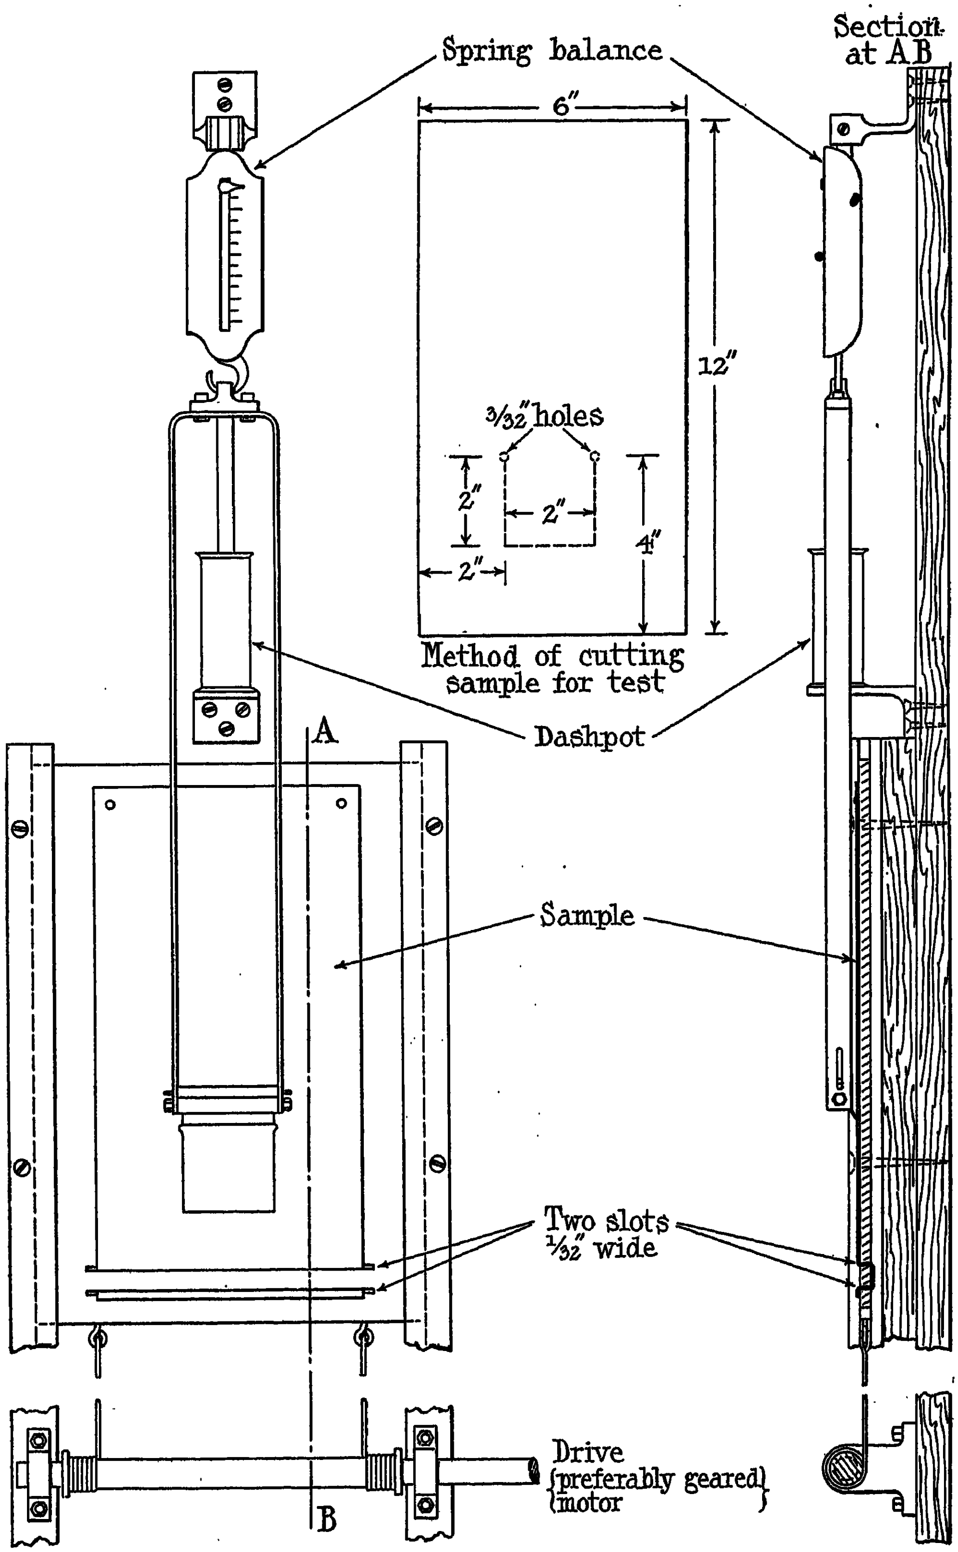

Fig. 2.—Apparatus for measuring the Tearing Strength of Fabric.

The method of carrying out the tearing test shall be as follows :—

Prepare the fabric specimen as shown in Fig. 2. Attach the lower end of the specimen to the sliding board by passing the fabric through the slots and pulling it tight. Grip the tongue of the fabric already cut out, as indicated by the dotted line, by passing it round and between the rollers which are attached to the spring balance. Pin the upper portion of the fabric to the board by two pins as shown in Fig. 2.

Rotate the winding gear so that the fabric tears at the rate of approximately 12 inches per minute. (A motor drive is recommended.)

Watch the balance and average the slightly varying values of the pull observed.

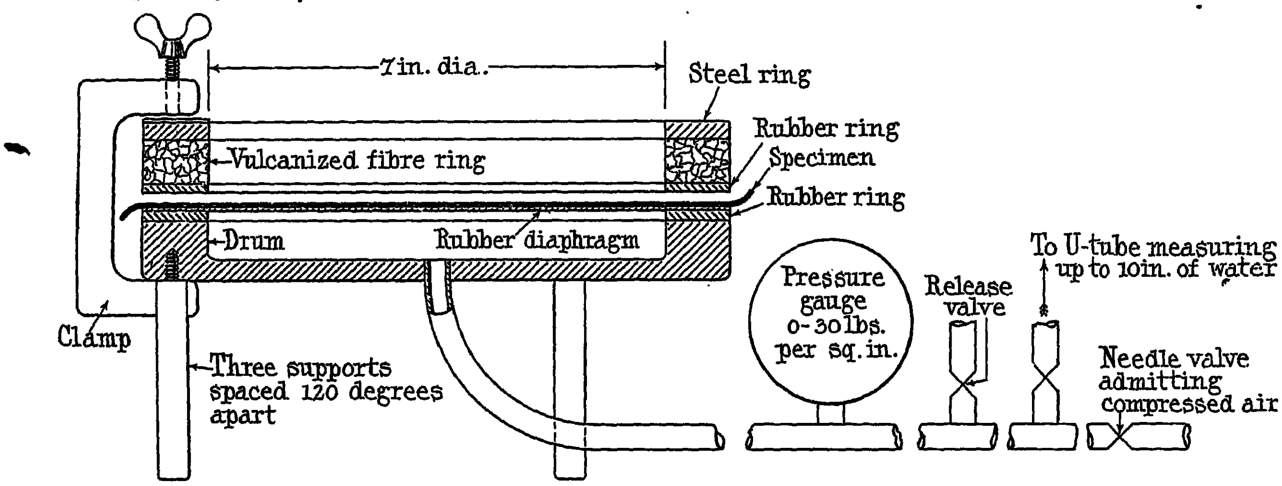
The maximum, minimum and mean values of the tearing strength in the directions of the warp and weft respectively shall be stated.

a rate that the radii of curvature of the fabric can be determined by means of a suitable spherometer. Sufficient readings shall be taken to enable a curve to be plotted showing the relationship between the air pressure and the radius of curvature of the fabric.

37. Ageing.

The tendency of the fabric to deteriorate with age shall be determined by the change in the bursting strength after it has been heated at a temperature from 90° C. to 95° C. for four weeks.

Bursting strength tests shall be carried out as specified in Clause 36 as soon as the temperature of the specimen has fallen to 20° C. (± 5° C.), and also after the fabric has been subjected to the controlled atmosphere specified in Clause 28 for not less than 18 hours.



NOTE:—The rubber ring and diaphragm are shown apart, but when in use they are brought into contact with the specimen and fixed by clamps, one of which is shown in position.

Fig. 3.—Apparatus for measuring the Bursting Strength of Fabric.

36. Bursting Strength and Extensibility of Fabric.

The fabric shall be conditioned as specified in Clause 28 before the tests for bursting strength and extensibility are carried out.

The bursting strength tests shall be carried out by means of the apparatus shown in Fig. 3 as follows :—

The fabric shall be placed over the rubber diaphragm and clamped between the rubber insertion rings fitted on top of the steel drum so as to make an airtight joint. Air shall be pumped into the drum at such a rate that the pressure on the fabric is increased gradually at the rate of approximately 30 lb. per square inch per minute until failure occurs.

Note.—Care must be taken to release the air pressure immediately the fabric fails so as not to damage the rubber diaphragm.

The test for extensibility shall be carried out on the apparatus shown in Fig. 3 as follows :—

The fabric shall be clamped between the rubber rings as before. Air shall be pumped into the drum at such

38. Tests for Acidity and Alkalinity.

(*a*) *Test with Distilled Water.*

A sample of fabric 6 inches square shall be boiled in a beaker for 5 minutes in 50 cm^3 of distilled water, the solution then being poured off into a flask, leaving the drained sample in the beaker. A further 50 cm^3 of distilled water shall be added to the sample and boiled for 5 minutes, the solution being poured off into the flask containing the first extract. To the contents of the flask (which need not be cooled) 0·5 cm^3 of 1 per cent phenolphthalein solution shall be added, and the whole titrated with N/100 caustic soda if acidity is indicated, or with N/100 sulphuric acid if alkalinity is indicated. The number of cm^3 of N/100 NaOH or of N/100 H_2SO_4 shall be stated.

A blank test shall be carried out on the water and glass vessels used in this test.

(*b*) *Test with Alcohol.*

A sample of fabric 6 inches square shall be boiled in industrial alcohol, complying with British Standard

Specification No. 2 D. 9, in the same manner as in (*a*). The procedure for the determination of acid or alkali specified in (*a*) shall be followed, and the number of cm^3 of N/100 NaOH or of N/100 H_2SO_4 shall be stated.

A blank test shall be carried out on the industrial alcohol and glass vessels used in this test.

NOTE.—The glass vessels used for these tests shall be boiled out several times with distilled water before the tests are carried out.

39. DETERMINATION OF THE AMOUNT OF SIZING AND FILLING MATERIALS AND MINERAL ASH.

(*a*) *Sizing and Filling Materials.*

Not less than one square yard of the fabric cut into small pieces shall be boiled for one hour in the liquids given below. A separate sample shall be used for each extraction.

(i) Distilled water.
(ii) 0·1 per cent solution of caustic soda, followed by an hour's boil with 0·5 per cent solution of hydrochloric acid.
(iii) Benzol complying with British Standard Specification No. 2 D. 10.

The extracts obtained shall be evaporated to dryness and the residues examined.

NOTE.—It is impossible to specify any simple procedure for the examination of the residues. The investigator must be guided largely by what he suspects to be present. (*See* Appendix I, Clause 54.)

(*b*) *Mineral Ash.*

Not less than 50 grammes of the fabric shall be dried at a temperature from 105° C. to 110° C. and then weighed with the usual precautions to obtain the dry weight of the sample. The fabric shall then be completely ignited, with all precautions against loss. The residue of incombustible matter (mineral ash) shall be weighed, and the amount computed as a percentage of the weight of the dried sample.

APPENDIX 1.

INFORMATION RESPECTING THE RAW MATERIALS AND PROCESSES EMPLOYED IN THE MANUFACTURE OF COTTON, LINEN AND SILK FABRICS.

40. CLASS AND SOURCE OF RAW COTTON.

Cotton is the seed hair from several species of the genus Gossypium—plants of the mallow family. The fibre is hollow and when growing is a single straight cylindrical cell, but on ripening the tube flattens and becomes contorted and twisted. The presence of these twists in the fibre makes it possible to spin it. Similar seed hair fibres to those found in the varieties of cotton used, but having no natural small twists in the fibre itself, are common, but cannot be spun economically. The number of twists in a mature cotton fibre varies from 150 to 400 per inch, the longer staple fibres having the highest number of twists per inch. The diameters of the fibres vary from 0·63 to 0·84 mil, the long staple Sea Island and Egyptian yarns having smallest diameters.

The actual number of plants from which commercial cotton is obtained is probably only seven, although "Index Kewensis" lists forty-two species and mentions eighty-eight others.

The seven species are :—

(1) *Gossypium arboreum* ..	Ceylon and Arabia.
(2) *Gossypium herbaceum* ..	Indian cottons.
(3) *Gossypium hirsutum* ..	U.S.A. Southern States cotton.
(4) *Gossypium barbadense* ..	Sea Island and West Egyptian and some Peruvian cottons.
(5) *Gossypium Peruvianum* ..	Native Peruvian cottons and Brazilian cottons.
(6) *Gossypium Sandwichense*	Sandwich Island cotton.
(7) *Gossypium tahitense* ..	Pacific Island cotton.

The classes of cotton commercially obtainable in Great Britain are given in the table on page 143.

From the point of view of textile manufacture Sea Island cotton produces the best yarn. It is the strongest and most uniform cotton and is used to spin the finest counts and the highest quality yarns. Specially good Egyptian cotton is suitable for yarns of 100 count and upwards, but good yarns of 60 up to 90 counts can be spun from ordinary good quality Egyptian cotton, and the cost of such yarns is less than that of similar counts spun from Sea Island cotton.

41. GINNING.

The term "ginning" is used to denote the process of separating the cotton fibre from bolls, seeds, immature fibre, etc. The process is imperfect, as portions of the seed and immature fibre pass on. It is carried out at the cotton plantations before the raw cotton is exported.

42. OPENING (BREAKING, BEATING).

The terms "opening," "breaking" and "beating" are applied to the processes through which the raw fibre passes in preparation for "carding," and consists of disintegrating, loosening and cleaning the matted fibre from the bales. The cotton after passing these processes is left in the form of a lap, i.e. in the form of a sheet 3 ft. 2 in. to 3 ft. 6 in. wide by ¼ in. thick which is rolled on an iron spindle for convenience in handling.

43. CARDING.

The term "carding" is applied to the process of opening up and combing the fibres and removing short and immature cotton and the dirt left in at the opening process. The cotton leaves the carding engine in the form of a sliver, i.e. a continuous length of loose, undeteriorated fibres.

NOTE.—In the production of fine grade counts, the carding process is frequently supplemented by a refined carding process known as combing.

44. Drawing.

The term "drawing" is applied to the process of drawing and placing straight and parallel the sliver produced in the carding engine in successive stages, until it is in suitable form for spinning. Only such twist as is necessary to keep the sliver intact is imparted during the drawing process. Drawing is effected in four or more stages on machines known respectively as :—

(a) Drawing frames.
(b) Slubbing frames.
(c) Intermediate frames.
(d) Roving frames.

The cotton leaves the roving frames on bobbins suitable for spinning.

45. Spinning.

The term "spinning" is applied to the process of twisting the cotton as it is received from the roving frames into a yarn. This twist produces a hard yarn which is incapable of further drawing.

Two methods of spinning are in use :—

(a) Ring spinning, which delivers the yarn on bobbins.
(b) Mule spinning, which delivers the yarn on cops.

46. Weaving.

In the operation of weaving, the warp threads are placed in the loom, and the thread that is to form the weft is wound into a "cop," which is placed inside the shuttle. The warp threads are led from the beam through the "healds" to the roller at the front of the loom to which they are fastened. When the loom is set in motion alternate threads, in the case of a plain weave, are pulled up and down respectively by the "healds" in such a way that the shuttle with its weft thread can be shot by the "picker" through the space between the upper and lower threads of the warp. A comb-like structure called the "reed" now pushes the weft thread, which the shuttle has left behind, up to the point where the warp threads separate. Then the "healds" reverse so that the thread of weft is gripped between the two layers of warp threads.

In weaving, the warp threads are subjected to considerable friction, which is liable to chafe the yarn and cause breakages. To prevent this damage the warp yarn is almost invariably sized before being woven.

47. Class and Source of Flax (Linen).

Linen is a vegetable fibre obtained from the flax plant *Linum usitatissimum.* The fibres themselves are constituted from small cells consisting of practically pure unlignified cellulose. Their average length is approximately 18 inches, but variations between 12 inches and 36 inches are commonly met. The mean diameter of the fibre is approximately 6 mils (varies between 1·8 and 25 mils). The fibre is separated from the woody tissue of the plant by a process of decomposition in stagnant water. Linen is a better conductor of heat than cotton, but contains approximately the same amount of hygroscopic moisture (approximately 8·5 per cent).

The following sources of flax are generally recognized :—

Russia : In 1913 over 90 per cent of the world's supply of flax was grown in the Russian Empire. Russian flaxes are known as Slanetz (dew-retted), Motchenetz (water-retted), and Siretz (ungraded fibre). The three kinds of flax are exported from Russia in no less than 32 varieties.

Holland : Dutch flax is exported in 6 grades.

Belgium : Flemish flax (blue flax) includes Bruges, Thisselt, Ghent, Lokeren and St. Nicholas, and is graded into 7 grades.

Courtrai flax is also graded into 7 grades.
Furnes and Bergues flax is graded A, B, C and D.
Walloon flax is graded II, III and IV.
Zealand flax is graded VI, VII, VIII and IX.
Friesland flax is graded into 10 grades.

France : French flax is known by districts in which it is grown, and includes Wavrin Fluies, Douai, Hazebrouck, Picardy and Harnes.

Ireland : Irish flax is known by the names of the counties in which it is grown.

Canada : Canadian flax is in no definite grades.

Austria-Hungary, Bulgaria, Italy, Netherlands also produce flax in smaller quantities.

(Attempts attended with a certain degree of success are being made to grow flax in Egypt, Bihar (India), Transvaal, Orange River Colony and various Australian districts.)

The flax passes through the following processes before it becomes the yarn used in the manufacture of linen tape and fabrics :—

48. Rippling.

The term "rippling" denotes a mechanical process of combing the flax seed capsules and other extraneous matter away from the actual stems (or "straw") of the plant itself.

49. Retting.

The term "retting" denotes the process of immersing the "straw" after rippling in stagnant water, so that by processes of decomposition and fermentation the pectoses and woody tissue of the plant are removed, leaving free the bast fibres.

50. Breaking.

Breaking is the term used to define the process of passing the retted fibre through rollers to break up the woody part of the stem in order that it may more easily be removed in the scrutching process.

51. Scrutching.

Scrutching is the term used to define the process of removing the woody parts of the stems to leave the fibres clean and free for subsequent spinning and weaving processes.

Linen yarn is available either "dry spun" or "wet spun." Wet spinning is employed to get higher counts

Class	Commercial name	Spins up to, counts	Quality	Colour	Staple length, inch
1	Sea Island	300	Regular and fine	Cream	$1\frac{3}{4}$
2	Meade	120	Regular and fine	Cream	$1\frac{3}{4}$
3	Egyptian :				
	Sakellaridis	150	Fine and soft	Ivory	$1\frac{1}{2}$
	Nubari	100	Fine, variable and rather harsher than above	Light brown	$1\frac{3}{8}$
	Abassi	100	Fine	White	$1\frac{3}{8}$
	Upper	60	Poorer and liable to be dirty	Dirty brown	$1\frac{1}{8}$
4	Sudan :				
	Sakellaridis	150	Fine and soft. Equal to good Egyptian Sakel	Light ivory	$1\frac{3}{8}$
	Zeidabi	60	Good grade, but liable to be dirty	White	$1\frac{1}{4}$
5	Brazilian :				
	Ceara, etc.	60	Hard and dirty	Dirty white	1
	Pernams, etc.	60	Hard and dirty	Dirty white	$1\frac{1}{8}$
6	Peruvian :				
	Sea Island	100	Soft and good grade	Varies	$1\frac{3}{8}$
	Mitafifi	100	Regular	Ivory	$1\frac{3}{8}$
	Tanguis	80	Good substitute for Egyptian and American extra staples	White	$1\frac{1}{4}$
	Smooth	60	Soft and good grade	White	$1\frac{1}{8}$
	Rough and mod. rough	—	Used chiefly for making shoddy, etc.	—	$1\frac{1}{4}$
7	American :				
	Orleans	60	Good grade, soft and strong	White	$1\frac{1}{8}$
	Uplands	50	Good grade and soft	White	1
	Texas	50	Good grade and soft	White	1
	Mobile	50	Moderate	White	$\frac{7}{8}$
8	East African :				
	American (Allen) ..	60	Substitute for American	White	$1\frac{1}{8}$
9	West African	—	This cotton is being developed, and is similar to American Uplands	—	—
10	Queensland :				
	American (Durango) ..	60	High grade, clean	White	$1\frac{1}{8}$
11	Indian :				
	Tinnevelly	20	Good grade, strong (can be spun in mixture with American)	Light brown	$\frac{7}{8}$
	Suntee Broach ..	20	Good grade, strong	White	$\frac{7}{8}$
	Madras Western ..	20	Moderate	Light brown	$\frac{3}{4}$
	Scinde	10	Inferior quality	Dirty white	$\frac{5}{8}$
	Bengal..	10	Hard and dirty	Light brown	$\frac{5}{8}$
12	Smyrna	20·5	The quality of this and other Turkish cottons is liable to vary on account of the tendency to grow native varieties	—	$\frac{7}{8}$
13	China	12	Although extensively grown and mostly used in China, in general is a good grade white cotton and short staple	—	$\frac{3}{4}$

(30 to 80), but dry-spun yarns are finer and are spun in counts 5 to 30.

52. Class and Source of Raw Silk.*

Silk is an animal fibre consisting of a continuous thread which is spun by the silkworm. This thread may be as long as 1 300 yards (2 000 yards for wild silks), and has a diameter varying from 0·5 mil to 1·0 mil (average 0·83 mil). The fibre is not cellular, but in its natural state consists of two continuous filaments, an inner substance known as fibroin and an outer substance known as sericin, cemented together. In silk in its manufactured state this cement is frequently partially removed (degumming).

Silk is an extremely hygroscopic material, and under favourable conditions may absorb 30 per cent of its weight of moisture and yet still appear dry. In its normal commercially "conditioned" state, silk contains 9·91 per cent moisture ("regain" 11 per cent), and is therefore some 40 per cent more hygroscopic than cotton.

The following table shows the chief varieties of silk :—

Bombyx mori	Japan
Bombyx mori	Italy
Bombyx mori	China
Bombyx fortunatus	Bengal
Bombyx textor	India
Antheræa mylitta	India
Attacus ricini	India
Attacus ricini	America
Attacus cynthia	India
Attacus silene	India
Attacus atlas	India
Antheræa yamamai	Japan
Cricula trifestrata	India
Antheræa peruyi	China

The filaments from the cocoon may be worked up and put on the market either as :—

(*a*) *Thrown Silk Yarn.*

Thrown silk yarn is made from silk filaments by running any number of them together and applying a slight twist.

(*b*) *Spun Silk Yarn.*

Short filaments of silk can only be made into yarn by the application of considerably more twist than that employed for thrown silk yarn. Spun silk is generally composed of filaments from 1 to 3 inches long, held together by a comparatively large number of twists per inch, in the same manner as a cotton thread. Spun silk is invariably made from filaments from which all the gum has been removed.

(*c*) *Schappe.*

Schappe is the name given to certain spun silk obtained from the Continent. It is usually of a slightly inferior quality to ordinary spun silk and is often made from silk waste containing from 5 to 10 per cent of gum.

* The E.R.A. is giving further consideration to the study of silk, the results of which will be issued in due course.

53. Raw Silk : International Titre.

The fineness of raw silk thread is expressed according to the International Standard as the number of deniers (0·0531 gramme) a skein of 500 metres length will weigh. This number is frequently referred to as the "international titre" and may be converted to the titres of other nations as follows :—

To Turin titre by multiplying by 0·8931.
To Milan titre by multiplying by 0·9315.
To French titre by multiplying by 0·8964.
To Italian (legal) and Swiss titres by multiplying by 0·9000.

54. Sizing Materials.

In the weaving process the warp threads are subjected to considerable stress and friction, which are liable to cause breakage and fraying of the fibres of which the yarn is composed. To prevent this damage to the warp thread it is almost invariably sized before being woven.

The materials used for sizing may be divided into three classes according to the purpose for which they are added.

(*a*) *Agglutinants.*

The function of an agglutinant is to hold together the individual fibres of the yarn, rendering them less liable to be frayed during the process of weaving and also to smooth and consolidate the yarn to enable it to withstand the stress and friction to which it is subjected whilst being woven. An agglutinant is used in addition to bind together the particles of clay or other mineral matter in the interstices of the yarn.

The materials used as agglutinants are as follows :—

Wheat flour.
Farina.
Corn starch.
Sago.
Rice flour.
Tapioca.
Dextrin.
Soluble starch.
Iceland and Irish moss.
Gum tragacanth.
Gum tragasol.

(*b*) *Softening Materials.*

The starch or gummy materials mentioned above, when applied in the pure state to the yarn, render it too stiff and harsh for satisfactory weaving, and it is necessary to add something that will give pliability and softness to the sized threads.

The softening materials generally employed are as follows :—

Tallow.	Japan wax.
Palm oil.	Spermaceti.
Castor oil.	Oleine oil.
Cotton-seed oil.	Soap.
Coco-nut oil.	Magnesium chloride.
Stearine.	Calcium chloride.
Paraffin wax (not for bleached fabrics).	Glycerine.
	Glucose.

(c) *Antiseptics.*

Flour, which is one of the most common ingredients of size, is a material well suited for the growth of mildew provided the conditions are favourable. To prevent the possibility of the formation of mildew it is necessary to make a further addition to the size, in the form of a "poison" which is termed an "antiseptic."

The antiseptic most frequently employed is :—

Zinc chloride.

Other antiseptics less frequently used are as follows :—

Zinc sulphate.	Salicylic acid.
Carbolic acid (phenol).	Thymol.
Cresylic acid.	Formaldehyde.

(d) *Remarks.*

It will be noted that the quality and quantity of the sizing materials used vary considerably. They differ in chemical composition in the properties that they impart to the yarn, and are as a rule more liable to undergo chemical change than cotton. The materials employed as softeners in sizing sometimes contain appreciable quantities of free acid and other impurities. Moreover, wax may prevent the varnish from adhering firmly to the fibres.

If size ingredients are left in a fabric, chemical action may develop which will be injurious to the cotton and the varnish. Thorough scouring therefore appears to be essential, and only such materials should be used in size as are harmless and can be removed readily from a fabric by scouring.

APPENDIX II.

MISCELLANEOUS.

55. SELECTION OF SUITABLE COTTON YARNS.

The selection of suitable counts of cotton yarns, the determination of whether the yarns shall be carded or combed, single or folded, and the number of spinning or spinning and doubling twists to be put into each inch of yarn are matters of great importance.

A count of yarn may be too high or too low for a given fabric, but the nature of the processes adopted to spin and double a yarn will in other respects determine its suitability.

The quality of a yarn is determined by the properties of the fibres of which it is composed and by the treatment they receive. For example, a carded yarn is inferior to a combed yarn in strength, uniformity of structure and homogeneity, even when both are made from the same class and grade of cotton. The number of spinning twists per inch of thread has a marked effect upon the strength of the thread, and doubling affects it still further.

Single commercial cotton yarns are much cheaper than folded yarns of equal count, and are spun from cotton of less value than that used for folded yarns. Two-fold commercial yarns are 25 per cent (or more) stronger than single yarns of equal count. When, however, single and folded yarns are spun from the same cotton the difference in strength will be less, as exceptionally good cotton is used for the single yarn, whilst normal quality cotton is employed for the two-fold yarn. Single and two-fold yarns of equal count differ in every respect, except that the same length of each has the same weight.

Good two-fold yarns are stronger, more durable, more uniform in strength and diameter than single yarns of equal count.

56. TWIST IN YARN.

Spinning twist binds together the short fibres composing a yarn and thus prevents them from slipping asunder when the yarn is subjected to tensile stress; it is a compression force that appears to act on the fibres in arithmetical retrogression. Thus, assuming a thread to have 12 twists to 1 inch, the sum of the numbers 1 to 12 is 78, and the compression which results from the first twist is 12/78 of the total compression; that of the second twist equals 11/78 and so on down to the twelfth, which equals 1/78. The number of spinning twists, however, and the strength of a yarn are not comparable, for each additional twist strengthens the yarn until a certain number per inch has been reached and then the strength decreases with each additional twist. Moreover, neither the increase nor the decrease in strength per twist is uniform. Twist has ceased to be beneficial when a shearing stress is produced, but this occurs after the maximum strength is attained. A yarn possessing the maximum strength is always hard, and has a tendency to kink and to snap when under tensile stress. Varnish cannot readily permeate a hard spun or twisted yarn, and in comparison with a normally twisted yarn of equal count there are larger interstices between the threads of a fabric.

A spinner generally puts the minimum number of twists into a yarn, as each additional twist reduces the output of a machine. Slight changes, however, have to be made from time to time as the spinning properties of one consignment of cotton differ from those of another. The twist is based upon the square root of the count number multiplied by a constant, but spinners of different cottons use different constants.

The strength of a yarn is also influenced slightly by the direction of the twist during spinning. In the textile industry the direction of twist is referred to as "twist way" and "weft way"; the former means that the fibres are twisted clockwise and the latter counter-clockwise.

57. SELECTION OF A SUITABLE WEAVE.

The type of the weave influences the number of warp and weft threads that may be used with advantage in each inch of fabric, and upon the number selected the value of the resulting fabric will depend to a large extent. With a plain weave it is impossible to use as many threads per inch as with such weaves as matt, twill, satin and double texture, but a plain weave holds every thread in position more securely than those mentioned above. It is on this account that plain woven fabrics tear so readily, as when a tearing stress

is applied the threads break one by one in regular succession. In less firmly united fabrics the threads slide against each other when under stress, and this prevents them from being broken singly. The bursting strength of a plain woven fabric is also less than that of any of the weaves mentioned above.

58. Information regarding Regain.

(*a*) When referring to weave, the term "regain" denotes the difference between the length of a fabric and that of a thread when removed from the fabric. Regain is, in general, an indication of good or bad weaving,* for, if it is different in the warp and the weft of a scoured plain woven fabric, the fabric will not stretch uniformly under tensile stress in both directions. If the regain in the warp exceeds greatly that in the weft it suggests that the tension upon the warp was insufficient during weaving. Should the regain in the weft exceed greatly that in the warp the inference is that the warp was excessively taut during weaving.

(*b*) When referring to moisture, the term "regain" denotes the percentage to be added to the dry weight of a material in order to obtain the weight of that material under normal humidity conditions.

The amount of regain is a more or less arbitrary percentage, and the values have been agreed upon in the textile industries, as follows :—

Material	Percentage regain
Cotton	$8\frac{1}{2}$
Linen	12
Silk	11

Note.—Many materials are naturally hygroscopic, i.e. possess the property of absorbing moisture from the atmosphere. The factors controlling the amount are various—the principal being temperature and humidity of atmosphere.

Under normal conditions there is an average moisture content which is peculiar to the material in question.

Textile fibres possess this property in varying degrees, depending to some extent on origin and manufacture.

In buying and selling, therefore, on a basis of weight, the moisture content becomes a very important factor.

There are official "conditioning houses" which determine the moisture content, and therefore the dry weight of the raw textile materials, by drying to constant weight at 105° C. to 110° C. To this dry weight is added a fixed percentage, which is assumed to be the percentage moisture content due to normal conditions of temperature and humidity. The new total weight is the "normal" weight for these conditions. The fixed percentage added is the "regain."

* This is a highly technical matter, and depends on the weight and build of the fabric.

A SURVEY OF AUTOMATIC ALTERNATING-CURRENT PROTECTIVE APPARATUS.

By B. NUTTALL, Student.

(ABSTRACT *of paper read before the* NORTH-WESTERN STUDENTS' SECTION, 19*th February*, 1924.)

ESSENTIAL CHARACTERISTICS FOR AN IDEAL PROTECTIVE SYSTEM.

(1) *Instantaneous isolation.*—Faults must be cleared quickly whilst only a small current is flowing, thus greatly reducing their destructive effects so that sound sections are not isolated and thus cause the supply to numerous consumers to be interrupted.

(2) *Property of discrimination.*—The apparatus should not operate on a heavy overload such as may be caused by a fault external to the area being protected.

(3) *Finality in adjustment.*—Once the protective gear is installed and adjusted on any feeder, there should be no readjustment of relays to suit any later modifications in any part of the network.

(4) *Simplicity of apparatus.*—The number of transformers and other component parts should be kept down to an absolute minimum as, generally speaking, the simpler the apparatus the more reliable it is in operation. The installation of a protective device must not incorporate any component part which is more liable to get out of order than the apparatus which it is desired to protect.

(5) *Adaptability to existing gear.*—With this should be associated flexibility for future extensions.

PROTECTION OF INDEPENDENT FEEDERS.

The removal of a fault on this type of feeder is necessarily accompanied by a temporary shut-down of the plant fed by the defective feeder. The object of protective gear for this type of feeder should be to confine the trouble to the part in question, and reduce to the smallest possible amount the duration of the dangerous condition. The following devices in more or less varied forms are employed for this purpose.

Plain overload devices.—The tendency except on very small systems (where fuses are installed) is to employ automatic circuit breakers in order to rupture the circuit safely with a minimum amount of disturbance, and thus save delay and expense in restoring the circuit. The drawback in most cases with plain overload trips is that transitory surges or momentary overloads necessitate settings which must be high enough to prevent the automatic features of the breakers from functioning and thus causing undesirable interruptions to supply. This procedure will result in the dangerous conditions—which it is desired to avoid—being permitted on the system, and these may be serious enough to cause extensive damage to the plant.

Time-limit overload devices.—To overcome this difficulty a device having an inverse time limit is usually employed. Two distinct types of time elements are available; one in the form of fuses and the other embodying some kind of air or oil dashpot device, or a piece of clockwork or equivalent mechanical device.

Leakage devices.—The modern tendency is to disconnect circuits when the insulation becomes so defective as to permit small leakages of current, for if these leaks are allowed to remain on the system and develop, there is a risk of fire and shock to the system, due to open sparking at the point. Overload devices will not protect against this condition, although if the leak occurs between phases it will probably develop into a short-circuit and thus cause the overload device to operate. All three-phase systems have their mid-point earthed through condensers connected in star fashion through the capacity of the cable. If there be no earth fault on any particular feeder or on the network connected thereto, the sum

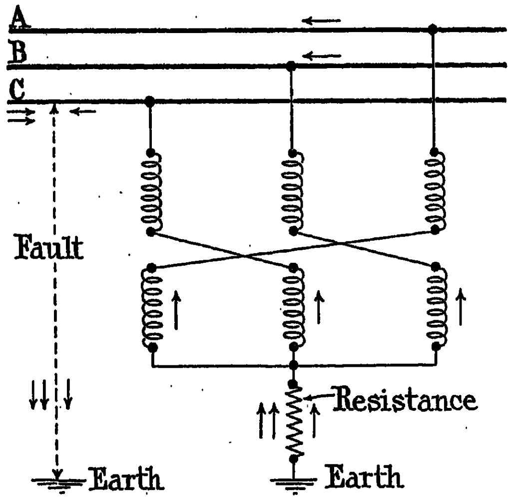


FIG. 1.—Zigzag method of earthing an insulated system by means of a static balancer.

total of the currents in the three cores must be zero at any instant.

Assume that a fault to earth develops on one phase, thus bringing this point of the system to earth potential. The capacity current from the other two phases must find its return path through the third phase lead, but as this lead is at earth potential the current cannot be passing via the dielectric and therefore the whole of the capacity current must pass from earth to the third phase via the fault.

A ring-type transformer of special design can be designed to operate a relay with 20 amperes fault primary current (or even less), and this relay may in turn close the trip circuit of the circuit breaker. We should thus have a protective arrangement capable of

being applied to any extensive distribution with unearthed neutral, whereby any cable would be automatically disconnected should a core develop a fault to earth, and this without any excessive rush of current with consequent shock to the system. The same result would be obtained in a system of much smaller capacity by connecting the neutral point to earth through a relatively high resistance, capable of passing, say, only 20 amperes if a pole became earthed. From the above it will be seen that it is advisable to earth the star connection of the system or, if this is not available, to earth the system through a transformer connected across the phase bars in zigzag fashion, one arrangement of accomplishing this being shown in Fig. 1.

Leakage devices operating on the principle outlined above are of two types; one in which the magnetic balance of the cores is utilized, and the other the current-balance method.

Protection of Interconnectors, Ring Mains and the Component Pieces of Apparatus of Generation, Transmission and Distribution Systems.

Under normal conditions the flow of power in an interconnector or ring main may be in either direction according to the load taken by the substations or large consumers "teed" off or connected directly to the system. It follows, therefore, that reversal is not a sign of leakage. This does not infer that reverse relays cannot be employed but is mentioned to point out that the use of reverse-power relays, even with a selective timing action, is restricted to comparatively simple arrangements. The use of reverse-power relays has a fairly wide range of application on existing systems, where little expenditure or little modification to switchgear is required, or where there is little or no synchronous machinery to fall out of step due, in certain cases, to the large time-lag on the relays.

The Merz-Price systems of protection.—There are two distinct types of protection under this heading, the circulating-current system and the balanced-voltage system. In each case a facsimile of the primary circuit condition at each end of the apparatus to be protected is reproduced in the secondary connections through the medium of current transformers, and these conditions are compared through the interconnection of the transformers by means of a pilot cable to determine whether the circuit conditions are normal.

Fig. 2 illustrates diagrammatically the circulating-current system, while the balanced-voltage system is shown in Fig. 3.

It will be observed that in both types a leak must occur within the protected zone for an unbalanced condition to be present in the secondary circuit. This unbalanced condition causes a current proportional to the leak to flow through the coil of the relay, and use is made of this facsimile of the primary leakage current, either directly or indirectly, to trip the breakers in the protected zone.

Compensated-pilot balanced-voltage Hunter-Beard system.—To eliminate the capacity effect of the pilot wires and thereby increase the stability and sensitiveness of the relays, the compensated-pilot system was invented. In this system each core of the pilot cable is surrounded by a sheath which is discontinuous at the centre, so that all the capacity current must flow

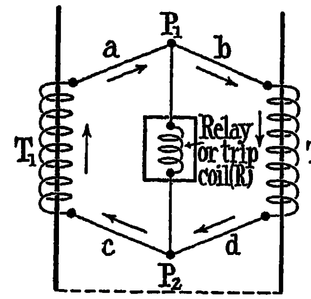

FIG. 2.—Diagrammatic representation of the Merz-Price circulating-current system of protection.

from the core to the sheath. The sheath is connected in such a way that the capacity current circulates in the circuit comprised by the pilot core, sheath and protective transformers. Consequently the capacity current is shunted from the relay coils, and the system becomes immune from any tendency to operate due to the passage of heavy short-circuit currents.

Merz-Hunter split-conductor protective system.—This system may be looked upon as a parallel-feeder system or duplicate ring-main system, having the advantages that for a given total current-carrying capacity, (1) it is more economical both from the point of view of initial cost of cable and switchgear and also from

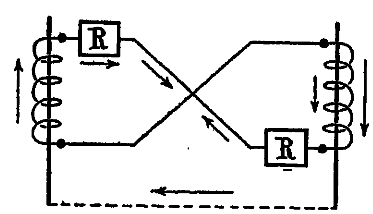

FIG. 3.—Diagrammatic representation of the Merz-Price balanced-voltage system of protection.

economy in operation, and (2) it is more sensitive to faults and more reliable in operation than separate cables protected by interlocked current-balance relays, Merz-Price balanced-voltage or other feeder systems which necessitate separate cables for each three-phase circuit. The system can also be applied to a limited extent to parallel feeders of similar capacity. The principle of operation is based on the fact that parallel conductors of equal impedance will share the current equally.

THE EFFECT OF OXIDATION ON THE HIGH-FREQUENCY RESISTANCE OF AERIAL WIRES: WITH A NOTE ON MEASURING THE RESISTANCE OF THICK WIRES.*

By L. B. TURNER, M.A., Member.

(*Paper received 26th September, 1924.*)

SUMMARY.

Measurements are made on thick solid and stranded wires to ascertain the effect on their high-frequency resistance of the oxide film formed by weathering. It is found that the weathering produces no sensible effect, under either dry or wet conditions.

The several methods of measuring high-frequency resistance are compared in respect of their suitability for determining the resistance of stout straight conductors.

(1) INTRODUCTION.

Recently studied methods † of reducing earth losses occurring near the aerial in high-power wireless transmitters have so much reduced the total resistance of the aerial circuit that the heat losses within the copper aerial and earth wires themselves assume considerable importance. Each of the wires, being substantially straight and remote from its neighbours, possesses a high-frequency resistance exceeding the direct-current resistance sensibly only on account of the "skin effect"; and this in straight, solid, circular, isolated conductors is calculable from well-known theoretical formulæ.‡ The wires of an aerial or earth system are, however, often stranded, so upsetting the circular distribution of current density on which the skin-effect calculations are based; and they are, moreover, usually coated with a more or less insulating covering of oxide or sulphide.

Theory indicates that with the solid wire the effect of such oxide film must be a rise in the high-frequency resistance, and it did not seem certain that there might not be—perhaps at the oxide-metal surface or in rain—a poorly conducting layer in which considerable losses would occur. With the stranded conductor the film might cause either a rise or a fall in the high-frequency resistance, according to the completeness of the insulation between the strands.

An admirable series of measurements on thick wires of various forms has been made by Kennelly and Affel.§ Their results with solid, round wires agree closely with theory; but although they investigated stranding they do not appear to have examined the effect of oxidation.

For these reasons the present measurements were made * on new bright and old black samples of solid and stranded wire, at wave-lengths ranging from 4 000 to 20 000 m. The familiar method was employed in which the resistance of the specimen is determined as the differences between the resistances of an oscillatory circuit when the specimen is included and when it is excluded.

In view of the suspicion with which high-frequency measurements of this sort must always be regarded by the critic † —and more especially when, as here, the conductor whose resistance is to be determined necessarily occupies a large space—the first series of resistance determinations was made in two quite different ways: (i) by the inserted resistance method (Lindemann), in which the unknown resistance is obtained in terms of a known resistance; and (ii) by the distuning method (Bjerknes), in which the unknown resistance is obtained in terms of known capacities and frequency.

(2) TESTS WITH SOLID HARD-DRAWN COPPER WIRE, 150 LB./MILE.

The test circuit employed is shown in Fig. 1. Here R_n and R_o are the specimens of wire, new and old ‡ respectively. Each was about 106 m long, wound in a zigzag form (a very flattened helix) over two parallel strips of wood as shown in Fig. 2. One or both of these specimens was short-circuited by the plug switches P_1 and P_2.

The main inductance coil L_1 consisted of 4 open spirals of copper tape, about 58 cm in diameter and of overall axial length 28 cm. The spirals were mounted on an axial wood rod, and were connected in series. The coupling coil L_2 (stranded wire, inductance 21μH, d.c. resistance 0·20 ohm) served to couple the test circuit very loosely to a triode oscillator set up at a distance.

The known resistance (r), insertable by removing the

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† For example, Alexanderson's multiple-earth antenna (*Proceedings of the Institute of Radio Engineers*, 1920, vol. 8, p. 263); Meissner's multiple earth connections (*Jahrbuch der drahtlosen Telegraphie*, 1921, vol. 18, p. 322) and T. L. Eckersley's earth screen (*Journal I.E.E.*, 1922, vol. 60, p. 581).

‡ It happens that aerial wires often lie between the useful ranges of the Rayleigh and Russell formulæ; but the comprehensive tables of Pedersen (*Jahrbuch der drahtlosen Telegraphie*, 1911, vol. 4, p. 505) or Circular No. 74 of the Bureau of Standards, p. 309, may conveniently be used.

§ "Skin-effect Resistance Measurements of Conductors at Radio Frequencies up to 100 000 Cycles per Second," *Proceedings of the Institute of Radio Engineers*, 1916, vol. 4, p. 523.

* At the Engineering Laboratory, Cambridge. The wire was supplied by the Post Office Engineering Dept., and the inductance coil in the test circuit was loaned from the Wireless Section, Engineer-in-Chief's Office, G.P.O., for the purpose of the tests.

† Every serious experimentalist with high-frequency currents knows that a good deal of experience, and after that a good deal of care, are required if quite gross errors are to be avoided. For an elaborate examination of the conditions for precision in this type of measurement, see S. LOEWE (*Jahrbuch der drahtlosen Telegraphie*, 1913, vol. 7, p. 365). With tedious precautions and corrections Loewe was able to reduce the final uncertainty to some 0·5 per cent. His difficulties, however, would have been somewhat reduced by the use of the modern triode generator.

‡ In use on a Post Office line for about 20 years.

plug P_3, was of fine eureka wire, and its value was either 1 or 2 ohms throughout the tests.

The condenser C was a mica plug box of high quality, supplemented by an adjustable air condenser showing a d.c. insulation resistance of over 100 megohms.

The measuring instrument M.V. was a Moullin voltmeter, calibrated by the makers between 0·4 and 1·5 volts at some acoustic frequency. The proportionality of the scale markings was checked at a wave-length of 4 km and found to be accurate.

In method (i), two tuned voltmeter readings V_1 and V_2 are obtained,* respectively without and with the known resistance (r) in circuit. The resistance R of the whole circuit (excluding r) is then given by $R = r/\{1 - (V_1/V_2)\}$. In method (ii), if C_1 and C_2 are the capacities at which the voltmeter reading is $1/\sqrt{2}$ of the tuned reading,† then

$$R = 1\,060\lambda(C_1 - C_2)/(C_1 + C_2)^2 \ddagger$$

where R is measured in ohms, λ in metres, and C_1 and C_2 in micromicrofarads. The resistance of the measurements made at the terminals of condenser C (set to zero) are set out in Table 1.

In order to exhibit the sort of agreement between resistance values measured by the two methods, they

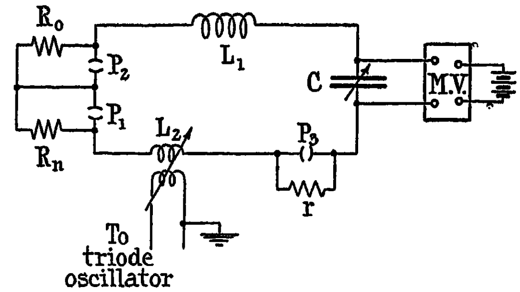

FIG. 1.

are set out side by side in Table 2, under "Circuit only" for the circuit of Fig. 1 with P_1 and P_2 plugged, under "Circuit + R_n" for plug P_1 out, and under "Circuit + R_o" for P_2 out.

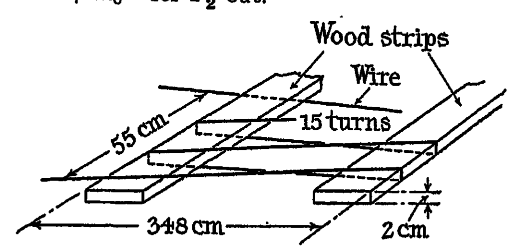

FIG. 2.

It will be seen that there is good agreement between the two independent methods; and it may be inferred that, even with an exceptionally awkward and wide-

specimen, R_n or R_o, was found as the difference of the measured resistances of the whole oscillatory circuit when the specimen was included and when it was short-circuited. Two pairs of voltmeter or condenser readings were thus necessary for each determination.

The results of direct-current and low-frequency spread circuit such as obtains here, reliable measurements of high-frequency resistance can be made by either method.

The values of the high-frequency/direct-current resistance ratios taken from Table 2 [means from methods (i) and (ii)] are set out in Table 3. This table clearly shows that the presence or absence of a dry oxide film is quite without practical significance in solid

* V_1 was always made about 1·4 volt, and V_2 between 0·8 and 1·0 volt.
† Always made 1·40 volt.
‡ In lowly damped circuits as here.

TABLE 3.

High-frequency/Direct-current Resistance Ratios for Specimens of New and Old Solid Wire.

Wave-length	New wire	Old wire
km		
4	3·22	3·22

8	2·06	1·96
10	1·78	1·71
15	1·38	1·35
20	1·10	1·06

wires of such size and at such wave-lengths as here tested.

The effect of wetting was examined at wave-lengths of 4 and 20 km by thoroughly spraying the wires with rain water from a rose sprayer. In no case did the resistance of the specimen change by as much as 1 per cent.

(3) TESTS WITH STRANDED PHOSPHOR-BRONZE WIRE (7/19 S.W.G.).

This series of tests resembled that of section (1) almost precisely except that only the inserted resistance method [method (i)] was used, and that most of the space previously occupied by both solid specimens side by side was now occupied by either the new or the old stranded specimen. Measurements were therefore made at all wave-lengths on one specimen, which was then unwound and replaced by the other specimen.

The lengths of wire were each about 161 m; the d.c. resistances were 0·97 ohm (new) and 0·95 ohm (old). The observed high-frequency/direct-current resistance ratios are given in Table 4.

TABLE 4.

High-frequency/Direct-current Resistance Ratios for Specimens of New and Old Stranded Wire.

Wave-length	New wire	Old wire
km		
4	3·39	3·40
5	2·82	2·90

8	2·00	2·01
10	1·66	1·71
15	1·39	1·48
20	1·21	1·26

As in the case of the solid wire, wetting had no perceptible effect.

Again we find no important change of resistance due to oxidation, wet or dry.

As a further deduction from the results of these tests on aerial wires, it seems very improbable that appreciable gain is to be had by lacquering (or silver-plating) the large copper tubing used for inductance coils and connections in transmitting circuits.

(4) METHODS OF MEASURING RESISTANCE OF THICK WIRE.

The circuit method of resistance measurement, in either of the two forms here used, is so convenient, employing only simple apparatus found in any wireless laboratory, that it is worth inquiring whether the measurements described are capable of giving the true resistance of straight thick conductors such as may be used for aerials and earths. Two other methods have been employed for this purpose. Fleming* devised a balanced calorimetric method which appears to have given satisfactory results with very short lengths of rather thin conductors; and Kennelly and Affel † have published a full and excellent account of measurements of small resistances by a bridge circuit, in which the resistance of the specimen in one arm is balanced by

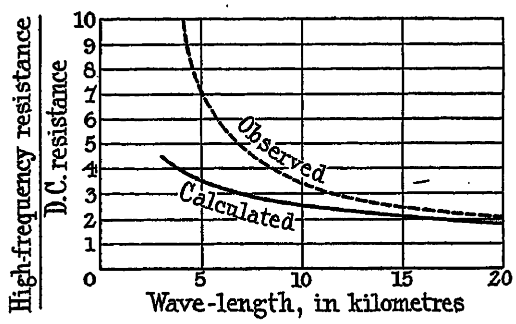

FIG. 3.—High-frequency/direct-current resistance ratio for solid copper wire, 300 lb./mile.

a known adjustable resistance in the other arm. Both these methods are more direct than the circuit method, but they require much more specialized apparatus which cannot be assembled from the everyday equipment of a laboratory.

Fig. 3 shows the calculated (i.e. true) high-frequency/direct-current resistance ratios for straight solid copper wire of 300 lb./mile (diam. 0·35 cm), together with values obtained experimentally precisely as in the case of the stranded wire in section (3). The divergence between the two curves shows that the form of the specimen and/or the circuit conditions were not such as to yield the resistance ratios actually sought.‡ In the following examination of the circuit method of measuring wire resistance, these tests on the 300 lb./mile wire form a convenient case for numerical reference.

Since the resistance (say a) of the specimen is obtained as the difference of the resistances of the oscillatory circuit with and without the specimen (say $A + a$ and A respectively), a must not be very much smaller than A. In the present instance A and a were about 2 ohms and 1 ohm respectively.§ In order to make a as large

* "Principles of Electric Wave Telegraphy and Telephony," 3rd edn., p. 144.

† *Loc. cit.*

‡ This does not vitiate the comparison between new and old wires in sections (2) and (3), since the new and old specimens were made rigorously similar.

§ At 10 km wave-length, $A = 1·80$ ohms, $a = 1·02$ ohms; d.c. resistance of specimen = 0·310 ohm.

as this, it was necessary to use as much as 161 m of the wire to form the specimen, which in consequence had very considerable stray capacities and an inductance of 214 μH (22 per cent of that of the rest of the circuit).

It would be difficult and costly to build up a circuit with much smaller resistance A using a coil of this inductance (L_1 of Fig. 1); and if the circuit were reproportioned with much smaller L_1 and correspondingly larger C, the change in the latter on retuning when the specimen is cut out would be so large as to necessitate an accurate knowledge of the condenser losses.

We are thus driven to use a large coil L_1 and a large length of wire in the specimen, and two factors making for error have therefore to be faced, viz.

(*a*) Effect of stray capacities, and
(*b*) Effect on each portion of the specimen of the neighbouring portions (proximity effect).

(*a*) *Effect of stray capacities.*—In the circuit of Fig. 4,

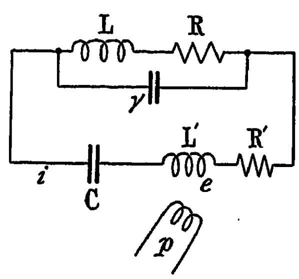

FIG. 4.

where γ may represent the self-capacity across a portion L, R of the circuit, it is easily shown that

$$e/i = R' + [1/(a^2 + b^2)][\{aR + bpL\} + j\{apL - bR + (a^2 + b^2)(pL' - 1/pC)\}]\ *$$

where $a = 1 - p^2L\gamma$, $b = pR\gamma$, and $j = \sqrt{(-1)}$. When the circuit is tuned for maximum i by adjustment of C or L', the imaginary term vanishes and the $LR\gamma$ impedance becomes a pure resistance, say ρ, where $\rho = (aR + bpL)/(a^2 + b^2)$.*

Substituting for a and b, and solving for R, we find

$$R = \frac{1 - \sqrt{\{1 - 4p^2\gamma^2\rho^2(1 - p^2L\gamma)^2\}}}{2p^2\gamma^2\rho}\ *$$
$$\fallingdotseq \rho(1 - p^2L\gamma)^2 *$$

when $4p^2\gamma^2\rho^2 << 1$, as in cases of stray capacity with $L\gamma$ far below resonance.

To frame a rough estimate of the self-capacity of the specimen, we may note that the static capacity between two parallel wires 161 m long, 0·175 cm radius, separated 3 cm, would be some 1 400 $\mu\mu$F; so that we may take (say) 500–1 000 $\mu\mu$F as the ideal concentrated capacity shunting our specimen, whose inductance is 214 μH. At 4 km ($p^2 = 2 \cdot 23 \times 10^{11}$), the measured value would in consequence exceed the true value of the resistance as shown in Table 5. Hence, although appreciable correction for self-capacity of the specimen is needed at the shorter waves, the error does not approach the discrepancy existing between the curves of Fig. 3.

* These expressions, which are exact, are useful in other connections, where the shunting capacity γ is not small.

The error caused by the stray capacity bridging the coil L_1 is likely to be smaller. The self-capacity of L_1 is not likely to exceed 200 $\mu\mu$F, and as the coil inductance is 95 μH the ratios here would not exceed $\rho/R = 1 \cdot 09$.

TABLE 5.

γ	ρ/R
500 $\mu\mu$F	1·05 times
1 000 $\mu\mu$F	1·10 times

Since the coil remains in circuit whether the specimen is in or out, its self-capacity causes error only in so far as it is altered by short-circuiting the specimen.

(*b*) *Proximity effect.*—It is possible to estimate this

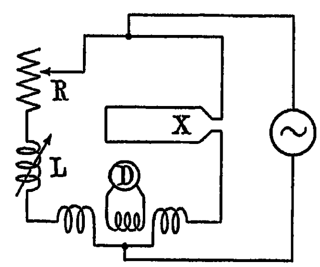

FIG. 5.

effect in our actual specimen only roughly, as the long pieces of thick wire, though nowhere allowed nearly to touch, spaced themselves unevenly except near the supports at the ends. Howe has shown* that an alternating magnetic field of frequency $p/(2\pi)$ and amplitude H C.G.S. electromagnetic units perpendicular to a round non-magnetic wire of radius r cm and resistivity ρ ohms per cm cube produces eddy-current heat at the rate of $(1/\rho)p^2H^2r^4 \times 3 \cdot 93 \times 10^{-17}$ watt per cm run. Remembering that H^2 is inversely proportional to the square of the space between wires, we may guess 1 or 2 cm as the equivalent uniform spacing in our specimen, and, doing so, may take the field cutting each wire as nearly that due to a single neighbouring wire. Using the above formula, we then find for the 161 m of copper wire, 0·175 cm in radius, at 4 km wave-length, a resistance additional to the straight-wire value of 6·1 or 1·5 ohms respectively. As the measured resistance at this wave-length was 3·2 ohms, it is clear that the proximity effect we are examining is competent to explain the discrepancy.

(5) THE MOST SUITABLE METHOD.

Although the circuit here used might with advantage have been modified in its dimensions—notably in spacing out the specimen more uniformly and widely—it is clear from the foregoing analysis that the circuit method is open to serious objections for the

* *Proceedings of the Royal Society*, A, 1916–17, vol. 93, p. 471.

measurement of the resistance of stout conductors; moreover, the difficulties discussed cannot be avoided by any variation of the manner in which the circuit resistance is measured, such as Pedersen's mercury-switch condenser-discharge method.* On the other hand, the calorimetric method is necessarily slow and troublesome; and, while it is capable of measuring quite short straight wires—75 cm in Fleming's apparatus—it requires the production and accurate measurement of large high-frequency currents. To develop heat in the specimen at the same rate as in Fleming's apparatus (about 1 watt per metre) a conductor no larger than our 300 lb./mile wire would require, at the wave-length of 20 km, a current as large as 18 amperes.

* *Wireless World and Radio Review*, 1922, vol. 10, p. 135.

Some bridge arrangement, such as used by Kennelly and Affel,* seems to be much the most suitable. Their circuit is shown in Fig. 5, copied from their paper, in which X is the specimen balanced by adjustment of L and R, and D is the detector. They used a generator current of some 5 amperes, and were able to measure low resistances such as 0·2 ohm with an uncertainty of only one-third of 1 per cent.

* *Loc. cit.*

INSTITUTION NOTES.

Members Practising as Consultants.

The attention of the Council was recently drawn to an advertisement of a Local Authority in which Chartered Electrical Engineers were invited to submit, in competition with each other, their terms for professional advisory work.

In the opinion of the Council such a proceeding is undesirable and not in the best interests of the Local Authority requiring advice.

The Council would consider it to be a breach of professional etiquette for a member of the Institution to reply to such an advertisement.

Where the names of a sufficient number of qualified consultants are not known to a Local Authority, the President of the Institution will always be willing to submit the names of qualified engineers for the purpose.

Associate Membership Examination Results: October, 1924.

Passed.

Officers of the Corps of Royal Engineers.

Passed.

de Lotbinière, 2nd Lieut. E. J.
Laurence, 2nd Lieut. K. St. G.
Rendell, 2nd Lieut. W. P.
Treays, Lieut. W. H.
Waring, 2nd Lieut. E.

Further results relating to candidates who sat for the Examination abroad will be published later.

Associate Membership Examination.

The next Examination will be held on the 2nd, 3rd and 4th April, 1925. Candidates must be either Students or Graduates of the Institution or have lodged with the Secretary a duly completed form "E" for election as Associate Member. Entry forms for the Examination, which must be completed and returned by the 1st February, may be obtained on application to the Secretary.

Supplementary Reserve of Officers.

The Council desire to draw the attention of members to the fact that it has been decided by the military authorities to form a Supplementary Reserve of Officers with a view to completing on mobilization the requirements of certain Arms and Branches of the Regular Army for which the existing Army Reserve does not provide. These requirements will be mainly technical, and officers commissioned into the Supplementary Reserve will be liable to serve, in the event of an emergency, with any unit or part of His Majesty's Land Forces in any part of the world, and they will be liable to be called out on service when the Army Reserve or any part of it is called out by proclamation. The liability to be called out in aid of the Civil Power will not, however, be enforced.

Officers will be divided into two categories, viz. those who are required to carry out training in peace

(Category B), and those who are not required to carry out any training owing to their duties after mobilization being similar to their peace-time professions (Category C). Personnel of both Categories are required for the Royal Engineers, and the Council hope that members of the Institution who are eligible will offer themselves for commissions in that Corps.

Candidates for commissions may be accepted from civil life, from the Regular Army Reserve of Officers, the Territorial Army, or the Territorial Army Reserve of Officers, and the maximum age limits are as follows :—

For appointment as

	Years
2nd lieutenant or lieutenant ..	30
Captain	35
Major	40
Lieutenant-colonel	45

Candidates must have qualified at an Army Entrance Examination or have passed the Matriculation Examination of a recognized university, or produce other evidence of their educational attainments. In addition, candidates will be required to furnish evidence of technical knowledge or qualifications fitting them for duty with the Corps.

Full particulars are given in Army Orders Nos. 284/1924, 285/1924, 286/1924, 287/1924, 299/1924 and 343/1924. Copies of these Orders can be obtained on application to the Secretary of the War Office, London, S.W., and applicants are requested to state that their attention has been drawn to the scheme by the Council of the Institution.

Representatives of the Institution on Other Bodies.

The following is a list of representatives of the Institution on other bodies, and the dates on which they were appointed.

Bradford Public Libraries Committee:
Mr. T. Roles (27 Feb., 1919).

Bristol University:
Mr. H. F. Proctor (6 Dec., 1917).

British Association, Fuel Economy Committee:
Mr. C. H. Wordingham, C.B.E. (9 Jan., 1919).

British Cast Iron Research Association:
Mr. E. B. Wedmore (25 Sept., 1924).

British Electrical and Allied Industries Research Association:
Mr. Ll. B. Atkinson (2 April, 1919).
Mr. F. Gill, O.B.E. (2 Nov., 1922).
Mr. R. T. Smith (30 Oct., 1919).
Mr. C. P. Sparks, C.B.E. (4 Oct., 1917).
Mr. C. H. Wordingham, C.B.E. (4 Oct., 1917).

Sectional Committee on Electric Control Apparatus Research:
Major H. C. Gunton (2 Feb., 1921).
Mr. C. H. Wordingham, C.B.E. (22 Nov., 1920).

British Electrical Development Association:
Mr. F. Gill, O.B.E. (13 Dec., 1923).
Mr. R. Hardie (18 Jan., 1923).
Mr. W. R. Rawlings (17 Jan., 1924).

British Engineering Standards Association:

Main Committee:
Mr. Ll. B. Atkinson (17 Jan., 1924).
Col. R. E. Crompton, C.B. (17 Jan., 1924).
Mr. C. H. Wordingham, C.B.E. (17 Jan., 1924).

Sectional Electrical Committee:
Mr. F. Gill, O.B.E. (21 May, 1914).
Mr. J. S. Highfield (21 May, 1914).
Mr. R. T. Smith (21 May, 1914).
Mr. W. B. Woodhouse (19 Dec., 1918).
Mr. C. H. Wordingham, C.B.E. (18 Nov., 1915).

Sectional Committee on British Standards in Colonial and Foreign Trade:
Mr. C. P. Sparks, C.B.E. (26 Oct., 1916).

Sectional Committee on Colliery Requisites:
Mr. C. T. Allan (3 July, 1924).

Sectional Committee on Illumination:
Prof. W. C. Clinton (28 Feb., 1924).
Lt.-Col. K. Edgcumbe (28 Feb., 1924).
Mr. P. Good (28 Feb., 1924).
Mr. H. T. Harrison (28 Feb., 1924).
Prof. J. T. MacGregor-Morris (28 Feb., 1924).

Sectional Committee on Machine Parts and their Gauging and Nomenclature:
Mr. J. H. Rider (8 Feb., 1917).

Sectional Committee on Petroleum Products:
Mr. H. W. Clothier (1 Feb., 1923).

Electrical Instruments Sub-Committee:
Lt.-Col. K. Edgcumbe (15 Feb., 1923).

Electrical Nomenclature and Symbols Sub-Committee:
Mr. C. C. Paterson, O.B.E. (8 Jan., 1920).

Overhead Transmission Lines Material Sub-Committee:

AUTOMATIC AND SEMI-AUTOMATIC MERCURY-VAPOUR RECTIFIER SUBSTATIONS.

By G. ROGERS, Associate Member.

(*Paper first received* 1st *September, and in final form* 7th *October,* 1924; *read before* THE INSTITUTION 20*th November, before the* DUNDEE SUB-CENTRE 13*th November, before the* NORTH MIDLAND CENTRE 25*th November, before the* WESTERN CENTRE 1*st December, before the* SOUTH MIDLAND CENTRE 3*rd December, before the* IRISH CENTRE 11*th December; before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE 15*th December, and before the* NORTH-WESTERN CENTRE 16*th December,* 1924; *also before the* NORTH-EASTERN CENTRE 12*th January, before the* SCOTTISH CENTRE 13*th January, and before the* TEES-SIDE SUB-CENTRE 5*th February,* 1925.)

SUMMARY.

The paper discusses briefly the principal features of the mercury-vapour rectifier, and describes a number of novel and successful applications of the use of automatic and semi-automatic mercury-vapour rectifier substations, designed for developing an efficient and economical direct-current supply to areas remote from existing sources of supply.

A method is given of feeding into an existing low-tension direct-current network by means of automatically controlled rectifiers for the purpose of improving the voltage and assisting already overloaded feeders. A specific case is considered, and the cost of three methods of dealing with this particular case is analysed.

The three methods considered are:—

(1) By means of new low-tension feeders from existing substations.
(2) By means of one new manually-operated substation and new low-tension feeders.
(3) By means of a number of automatic mercury-vapour rectifier substations.

Arrangements for the automatic and semi-automatic control are given, together with a description of the means adopted for automatically regulating the d.c. voltage.

A method of giving a d.c. supply at 550 volts to a 6-mile length of double-sleeper tramway track by means of semi-automatic rectifier substations is described, and complete details are given with the cost of one of these substations.

Sites and buildings for each of these types of substations are discussed, and general lay-outs are given, with special reference to simplicity, safety and cheapness.

TABLE OF CONTENTS.

(1) INTRODUCTION.

Electric supply authorities are being required to give a supply of electricity in their outlying areas for domestic purposes wherever it is demanded. Rapid development is taking place in town planning; building estates are springing up on the outskirts of our large cities, and are often far removed from available sources of supply. Whatever means are adopted to give a supply to these areas, a large capital expenditure has to be faced, the greater part of which is necessarily absorbed in the feeder and distribution mains. Since it is impossible to estimate the ultimate revenue likely to be drawn from the opening up of new districts, it is desirable to keep the initial expenditure down to the minimum. It would not pay to erect and equip a manually operated substation with costly low-tension feeders to supply a large thinly-populated area, and in such cases it will be found necessary to adopt automatic plant requiring the minimum amount of attention and labour, and to eliminate low-tension feeders where possible.

It is outside the scope of this paper to discuss the advantages and disadvantages of alternating-current versus direct-current supply, but it may be said that where available supplies have a frequency of 40 and over, the problem is simple, as distribution on the four-wire three-phase system is easy, cheap and flexible. The network may be developed where required, by means of static transformer substations, and the cost of a low-tension distributing system can be kept to a minimum. Direct current, however, has distinct advantages over alternating current for domestic supplies for cooking and power purposes.

On the other hand, where the supply is generated at 25 periods, a.c. supply at this frequency is, in the opinion of the author, unsatisfactory for domestic purposes and it becomes necessary to convert to direct current or to change the frequency by means of frequency-changers. Converting by means of rotary converters or any other form of rotary plant is too expensive for outlying districts, owing to the high costs of labour and the skilled attention required. Automatic rotary-converter substation equipments of small capacities will be too expensive. To put down one large automatic rotary-converter substation at some central point and feed out to considerable distances by means of low-tension feeders would prove very expensive, owing to the large capital that it would

be necessary to sink in copper. The obvious solution is to put down small automatic converting substations at points where the load is required, and to make them as near as possible comparable with the a.c. distribution mentioned above.

Greater Birmingham had to face the problem described above, and after preliminary investigations and tests the city electrical engineer, Mr. R. A. Chattock, decided to develop a system of small automatic substations equipped with mercury-vapour rectifiers of the glass-bulb type. This was a bold course to take, since there were not in existence any similar type of substations designed to give a three-wire d.c. supply. The series of substations described later in this paper were the first of their kind to be equipped in this country.

(2) The Principal Features of Mercury-Vapour Rectifiers.

The mercury-arc or mercury-vapour rectifier is an apparatus for transforming, statically, alternating current into direct current. The different forms of rectifiers now on the market are developments of the small glass-bulb rectifier introduced by Mr. Cooper Hewitt in the United States some 20 years ago.

The non-return valve action of the arc, when operating in a vacuum under certain temperature conditions, allows the current to flow in one direction only, viz. from the anode to the cathode, the cathode bath of mercury being the positive pole of the d.c. circuit.* An anode is provided for each phase of the current that is to be rectified. The negative d.c. pole is coupled to the star or neutral point of the three-phase a.c. transformer through a reactance.

Brown-Boveri Rectifier.

This apparatus has been fully described in the technical Press and is familiar to most engineers.

Vacuum.—The vacuum in the steel cylinder is obtained and maintained by means of a special exhaust pump. The extent to which the pump has to be used varies with particular sets. The pump of the set referred to in this paper has to be used only once a week when half load is not exceeded, but above half load it has to be continually in service.

Forming.—In this type of rectifier, after erection it is necessary for the anodes to be formed, and the operation of forming after the vacuum has been obtained takes approximately two weeks.† This process consists of heating up the anodes one by one by means of current passed through them to the cathode. The value of the current is gradually increased until something more than normal full load has been passed.

The effect is to eliminate any gases that might be given off from the material forming the anodes, which gases under working conditions might cause an internal flash-over or "backfire" due to the vacuum being temporarily destroyed on a portion of the surface of the anode. During this process the pump is kept working continuously. Current may be passed from the anodes to the cathode by means of a suitable resistance across the d.c. terminals of the rectifier or, better still, by means of some external source of supply such as a low-voltage booster. Again, if the set has been out of service for more than 24 hours it is necessary to re-form the anodes;* this operation takes about half an hour and must be done by manual operation. This is a drawback to this pattern of rectifier, which otherwise lends itself admirably to a simple form of automatic control.

Cooling.—Water cooling is adopted for the anodes and for the main cylinder, and this method is quite efficient. 70 gallons of water per hour are required for the set described in the paper. The apparatus has been found to be reliable in operation, and the maintenance costs are low.

Capacity.—Cylinders are now built each capable of giving up to 1 500 amperes (d.c.) at 600 volts.

Hewittic Rectifier.

This rectifier is of the glass-bulb type, the vacuum being permanent.

Cooling.—Fan cooling is adopted, the fan being placed under the bulb and blowing air across it. No special forming has to be done after delivery. Bulbs may readily be put into service almost immediately on completion of erection. Also, no forming is subsequently required, however long the bulb has been out of service. This is a very useful feature.

Life of bulbs.—The lower-voltage glass bulbs have a much better life than one would expect. Provided a bulb survives transit—and very few are damaged—and proves satisfactory in service for a few days, its life is extremely long.

The sealing of the incoming leads has been brought to a very high state of efficiency, and bulbs are still in service that have been running on load for over 8 000 hours—25 per cent of this period being on full load. The higher-voltage bulbs (460–600 volts) also give long service, but experience shows that they do not have such a long life as the lower-voltage bulbs. The percentage of failures is naturally higher.

Automatic operation.—The automatic operation and control of this type of rectifier is comparatively simple, and the particular cases dealt with in the paper indicate how readily they adapt themselves to this purpose.

Capacity.—Bulbs are now made each capable of giving 150 amperes up to voltages of 600. By arranging bulbs in parallel any capacity of plant may be obtained.

Short-circuits.—When a short-circuit occurs in the steel cylinder of the Brown-Boveri rectifier or in the glass bulb of the Hewittic rectifier when the vacuum fails, it is very severe. In both types of plant under the author's observation, however, short-circuits have been few in number, and in the case of the glass bulbs for 230 volts no single instance of a short-circuit has occurred.

(3) Automatic Operation and Control of a 220-kW Brown-Boveri Rectifier Working in Parallel with a Three-wire Battery for Balancing Purposes.

This type of mercury rectifier has been fully described in the electrical Press.† This set was first installed for manual operation, but later was equipped for auto-

* For further particulars see *Electrical Review*, 1921, vol. 88, pp. 217 and 251, and *Engineering*, 1923, vol. 116, pp. 507 and 543.

† By the latest method of forming this period is now reduced to 4–6 days.

* The latest plant does not require this process, and the disability referred to does not apply.

† *Loc. cit.*

matic control. It is connected to a 5 000-volt, three-phase, 25-period supply, and gives direct current at 460 volts across the outers of a three-wire network. Fig. 1 is a complete wiring diagram of the automatic

It will be seen that by means of selector switches the rectifier can be left running continuously on the system and, under these conditions, will be automatically disconnected from the busbars in the event of a fault

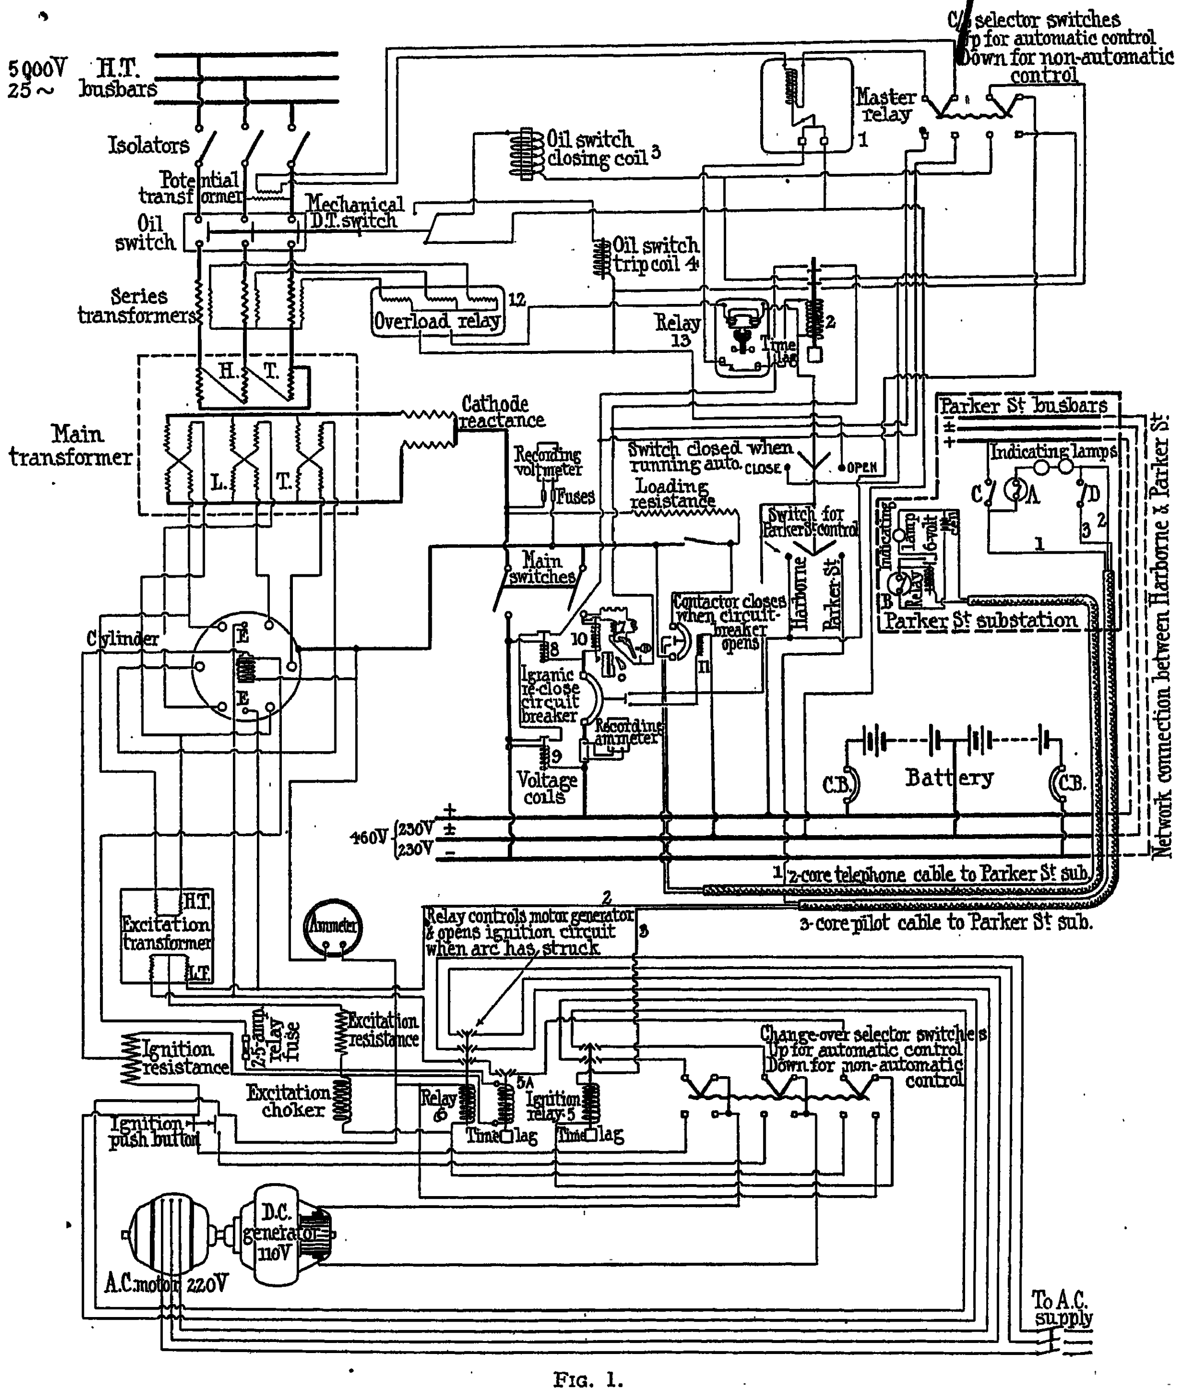

FIG. 1.

arrangements developed step by step until the necessary control was completed. The rectifier has been running now with this control for over two years, and no trouble whatever has been experienced with the set.

or a failure of the e.h.t. supply, and restarted as soon as conditions are again normal. It can also be arranged for remote control from another substation through pilot wires, in which case the rectifier can be started up and shut down at will, and while running will be auto-

matically disconnected and reconnected in case a fault develops, as in the first condition. By the simple addition of a voltage relay and a minimum-current relay, or by the addition of time switches, the set can be made entirely automatic in its operation.

The operation of the control gear is as follows, the action of the relays being described in their proper sequence of operation :—

(1) A master relay switch operated by the secondary of a potential transformer, which when energized closes the circuit operating relay (2) and, when de-energized due to failure of the a.c. supply, clears the set from the a.c. and d.c. busbars.

(2) A time-limit relay which, when energized, closes contacts operating oil-switch-closing solenoid (3) and, when de-energized, closes contacts which operate oil-switch-tripping solenoid (4). An interlock on this relay prevents the d.c. breaker from being closed or remaining closed when this relay is de-energized.

Immediately the oil switch closes, the pump and the ignition converter start up.

(5) The ignition relay which, when energized through interlocks on relays (5A) and (6), closes the ignition arc circuit. The action of this relay is delayed 10 seconds to allow the ignition motor-generator to become fully excited.

(5A) If the ignition arc fails to strike, this relay comes into operation and de-energizes (5), when the operation is repeated with an "in and out" movement until ignition is obtained.

(6) The coil of this relay is in series with the excitation circuit and operates immediately the ignition arc has been struck by relay (5). When energized, the relay shuts down the ignition motor-generator and de-energizes relay (5). The rectifier, after this operation, is ready for load on the d.c. side, and the d.c. breaker (an Igranic reclose circuit breaker) will now close and parallel the set to the busbars, provided that the voltage across the rectifier terminals is correct and the d.c. busbar voltage is not too high.

The closing coil of the d.c. circuit breaker is connected through an interlock on relay (2) and is also controlled by the adjustable voltage coils (7), (8) and (9).

(10) A series coil which opens the d.c. circuit breaker on overload. The operation of this coil is limited to three times, after which it remains open until reset by hand.

(11) A contactor which closes the loading resistance circuit when the d.c. circuit breaker opens.

(12) A three-phase inverse time-limit overload relay the operation of which shuts down the set.

(13) A relay which is operated by the action of relay (12) and prevents the oil switch being closed until reset by hand.

For remote control, the supply to relay (2) is provided by means of one core of a pilot cable through a control switch, and the coil circuit of ignition relay (5) is looped through pilot wires to a switch at the control substation.

The lamps shown on the control substation end clearly indicate :—

(1) When the oil switch closes or opens.

(2) When the excitation arc is struck.

The opening or closing of the d.c. circuit breaker is indicated by the low-voltage lamp connected to two cores of a telephone cable.

(4) Small Automatic Three-wire Rectifier Substations for Outlying Areas, Housing Schemes, Etc.

Fig. 2 shows an outline map of the Birmingham area, indicating the position of the generating stations, the existing manually-operated rotary-converter substations and the position of the rectifier substations in the outlying areas, each having its own distributing network.

These outlying areas are comparatively thinly populated. A 5 000-volt three-phase ring main passes through this area, looping into the various substations. Connections have also been made to other existing ring mains in the area.

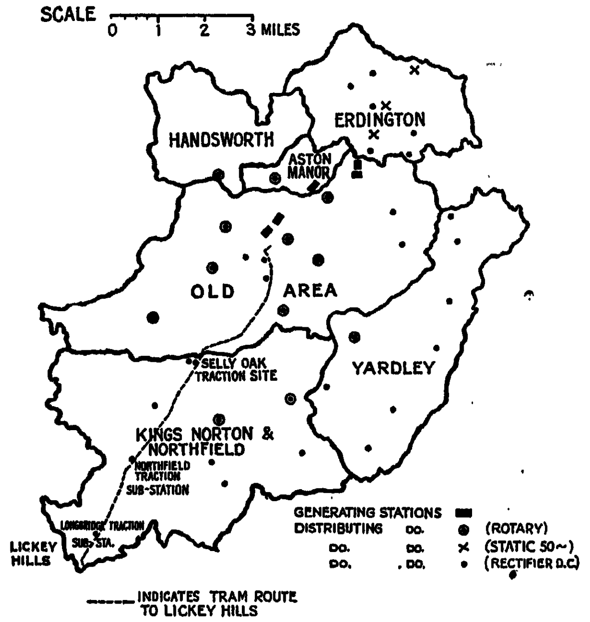

Fig. 2.—Map of Greater Birmingham, showing position of rectifier substations.

It was decided to commence operations with a three-wire unit having a capacity of 46 kW, the transformer supplying the two 23-kW rectifiers being designed for an ultimate load of 92 kW. Two 100-ampere 230-volt bulbs were connected in series across the outers of the three-wire network, the neutral or third wire being connected between them; and later, by the addition of two further bulbs of the same capacity in parallel, the unit was brought up to its full capacity of 92 kW.

Certain of these substations have already been brought up to the 92 kW capacity, owing to the rapid growth of the demand in these areas. Fig. 3 shows this development over a period of 12 months.

Provision is made in each case for an extension to the building when necessary. It is proposed to install in the extension a unit having a capacity of 138 kW, making the total capacity of each of the small substations 230 kW. This extra capacity has now been added in several cases and is likely to be enough for any particular area. When the full capacity of the

station has been reached, it is intended to develop areas in the district by means of further similar substations.

Lay-out of plant.—Fig. 4 shows the general lay-out of the plant in one of these substations. It will be seen that the dimensions of the substation have been kept

arrangements of the rectifier. It will be seen that the high-tension feeder is looped into the substation, the oil switches being non-automatic in operation.

The transformers, on the other hand, are protected by overload coils in each phase. Leakage protection is also provided by means of a current transformer in

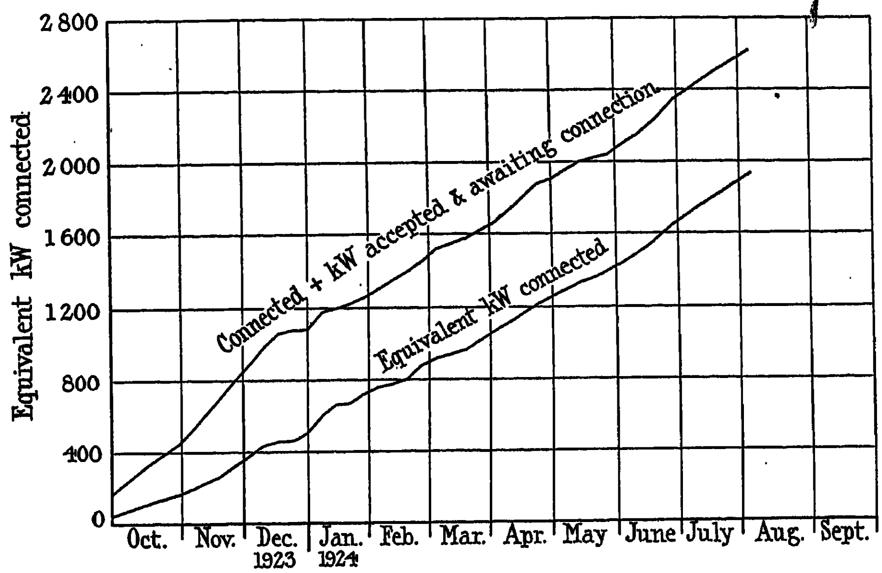

FIG. 3.—Curves showing progress of demand (mostly domestic load) in new districts opened up by means of rectifier substations.

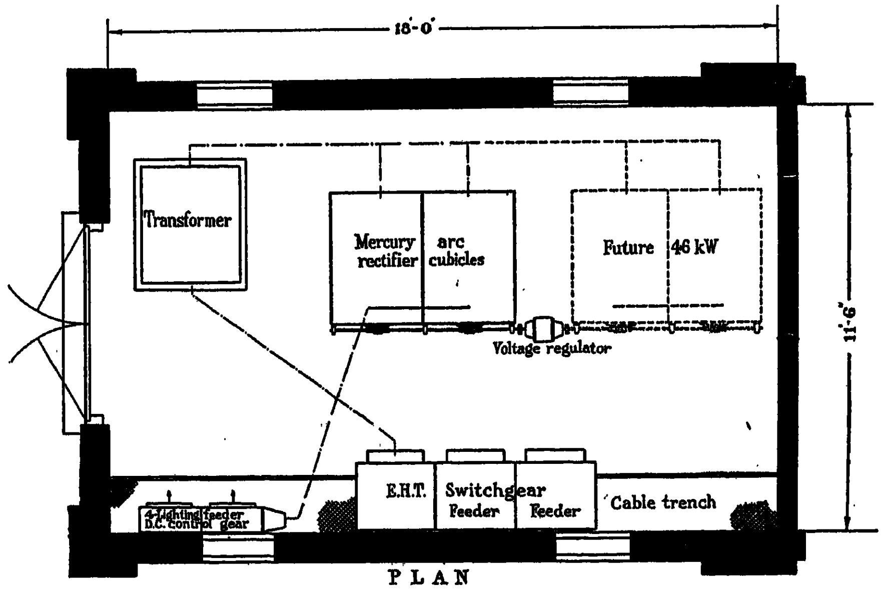

FIG. 4.—Lay-out of 46-kW 3-wire rectifier lighting substation.

as small as possible, due regard being given to ample passage ways and easy removal of the plant.

The rectifier cubicles are totally enclosed and no live parts are exposed. The high-tension and low-tension switchgear is also totally enclosed, and every care is given to provide safety and simplicity in operation.

Fig. 5 shows the general electrical connections in a complete substation, but does not include the internal

the "earth" connection of the transformer tank. A leakage of 2 to 3 amperes to earth is sufficient to cause the main oil switch to open. The current passing through the current transformer operates a special relay which, in turn, closes the trip circuit energized from the 230-volt circuit.

The rectifier itself is equipped with automatic gear which, in the event of a failure of the a.c. supply, will strike the ignition arc in the bulbs when this is restored,

and resume the supply to the external d.c. circuit. No automatic switchgear is provided on the d.c. side. Each connection to the distributing network is pro-

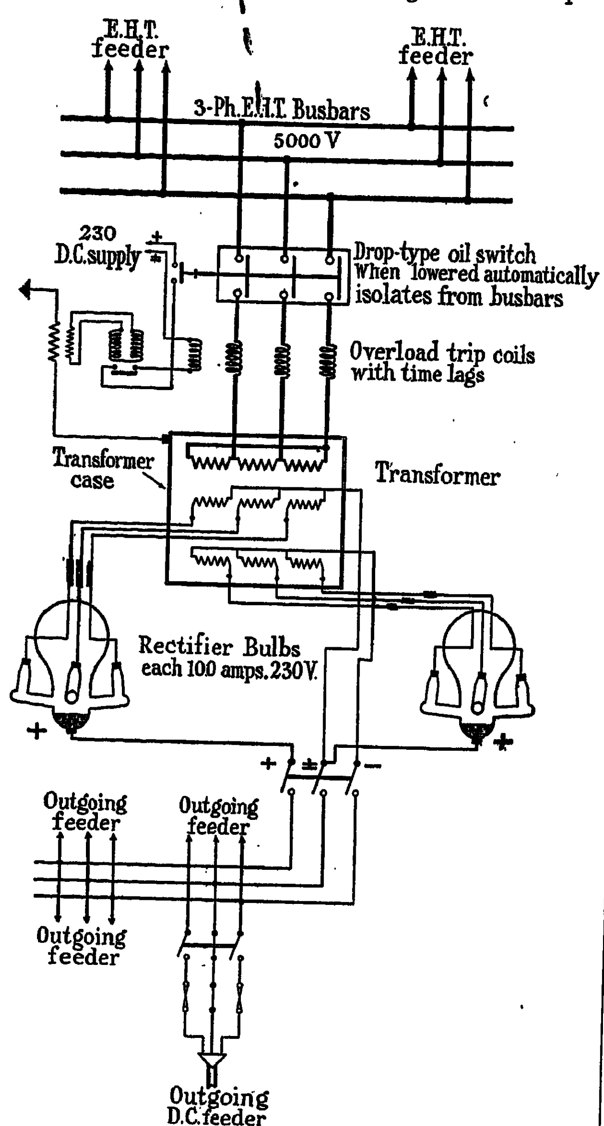

FIG. 5.—Diagram of connections of 46-kW 3-wire lighting and power rectifier substation.

tected by means of fuses. It may be necessary later to equip each of the rectifiers with a reclose overload circuit breaker, but up to the present it has not been found necessary on the small sets.

Efficiency and power factor.—The efficiency and power factor of a 92-kW three-wire rectifier equipment are shown in Fig. 6 (*a*). The complete cost of one of these substations, including plant, building, cabling and erection, is given in Appendix 1.

Cabling.—The cabling throughout is lead-covered, and the high-tension supply to the transformers is given by means of either a three-core armoured cable with the necessary sealing boxes at either end, or lead-covered single-core cables. All internal wiring and cabling of the rectifier equipment is of fireproofed cable.

Voltage regulation.—The d.c. voltage of a mercury-vapour rectifier is directly proportional to the a.c. voltage supplied to the anodes of the bulb. It follows, therefore, that in addition to the voltage-drop of approximately 5 per cent from no load to full load, there may be variations due to the variations in the a.c. pressure. If, as in this particular case, the ring-main feeder is fed from the same feeders that supply large power consumers, such variations may be fairly large. To meet this, an arrangement has been developed to operate the voltage regulator automatically. The rectifiers are provided with a regulating transformer having a number of tappings, and by means of sliding contacts the voltage of the supply to the anodes may be varied.

Fig. 7 is a facsimile of two voltage charts, one with no regulation and the other with the automatic voltage regulator in service. The electrical connections for the complete automatic control of the voltage regulator are shown in Fig. 8.

The operation of the automatic regulator gear is as follows :—

A voltage relay (1) connected across the d.c. terminals of the rectifier closes either of a pair of contacts at predetermined maximum and minimum voltages. The relay may be set to operate with any degree of closeness required.

The closing of either relay contacts energizes one of two solenoids (2), which in turn operates an arm carrying a set of contacts (2*a*). Each arm carries three contacts, two of which control the supply to the small operating motor (3) and are closed when the solenoid is energized, and one which short-circuits the armature of the motor when the solenoid is de-energized. The two solenoids are mechanically interlocked so that only one can operate at a time.

Each arm is also equipped with a time-lag (4) which prevents the operation of the motor due to a momentary change in voltage. The operation of one solenoid causes the motor to revolve in the forward direction,

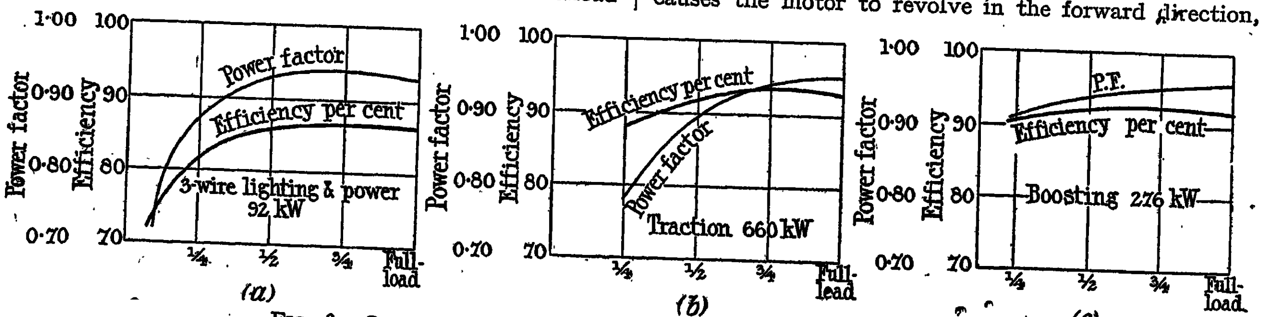

FIG. 6.—Curves of power factor and efficiency taken from tests.

and the operation of the other solenoid causes the motor to revolve in the reverse direction.

The motor shaft is connected directly to the operating spindle (5) of the regulator by means of worm reduction gearing. After either of the solenoids has been energized by the voltage relay, the motor continues to revolve until one complete revolution of the regulator spindle has been completed, whether the contact of the voltage relay (1) has opened circuit or not. At the end of each complete revolution the motor armature circuit is opened by means of a contact (6) on the spindle. If the contact of the voltage relay is still further closed, the motor will continue to make further revolutions, raising or lowering the d.c. voltage until the said contacts break the circuit.

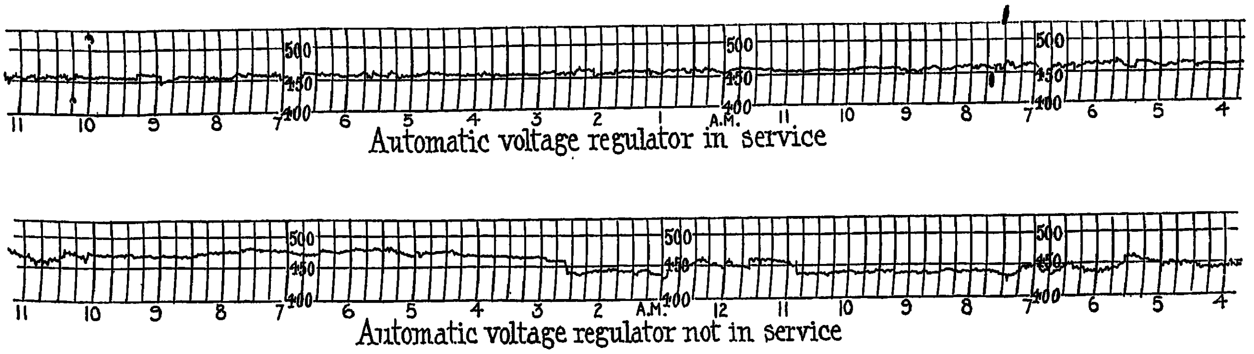

FIG. 7.

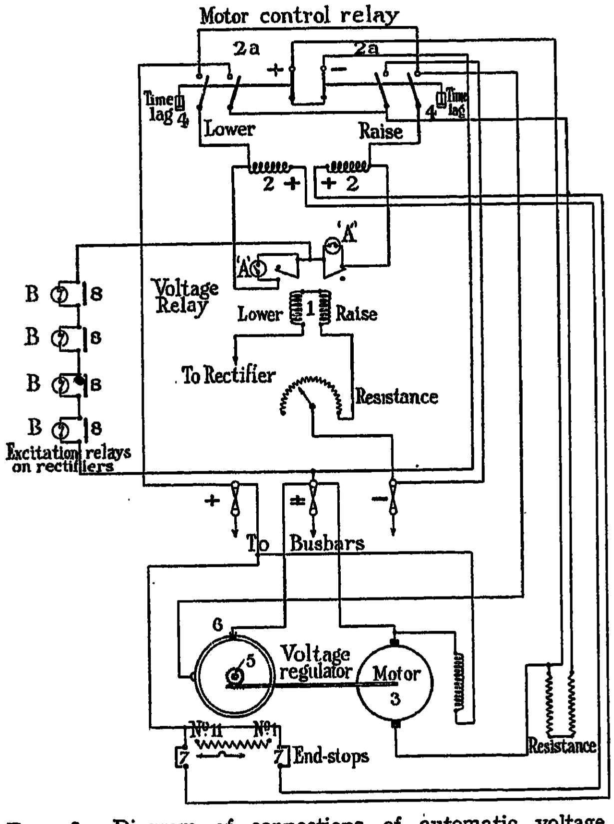

FIG. 8.—Diagram of connections of automatic voltage regulator (shown connected to one rectifier only).

End-stop switches (7) open the motor circuit by de-energizing solenoid (2) at the end of the travel to prevent over-running. The supply to the motor is so interlocked with the excitation relay (8) of each rectifier bulb that a failure of a.c. pressure or a failure of any one bulb opens the motor circuit.

Switches (A) are provided in the voltage relay circuits to allow of the operation of the regulator independently of the voltage relay, and switches (B) are also provided in the excitation relay circuit to close the interlock on any one bulb or pair of bulbs if not in service.

Suitable resistances are provided in the relay and operating motor circuits.

No attempt is made to balance the voltage of the two sides, care being taken to balance the external load as nearly as possible. It would be possible, however, to arrange for independent voltage regulation of the two halves of the three-wire set. Some 15 of these substations have now been put into service and the total capacity of the plant installed is approximately 1 850 kW.

Provision is made for earthing the neutral of the three-wire system at each of the substations. In practice two or more substations are in parallel through the network, the networks being connected solid on the neutral and through fuses on the outers.

(5) AUTOMATIC BOOSTER RECTIFIER SUBSTATION FOR FEEDING INTO EXISTING D.C. NETWORKS.

Many supply undertakings are now finding their existing d.c. feeders from the generating stations and rotary substations overloaded on the peak. Many of these feeders have been run out to considerable distances, with the result that when loaded up there is a big drop in voltage, necessitating the use of special boosters. The use of boosters is very inefficient, and to deal satisfactorily with large currents and big voltage-drops involves boosters which are very expensive pieces of apparatus. To deal with the load, it becomes necessary either to lay new feeders or to build and equip new substations. One method of solving this problem was described in a paper * read before the Institution by Mr. P. J. Robinson, of Liverpool. This method was to install automatic rotary-converter substations feeding direct into the net-

* *Journal I.E.E.*, 1923, vol. 61, p. 417.

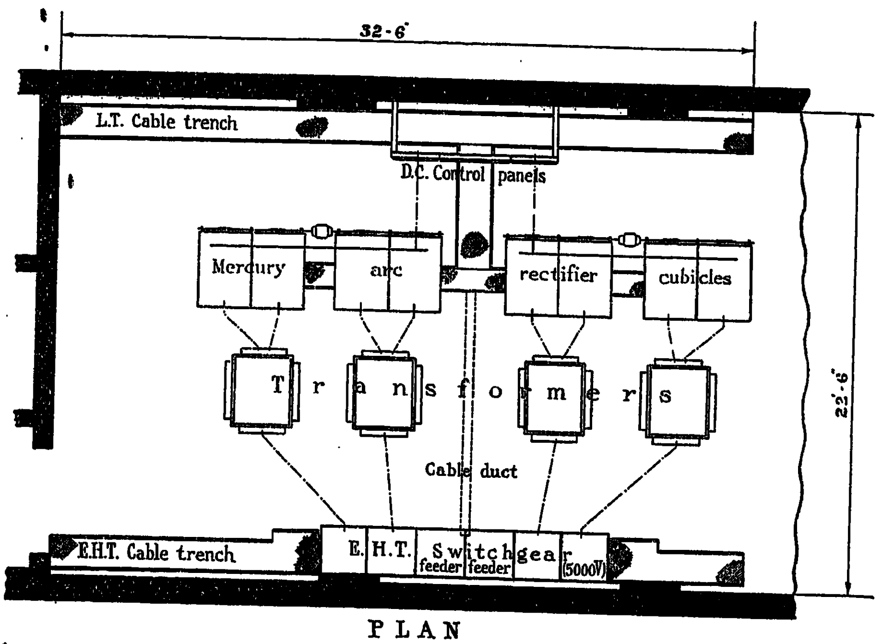

FIG. 9.—Lay-out of completely automatic substation consisting of two units each of 276-kW feeding into existing networks.

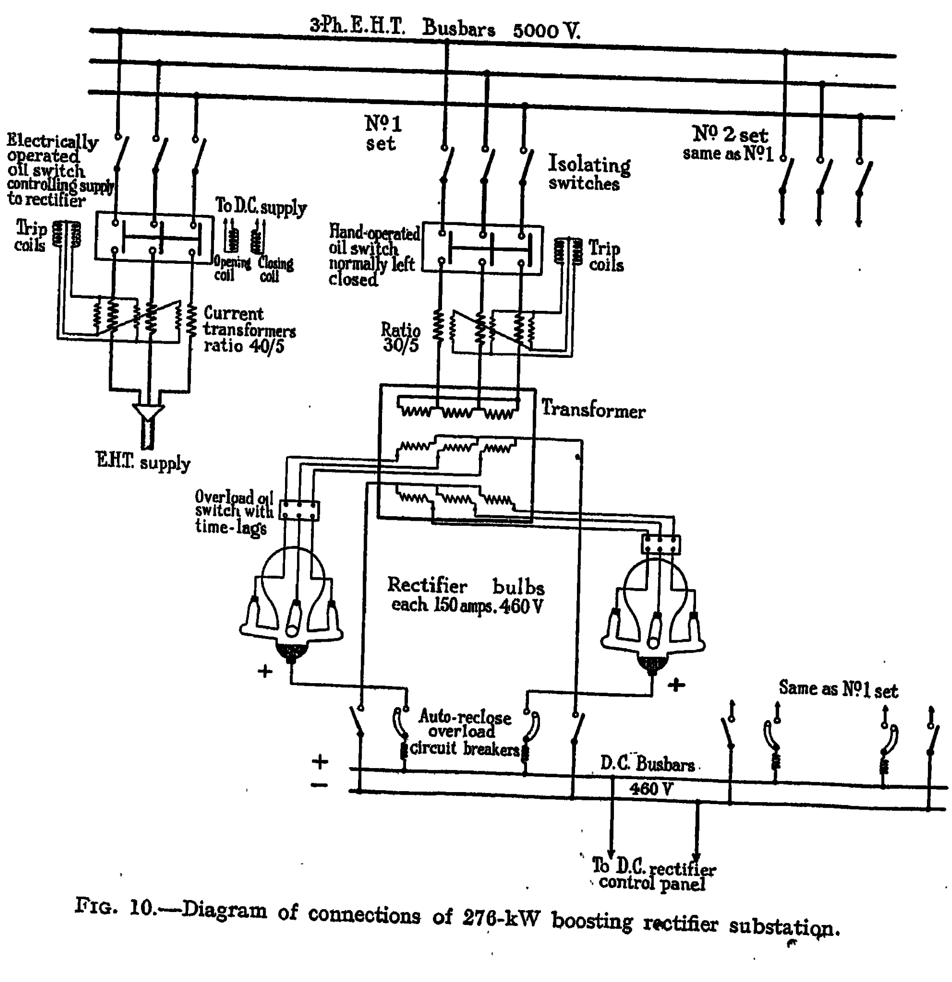

FIG. 10.—Diagram of connections of 276-kW boosting rectifier substation.

work at points of low pressure, and so to relieve overloaded feeders.

In Appendix 2 a particular case is taken, giving the estimated cost of three possible methods of dealing with the problem of overloaded feeders and bad pressures, and this shows a considerable saving in favour of the mercury-vapour rectifier equipment. It was decided to erect four small substations, each equipped with mercury-vapour rectifiers, having a capacity of 276 kW (that is, 600 amperes at 460 volts), feeding across the outers only, at a point in the network suitable for relieving the overloaded feeders and for improving the voltage. Each unit is made up of four 150-ampere bulbs (two per transformer) connected in parallel. In each case the overloaded feeder was 1 square inch in cross-section, and the rectifier substation was therefore capable of taking up

overload protection and recloses after a definite time interval when the overload condition is removed.

The method of starting up and shutting down the set as required is comparatively simple and follows the practice adopted for automatic rotary converters. It is, however, much simpler and requires a much smaller number of relays. The diagram of connections is shown in Fig. 11.

Starting Up.

(1) A master relay energized from a potential transformer across the high-tension supply which allows the following sequence of operations to take place only if the a.c. supply is normal. When the a.c. supply is normal, contacts (1*a*) are open. When closed the operation of relay (2) is prevented.

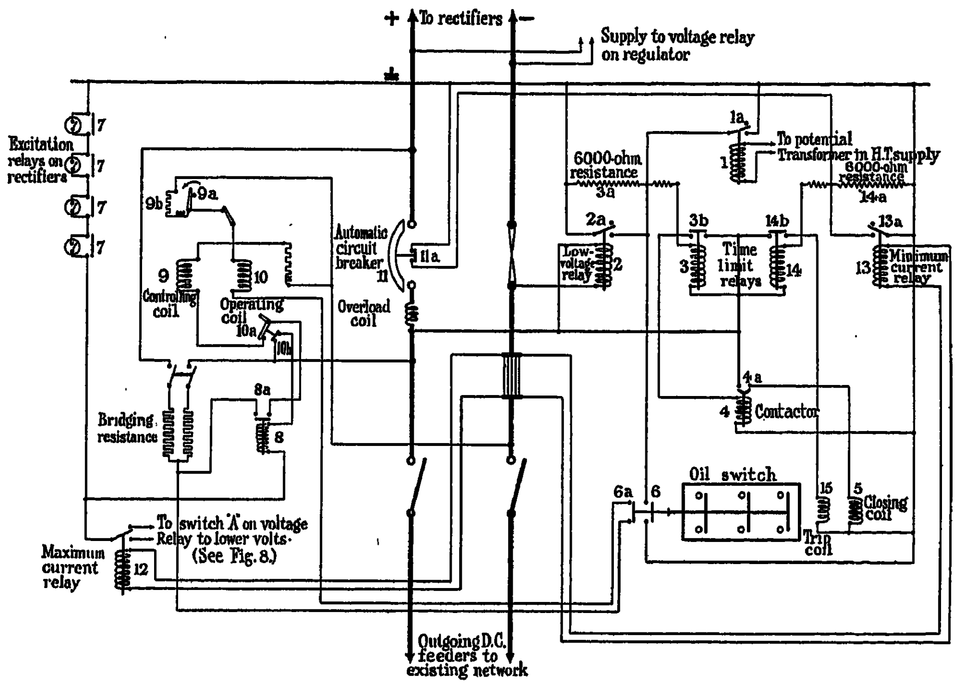

FIG. 11.—Diagram of connections for automatic control of one 276-kW 2-wire rectifier set.

approximately half-load on the peak. The plant in each of these substations is designed to be entirely automatic in its operation.

A typical lay-out of the plant in a substation containing two of these units is shown in Fig. 9; and the power factor and efficiency of one complete unit are shown in Fig. 6 (*b*).

The arrangement for controlling the voltage of the set is exactly the same as that already described for the small rectifier substations (Fig. 8).

Fig. 10 shows the main connections and the protective gear provided for each 276 kW unit. The e.h.t. supply to each transformer is controlled by means of a hand-operated oil switch provided with overload coils in each phase. These switches are normally left closed. The supply to the pair of transformers is controlled by an electrically operated oil switch, also provided with overload protection. The d.c. circuit breaker is provided with

(2) A voltage relay which opens contact (2*a*) when the voltage across the d.c. feeder falls to a predetermined value. The opening of contact (2*a*) de-energizes (3) a time-delay relay by inserting the high resistance (3*a*) in the relay coil. The contacts (3*b*) now close after a time interval (adjustable up to 5 minutes) which energizes (4) a contactor solenoid, causing the contact (4*a*) to close, which in turn closes the main oil switch supplying the transformer by energizing (5) the closing coil of the oil switch.

(6) An auxiliary switch which closes when the oil switch closes and which short-circuits the resistance (3*a*), again energizing the time-delay relay (3). The contacts (3*b*) open and the contactor (4) is de-energized, opening the closing-coil circuit. The transformer or transformers supplying the rectifier bulbs are now charged and the bulbs will tilt and strike the arc by the operation of the starting relays.

As soon as the excitation arc has been struck in all bulbs, the contacts (7) close. These contacts (one for each bulb) are in series, and can be short-circuited by (8a) close which in turn energize (9) the controlling coil of the auto-reclose circuit breaker. This circuit breaker is an Igranic reclose circuit breaker which is self-con-

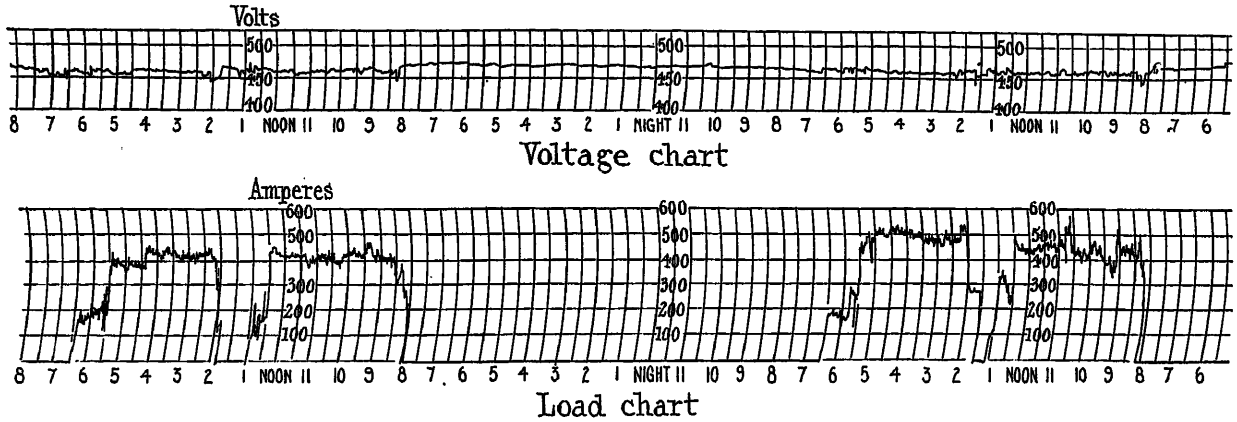

Fig. 12.

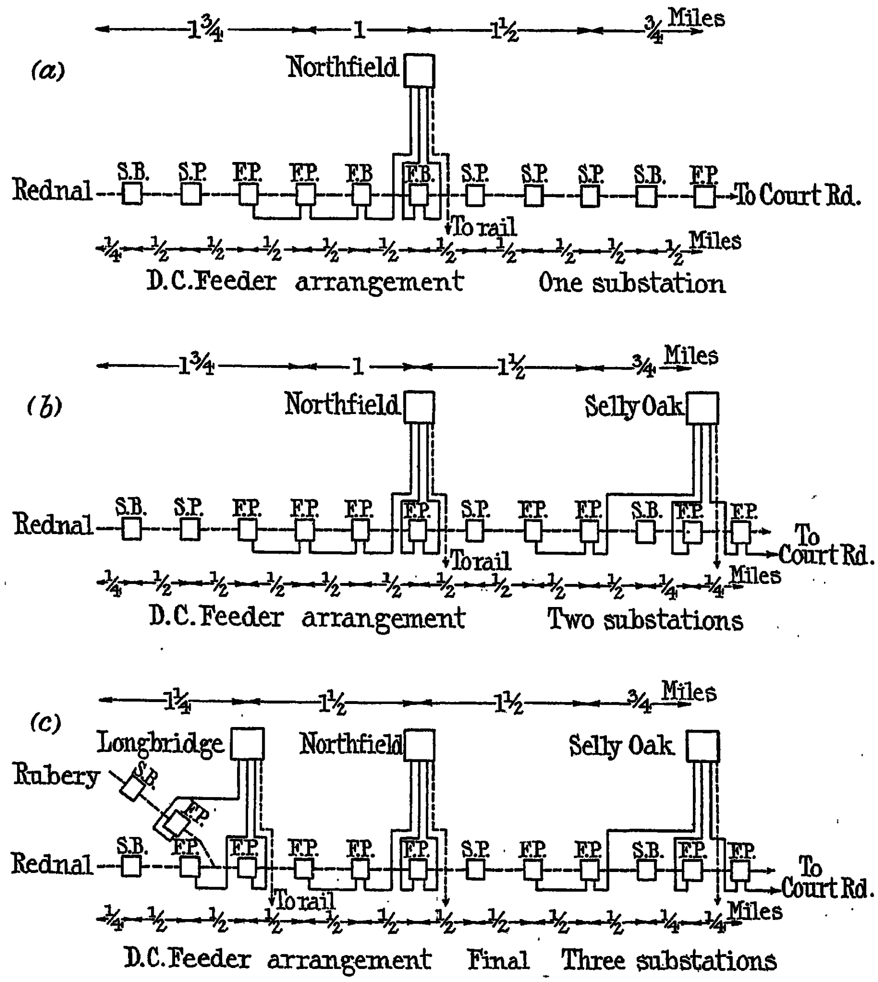

Fig. 13.

means of a switch in order that one or more bulbs can be cut out if not required.

(8) A solenoid relay is now energized and the contacts tained. Its function is to parallel the rectifier bulbs to the d.c. feeder supply. It is in the positive pole, the negative pole of the rectifier being connected to the

feeder negative through a knife switch and fuse. Its operation is as follows :—

The controlling coil (9), when energized, closes contacts (9*a*). This short-circuits the resistance (9*b*) and in turn energizes the operating coil (10) which closes the circuit breaker (11). The closing of the circuit breaker opens contacts (10*a*) and (10*b*) which de-energize the controlling coil (9) and the relay (8) respectively.

The operating coil of the breaker is also interlocked through contacts (6*a*) with the high-tension oil switch.

The voltage relay now comes into operation and adjusts the rectifier voltage to the particular setting of the relay. (The connections of the voltage regulator are shown in Fig. 8.)

A further relay (12), a maximum-current relay, comes into operation when the full load is exceeded, and operates to lower the voltage.

busbars and the d.c. positive circuit breaker is disconnected from the d.c. feeder, and the set will start up again when the d.c. voltage of the feeder falls low enough to operate the low-voltage relay (2), subject to the a.c. pressure being normal.

A typical load and voltage curve over a period of two days is shown in Fig. 12.

(6) Semi-Automatic Traction Substations.

An extension to the Selly Oak overhead tramway route from Selly Oak to Rednal and Rubery, a distance of approximately 5 miles (see Fig. 2), had to be supplied with current at 550 volts. The Selly Oak end of the existing route was about $2\frac{1}{2}$ miles from the nearest manually-operated rotary substation, and it was from this substation that the existing route received its supply.

Very heavy traffic was to be expected on this route at

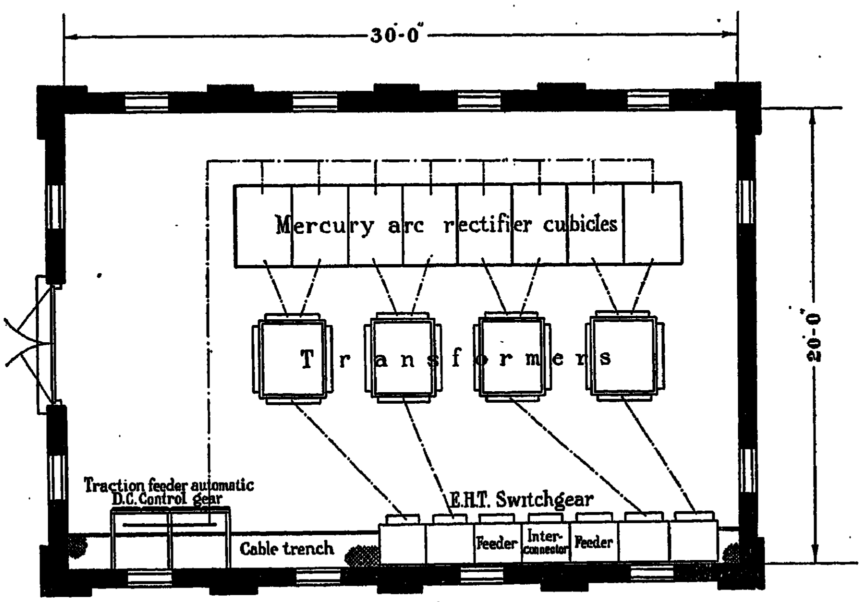

Fig. 14.—Lay-out of 660-kW rectifier traction substation.

The d.c. circuit breaker is set to operate on overload, reclosing after a definite time interval, provided that the excessive overload conditions are removed.

Shutting Down.

When the load falls to a predetermined value, relay (13), a minimum-current relay operated from a shunt in the feeder circuit, opens its contacts (13*a*) and de-energizes (14) a time-delay relay by inserting resistance (14*a*) in the coil circuit.

After a definite time interval, contacts (14*b*) close and energize (15) the trip coil, which causes the main high-tension oil switch to open.

The auxiliary switch (6*a*) opens when the oil switch opens and causes the d.c. circuit breaker to open.

Also, the opening of the d.c. circuit breaker closes the auxiliary contacts (11*a*), resetting the time-delay relay (14) by short-circuiting the resistance (14*a*).

The rectifier is now disconnected from the high-tension

holiday times and at week-ends during the summer, and it was necessary to provide plant and feeder cables capable of dealing with a half-minute service of cars. In addition to this holiday load, however, which would occur on only a comparatively few days in the year, there was a certain amount of rush traffic at certain times of the day. It will be clear, therefore, that for the greater part of the day and year a big proportion of the plant necessary to deal with the rush traffic would be idle.

It was obviously impracticable to supply the new route by means of new feeders run out from the existing substation, owing to the high cost involved. To build and equip a new manually-operated rotary substation somewhere on the new route would also have been prohibitive in capital and running costs. It was clearly a problem which admitted of only one solution, namely, automatic or semi-automatic plant which would require the minimum of labour and running charges.

After much consideration and comparison of the costs.

of various types of plant, it was decided to put down ultimately three substations, one at Selly Oak, one at Northfield, and one at Longbridge. Each of these substations has plant installed of a total capacity of 660 kW, making a total of 1 980 kW for the three substations.

Fig. 13 (*a*) shows the feeding arrangements when the Northfield substation was put in service. Fig. 13 (*b*) shows the second position when the Selly Oak substation was put into service, and Fig. 13 (*c*) shows the complete scheme with the three substations and the feeder arrangements from each substation. It will be seen that the negative return feeder is connected to the rails immediately outside the substation in each case. This arrangement enabled the cost of the d.c. traction feeder system and also the rail voltage-drops to be kept to a minimum, without undue expenditure on negative feeders.

The plant decided upon was the mercury-arc rectifier of the glass-bulb type. Each substation is equipped with eight rectifier bulbs, each giving 150 amperes at 550 volts. Each pair of these is supplied from one transformer, making use of the six phases of star-wound three-phase secondary windings. The complete unit of 660 kW capacity consists of four transformers, each supplying two bulbs in parallel. This arrangement gives great flexibility, since it is possible to run with any number of the bulbs in parallel. In the event of one transformer breaking down there is still 75 per cent of the plant available for service.

The high-tension supply to the substations is 25-period, three-phase, at 5 000 volts. The high-tension switchgear used is the same type as that used in the three-wire lighting stations. The lay-out of the plant in one of the substations is shown in Fig. 14. It is so arranged as to make the cabling as simple and as short as possible. All the rectifiers feed into a common positive busbar through Igranic reclose circuit breakers. The positive busbar is connected to the control panel for the low-tension traction feeders by means of cable. Each low-tension traction feeder is controlled by means of an Igranic reclose circuit breaker through a disconnecting switch of the knife pattern and a choking coil. This arrangement of control is shown in Fig. 15.

The control of this substation is only semi-automatic, it being the practice to leave the necessary number of sets running to supply the ordinary load and to switch in additional sets when required for extra load. The transformers are protected by means of series overload coils in the high-tension switchgear. Further protection for the transformers is obtained by means of a leakage relay placed in the earth circuit of the transformer. A small leakage of 2–3 amperes to earth from the transformer windings is sufficient to open the main oil switch.

The series overload coils are fitted with a time-lag which is so adjusted that in the event of any trouble on the d.c. side of the plant the low-tension switches would have a chance of operating first.

The low-tension secondary connections from the transformers to the rectifiers pass through special three-phase oil circuit breakers, also fitted with a time-lag. The d.c. Igranic circuit breaker in each rectifier gives further automatic protection in that it is designed to operate on overload and will reclose when the overload condition has been removed.

The main automatic features, however, are on the outgoing feeders themselves. The circuit breakers controlling these feeders are arranged to open instantly on a predetermined overload and will reclose after a definite time interval, provided that the overload conditions have been removed. These switches act perfectly and operate on overload or external short-circuits before

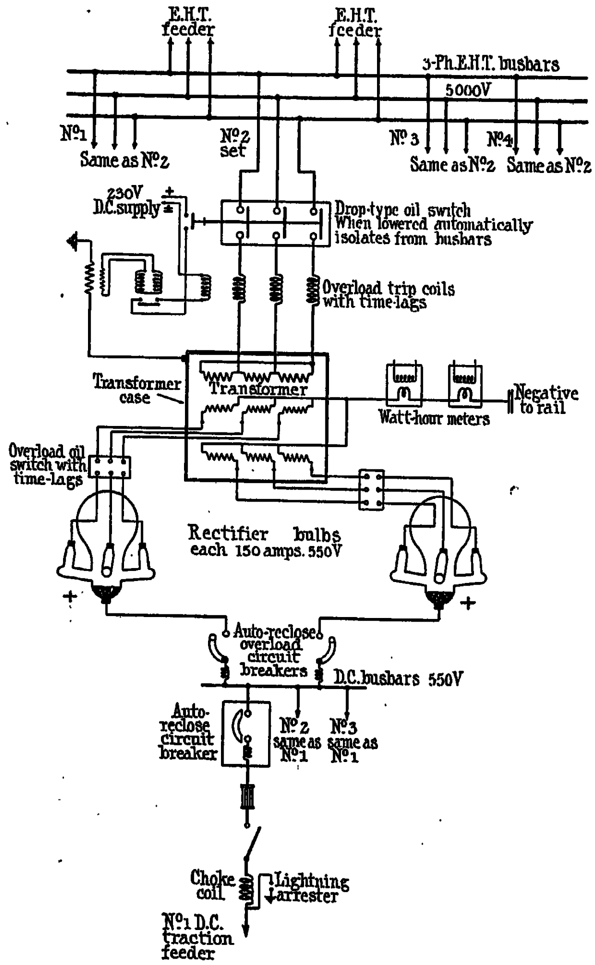

FIG. 15.—Diagram of connections for traction feeder substation (one set only).

any of the other protecting gear in circuit with the supply can operate. In the event of an overhead wire breaking down, the circuit breaker controlling the supply to that particular section will open and will not close again until the "earth" has been removed. Instantly the wire has been removed from the ground, the circuit breaker closes and the overhead wire is again made alive. Special instructions in this connection have been issued to the Tramway Department for the protection of their men.

In the event of a failure of the high-tension supply pressure, no switches will operate in the substation except the low-tension feeder and rectifier control switches if the station is isolated from any other supply,

and when the high-tension supply is restored the sets will automatically be started up and the supply restored to the d.c. feeders. This arrangement has up to the present worked perfectly satisfactorily, and every part has functioned correctly.

(7) Sites and Buildings.

Sites.—It is not a very difficult matter to obtain a suitable site for a comparatively small building on the outskirts of a city. Land belonging to the public authorities should first be exploited for possible sites; quite a fair percentage of the substations in Birmingham are erected on Corporation property belonging to other departments. Some are erected in the school playgrounds, and others in the grounds belonging to the Water Department. Failing a suitable site to be mutually arranged with other departments in this manner

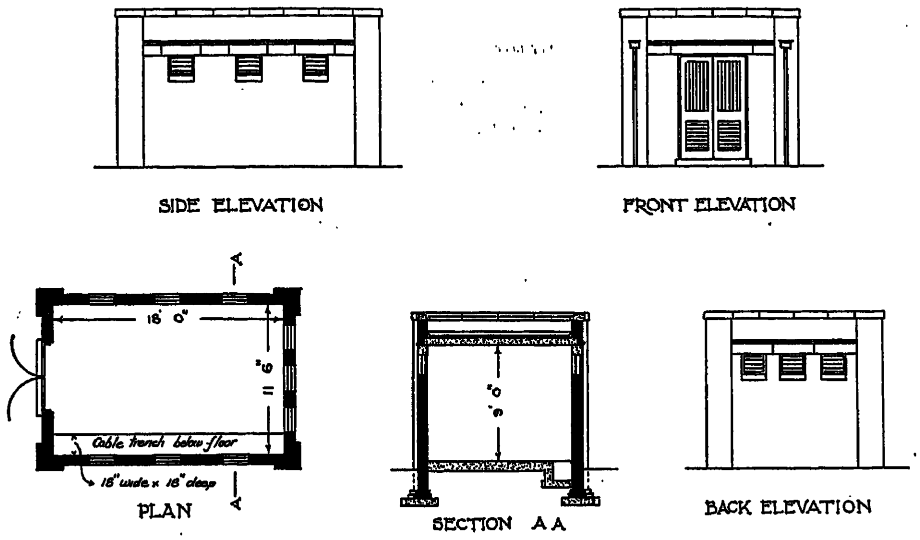

Fig. 16.—Standard 3-wire lighting substation.

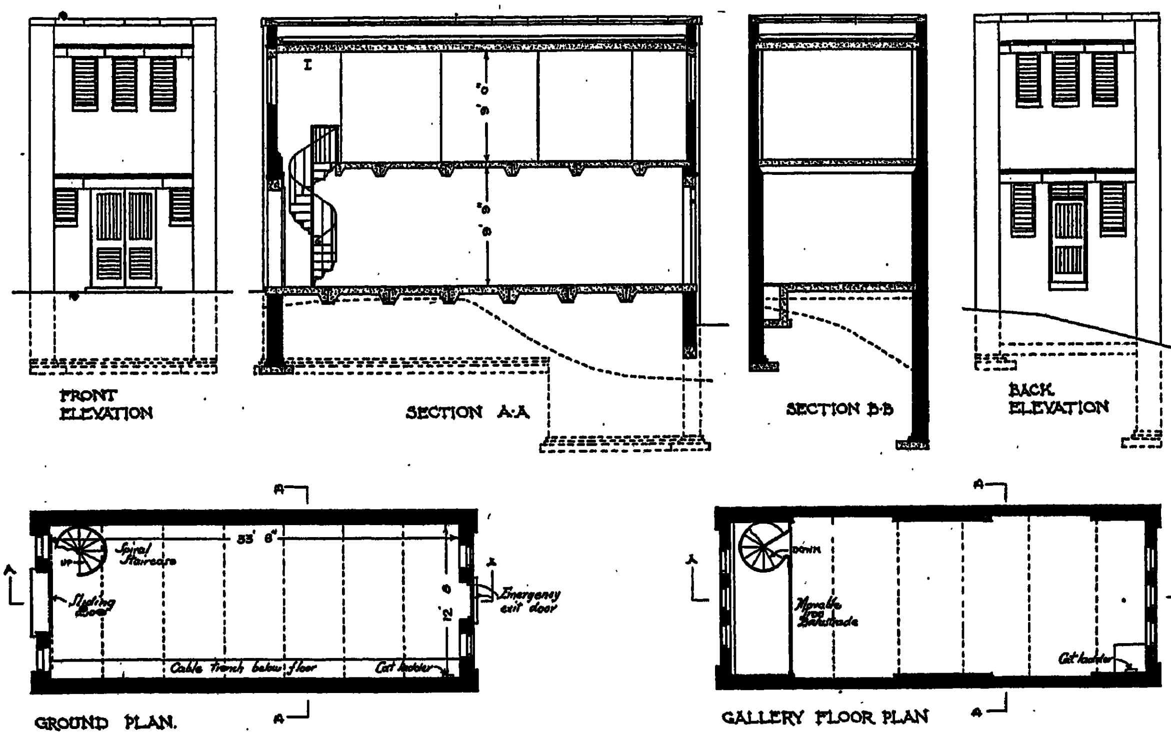

Fig. 17.—Two-floor boosting substation.

The power factor and efficiency of the traction rectifiers are shown in Fig. 6 (*c*). It will be seen that the efficiencies obtained are comparable with the efficiencies of rotary converters.

The total cost of one of these substations is detailed in Appendix 3.

it is possible, owing to the absence of noise from plant of this type, to buy or lease a small site, particularly when an area is being developed for building purposes.

In the city itself, however, a suitable site is often very difficult to obtain, and it may be necessary to adapt an old building or to build on an irregular-shaped site for the purpose of housing the rectifier plant. Some ingenuity and patience has to be exercised in this respect. The principal requirements of a site are suitability of access for plant and cable ways.

Buildings.—In designing buildings for this particular class of work, it must be borne in mind that simplicity, cheapness and freedom from fire risks must be the principal factors. There will be no attendants in these stations, and it is not necessary to have any idle floor space in the building. The plant does not require any lifting tackle, the transformers being mounted on wheels.

In most cases the question of appearance of the building and its relation to surrounding property in residential areas has to be considered. Many of the substations described in the paper had to be specially designed from an architectural standpoint to suit the wishes of the owners of surrounding property, and, of course, in every case to satisfy the city surveyor. Further, the bye-laws relating to buildings have to be observed, and it is therefore wise to put the design of new buildings of this kind in the hands of a good architect who will arrange to satisfy the many interested parties.

The peculiar light from the bulbs, and the flicker due to the rotating arc, make it advisable to prevent any direct light from the substation being seen outside. One way of doing this is to provide V-shaped louvres in the walls of the substation.

A suitable cable trench to bring in the necessary cables and suitable drainage from the roof for storm water must be provided.

Usually, a single-floor building is most suitable, but where the ground space available is small a two-storey building can be readily adapted for this purpose, the transformers being placed on the ground floor, and the rectifiers and switchgear on the first floor.

Ventilation.—Efficient ventilation can be obtained by means of the V louvres in the walls and doors of the substation, and by the provision of suitable roof vents.

Typical standard three-wire lighting substation (Fig. 16). —These buildings are erected with 9-in. brick walls strengthened at the corners with external piers 4½ in. thick and about 2 ft. wide. The inside of the walls is faced with ordinary common bricks having neat flush joints. The outside facing work is carried out with varying coloured Black Country bricks having white cement joints. Artificial stone is employed for the copings, which are weathered and throated, and similar stone for the heads to openings above doors and ventilators, these heads being slightly reinforced with steel bars.

The floor is formed with cement concrete 8 in. thick, reinforced with expanded metal and finished with a spreading of granolithic. The cable trench is also formed with concrete, similarly reinforced, the trench being covered level with the floor with chequered iron plating on iron curb and supports.

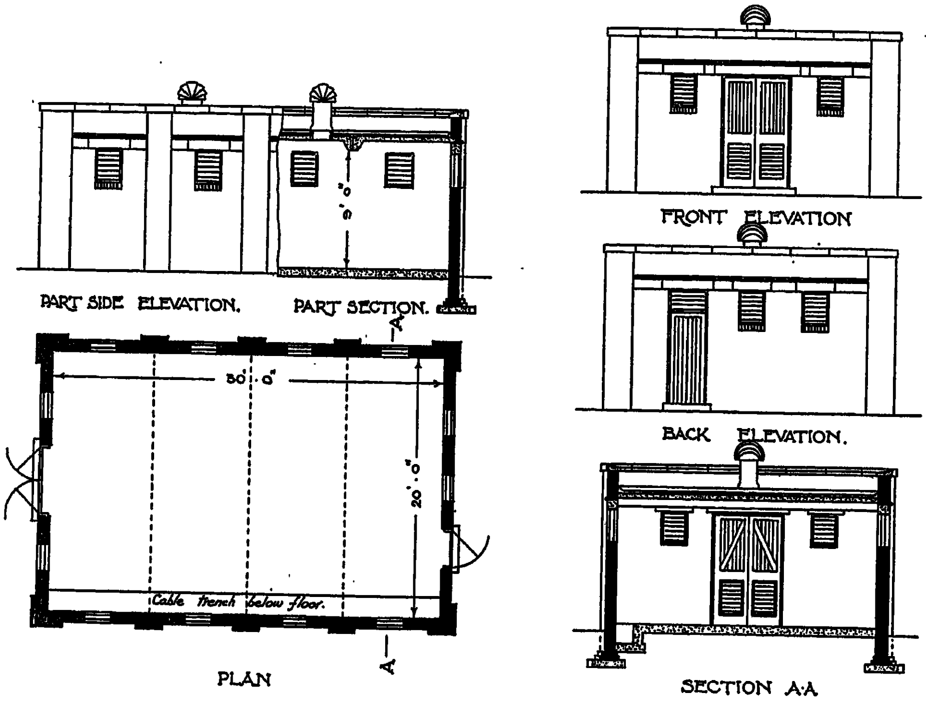

FIG. 18.—Traction rectifier substation.

The flat roof is formed with Seigwart pre-cast hollow beams, having on the top a screeding of cement laid to falls and covered with asphalte. The underside of the Seigwart beams has a fair face and no plastering is therefore needed, the joints being merely pointed with cement. This method of roof construction forms a very suitable fixing for cables and wires.

The ventilators consist of louvres in a frame, the louvres taking the form of an inverted " V," in order to allow a free passage of air and at the same time forming a screen to prevent the direct rays of strong flickering light penetrating to the outside.

The doors are framed, ledged and braced, the upper panels being filled in with narrow matchboards and the lower panels formed into louvre ventilators of similar construction to the above.

Typical two-floor substation (Fig. 17).—The station illustrated has been erected upon a narrow site having road frontage at either end, and the ground being bad it was necessary to carry the foundations deep. The construction of the walls is similar to that in the other stations, the flat roof being formed with Seigwart beams.

The ground and gallery floors are formed with suspended reinforced concrete, the latter floor being trimmed to form an opening, and a rolled steel joist is provided over this opening for hoisting the machinery to the gallery floor.

An iron spiral staircase is provided to give access to the gallery floor, and a cat ladder at the other end to serve as an exit in case of fire.

The doors are similar to those described for the other stations, except that the main entrance doors in this case are hung to slide in order to give clearance to the staircase.

Typical traction rectifier substation (Fig. 18).—These stations are erected in a similar manner to the lighting substations, the main difference being in the construction of the roof which, owing to the length of the span, is formed with suspended concrete reinforced with rolled steel joists and expanded metal. A small door is introduced into these stations to serve as an emergency exit in case of fire.

(8) Conclusion.

The author makes no claim that the type of rectifier substation described in this paper is complete or in final form, but takes the view that in each case an attempt has been made, with some success, to develop and use new plant for special purposes, to the end of reducing costs of development.

Attempts have been made to discriminate in each case the automatic features essential for the successful operation of the gear. It is possible to carry automatic control to almost any extent of completeness, but this only adds to the complexity of the switchgear and also increases the cost.

The author would like to express his indebtedness to Mr. R. A. Chattock, the city electrical engineer, for his kind permission to publish the information contained herein, and to his assistants, Mr. Thurman and Mr. Deeming, for their help in preparing the various diagrams included in the paper.

APPENDIX 1.

Cost of One 92-kW Three-wire Lighting Rectifier Substation.

The following is the detailed cost of a standard three-wire rectifier substation containing plant of 92 kW capacity, two high-tension feeder switch panels, one transformer high-tension switch panel, and low-tension iron-clad switchgear for controlling four outgoing three-wire low-tension distributors.

The costs include all the interconnector cables between the high-tension oil switch and the transformer, between the transformer and the rectifier, and from the low-tension side of the rectifier switchgear to the distributing gear.

The costs also include all labour charges and sundry materials.

	£
Cost of 92-kW 3-wire rectifier plant	1 478
E.H.T. switchgear, two-feeder panels, and one transformer panel	130
Low-tension d.c. switchgear	32·65
Automatic regulating gear and switches and resistance for B.O.T. earthing panel ..	85
Cabling	45
Labour costs for erection	40
Total	£1 810·65

The cost of the substation building for housing this plant, including cable trench, chequer plating, drainage, fencing, etc., is £320.

APPENDIX 2.

Automatic Boosting Stations.

It was necessary to relieve the load on four existing low-tension feeders in the Central City district. The areas concerned were at considerable distances from any of the existing stations or substations, and each of these feeders required boosting at the supply end.

The estimated costs of three alternative means of supplying this load are given as follows:—

(1) *By means of new low-tension feeders, from existing substations.*

Capital cost.	£
Cost of 4 × 1 sq. in. l.t. feeders	21 360
Sundry sub-feeders and linking-up mains ..	1 515
Additional rotary converter and booster capacity required, in existing substations	7 200
E.H.T. and l.t. switchgear	1 600
	31 675
Add 10 per cent for contingencies	3 167
Total	£34 842

The estimated annual running costs would be as follows:—

	£
Interest and Sinking Fund	2 803
Value of units lost in conversion and distribution, at ½d. per unit	760
	£3 563

(2) *By means of one new manually-operated substation and new low-tension feeders.*

	£
Estimated cost of building	2 000
Three 500-kW rotary converters	9 000
E.H.T. switchgear	800
D.C. switchgear	900
Internal cable connections	300
Cost of e.h.t. feeders and four l.t. feeders ..	13 890
Sundry sub-feeders and linking-up mains ..	1 515
	28 405
Add 10 per cent for contingencies	2 840
Total	£31 245

Annual running costs.

	£
To operate this substation two shifts of two men each would be required. The annual cost of wages would be	650
Value of units used for lighting	10
Value of units lost in conversion, at ½d. per unit..	360
Maintenance of plant	150
Loss in l.t. feeder cable, at ½d. per unit.. ..	200
Interest and Sinking Fund on plant, switchgear, cables, etc.	2 370
Interest and Sinking Fund on buildings ..	160
Total	£3 900

(3) *By means of a number of automatic mercury-vapour rectifier substations.*

	£
Estimated cost of four substation buildings at £400 each..	1 600
Four 276-kW rectifier equipments	8 986
E.H.T. switchgear	900
L.T. switchgear, including automatic control features, voltage regulator, etc.	1 400
Internal cable connections	200
Cost of e.h.t. cables and l.t. feeder cables ..	2 200
Sundry sub-feeders and linking-up mains ..	1 515
	16 801
Add 10 per cent for contingencies	1 680
Total	£18 481

Annual running costs.

	£
Value of units lost per annum in rectifier equipment and distribution, at ½d. per unit ..	360
Annual maintenance of bulbs and plant ..	150
Labour	200
Interest and Sinking Fund on buildings, plant, etc.	1 545
Total	£2 255

SUMMARY.

	Capital cost.	Annual cost.
Scheme 1	£34 842	£3 563
Scheme 2	£31 245	£3 900
Scheme 3	£18 481	£2 255

It will be interesting to compare the estimated cost of one of these substations with the actual cost.

The actual cost of one of these substations equipped with an automatic boosting set of 276 kW capacity is as follows :—

	£	s.	d.
Building	951	0	0
One 276-kW rectifier equipment	2 278	0	0
E.H.T. switchgear	218	0	0
D.C. switchgear, including automatic control and voltage regulator	361	11	10
Internal cabling	50	5	10
Cost of erection	168	5	2
Total cost of building, plant and erection	4 027	2	10
E.H.T. feeder extensions and l.t. feeder, etc...	1 120	0	0
Total	£5 147	2	10

It will be noticed that the cost of the building is much more than that allowed for in the estimate, but the building is large enough to house another similar equipment of larger capacity.

APPENDIX 3.

The following is the cost of one of the traction substations containing 660 kW of rectifier plant. The costs include two e.h.t. feeder switch panels, one busbar coupler switch, four e.h.t. transformer switch panels, the necessary automatic switchgear for controlling the supply to three low-tension traction feeders, the necessary cabling and the cost of the complete erection of the plant.

	£	s.	d.
660-kW rectifier plant complete	4 858	0	0
E.H.T. switchgear	323	0	0
D.C. switchgear and meters	181	0	7
Cabling, etc.	126	13	0
Cost of erection	168	9	0
Sundries	35	5	2
Total	£5 692	7	9

The cost of the building, including drains, fencing, etc., to house the above plant, which also provides space for the switchgear and plant for a complete 3-wire lighting unit of 92 kW capacity, is £480.

DISCUSSION BEFORE THE INSTITUTION, 20 NOVEMBER, 1924.

Captain J. M. Donaldson: The reason for using direct current at Birmingham is stated in the early part of the paper, but in view of the author's statements I think that the question of alternating current ought not to be put lightly on one side. As a matter of interest I have taken out a few figures showing what it really means from a financial point of view. On page 171 the cost of a rectifier substation with a capacity of 92 kW is given as something of the order of £1 800 exclusive of the building and exclusive also of the land on which the building is erected. That works out at about £20 per kW. I have taken out the figures for a little substation containing two 50-kW transformers, and the cost comes out at rather under £400, or about £4 per kW. The same building could easily take two 100-kVA transformers, and the cost would not be much more than £500, or £2 10s. per kW. Of course, that is rather a considerable item, and as a matter of fact it is not the only additional expense, because owing to the lower efficiency obtaining with a rectifier substation—of the order of about 10 per cent—the feeders have not quite the same usefulness that they have in an alternating-current system. The author rather infers that the question of pressure regulation is very difficult with static substations. I think that most people with experience of such substations do not find that difficulty; but in any case it is just as easy to meet it in a static substation as it is in a rectifier substation. In other words, a regulator similar to, though possibly on a different principle from, the one described by the author will do precisely the same thing if required. The overload capacity of a static transformer is considerable, but I think I am right in saying that mercury-vapour rectifiers will only take an overload of about 20 per cent for a few minutes. It is only fair to say, however, in comparing prices, that one of the reasons for the high cost is that two tubes are used in series in order to get the middle wire. It makes very little difference to the cost of the rectifier tube or bulb whether the pressure is 460 or 230 volts, but this device for obtaining the middle wire adds greatly to the expense. The other disadvantage of having the two tubes in series is, according to my estimate, that the efficiency is undoubtedly reduced by about 4 or 5 per cent, because the loss in the arc is a fixed amount—about 20 volts—and this is doubled when two tubes are in series. The efficiency as shown in Fig. 6 (*a*) is of the order of 87 per cent on the little 92-kW sets, and I do not think there would be any difficulty in getting an efficiency of 97 per cent or more in a static substation. The author compares the steel-tube (or Brown-Boveri) rectifier with the glass-bulb rectifier. I hold no brief for either, but I do not think that he has been quite fair to the steel-tube type. It would certainly appear from Fig. 1 that it is very complicated. I should like to know whether the ignition is still started mechanically in the glass-tube rectifier, as I imagine it is, or whether, as in the case of the steel tube, a separate ignition circuit is needed. I should also like to know why Birmingham, one of the pioneers in the use of the Brown-Boveri rectifiers, gave them up. Three sets of efficiency figures are given in the paper; one for the three-wire 92-kW set, one for a 276-kW booster, and one for a 660-kW traction set. It will be noticed that the traction and the booster sets, which are single-tube, have a very much higher efficiency, for the reasons I have already indicated, and also because in the traction set the voltage is higher. Were the efficiency curves obtained experimentally by the author's staff, and, if so, were they obtained by indicating instruments or by integrating instruments? The reason for my asking is that I do not think the two methods give the same results. My own impression is that integrating instruments undoubtedly give a very much lower value than do indicating instruments. To my mind, the integrating test is really the practical one. I believe that the reason is the rather curious wave-shape, and the fact that only one side of the wave is used. The main objection to the rectifier as a converting device is the question of regulation. The author refers to a figure as low as 5 per cent, but I do not remember getting anything as good as that. With the Brown-Boveri rectifier the figure is of the order of 9 per cent in order to keep the pressure up, and I have found it necessary to install an induction regulator in addition. The regulating device described in the paper appears to be a sort of booster transformer having a variable number of turns which can be cut in or out as the case may be. I should be glad if the author would give some additional information with regard to that point. As to the question of ripples, the Post Office maintains that a change-over from alternating to direct current increases the interference, and does not exonerate even rotary converters from blame. I rather think, however, that the ripples in the case of the mercury-arc converter are more pronounced than those due to rotary converters.

Mr. W. E. Highfield: The paper is really a study of one means of supplying the network of a 25-period three-phase system. I think that both in England and abroad the tendency has been in the direction of making the network 50- or 60-period, three-phase, and I do not think anyone would seriously state that that system is not the best; the reason being, of course, that the static transformer makes it very flexible and efficient. It is thought unorthodox to consider lighting at anything under 40 periods, and phase-changing is practically impossible on account of the cost. In other words, it is a very inefficient system, and it seems to me to be certain, in view of the number of 25-period systems in this country, that the d.c. networks will be extended. The author has put forward a very strong case for the mercury-vapour rectifier for certain specified cases; and, judging it both from the financial side and from the technical side, I do not think that that position can be seriously attacked. The mercury-vapour rectifier is the nearest approach to the static transformer that has been produced, and an apparatus that has no moving parts has a very great advantage over one that

has to revolve. The rectifier may not be in its perfected form, but it is good enough and there are bound to be improvements as its application goes on. One matter that is not mentioned in the paper, but which was referred to in one form by Captain Donaldson, is the fact that any form of rectifier introduces a harmonic into the primary. It is due to the difference between the primary and secondary wave-forms, and it is inherent in the system. The result is that the primary may suffer from over-voltages unless steps are taken to filter out the harmonics. It should not arise at Birmingham, because the primary voltage is low and rotary-converter substations are run in parallel on the same network, and the rotary converter is a very fine means of filtering harmonics. I feel sure that on any system employing rectifiers alone, and especially on those at extra high tension on the primary side, there will be considerable trouble due to harmonics introduced on the primary and possibly reflected on the secondary. The substations on the Midi Railway contain plant of both types. The d.c. voltage is 1 500, and the frequency is 50. The rotary-converter units are each of 1 000 kW. The rectifiers are of 1 200 kW capacity and are of the Brown-Boveri type. Both types of plant have given minor troubles, but I do not think there have been troubles to which any engineer could reasonably object, especially considering the novelty of the plant. Of course, there is a great difference between being in a rotary-converter substation and a rectifier substation. In the case of the former, if anything happens on the line a large load will be thrown on the station. A severe short-circuit outside the substation will probably cause a flash-over, and there will be a loud noise, but the energy will be dissipated without very much damage. The machines can be run up immediately. Now in the rectifier substation it is quite different. There is hardly any noise; nothing is heard except the air pump, and if a short-circuit occurs outside it is the linesman and not the substation attendant who has to attend to it. The rectifier is not affected by the short-circuit, but the harmonics it introduces into both primary and secondary circuits may cause, and do cause, breakdowns on the lines.

Mr. A. M. Taylor: In the cases referred to in sections (2) and (3) of Appendix 2, the showing is distinctly in favour of the rectifier substation. The reason why no spare rectifier bulbs are included in the estimate for the four substations is that each substation is virtually in parallel with the other three substations, under the particular circumstances of the area to be supplied. As regards the estimate in Appendix 1, I do not think that the author has made out a convincing case for using rectifier substations of very small capacity for very scattered areas. Owing to the fact that a neutral wire has to be supplied, each rectifier bulb must give only 230 volts. This involves a low efficiency and a very high capital cost (£16 per kW). I am not sure whether, in the case of an existing 25-period supply having to be extended into the sparsely populated districts, the method of supply devised by Mr. J. R. Beard might not with advantage be employed. No doubt the use of a static frequency-changer to inject a triple-harmonic E.M.F. into the neutral wire is a disadvantage, but under Mr. Beard's proposal it would be quite possible to arrange that the output of the frequency-changer was only about 1/9th to 1/15th of that of the substation. Hence, with an efficiency in the frequency-changer itself of only 85 per cent, the average efficiency of the whole substation may be considered to be equivalent to 96 per cent. Similarly, the cost of the frequency-changer is reduced to the equivalent of only, say, £1 per kW for the whole substation. The regulation of the frequency-changer designed by myself is 6 to 8 per cent, and therefore compares quite well with the inherent regulation of the rectifier. The power factor, it is true, is very low indeed (20 per cent), but if only 1/9th to 1/15th of the whole output of the substation has to be provided by the static frequency-changer, the total current supplied to the substation over the underground e.h.t. feeders is only increased by 50 to 33 per cent. Now the extra capital outlay, due to stiffening up the e.h.t. feeders to compensate for this, is only some 5 to 7½ per cent—quite a negligible amount. The low power factor is thus compensated for. The above argument is based on the assumption that, by employing Beard's method of supply, the cooking and heating and motive power load can be differentiated from the purely lighting load, which is the only one adversely affected by the low frequency.

Mr. H. Brazil: One or two speakers in the discussion have made a point of these rectifiers having to be run two in series, with the resultant loss of efficiency. This, of course, is quite correct if it is desired to balance, but even then it is not necessary to have all the bulbs two in series, as one or two sets can be balancing bulbs, and the rest may be put across the outers. It will be seen, therefore, that the objection that has been raised as to their inefficiency because two must be in series, is not entirely correct. The company with which I am connected was faced with the problem of compensating for a very heavy voltage-drop at two outlying points. The cost of providing additional copper in the low-tension feeders was prohibitive, and it was essential that the supply should be direct current in parallel with the existing network. When on a visit to Birmingham I saw several of the rectifier substations installed there, and was much impressed with their great simplicity, with the ease with which they were started up, and with their capacity for overload. As a result of what was seen there we have erected two rectifier substations which will be working shortly and will deal with the problem mentioned above. I feel sure that in cases of this sort, where a comparatively small amount of current is required at the point where the pressure is low, these glass-bulb rectifiers will be extremely useful, but on the other hand it seems clear that they cannot take the place of the main substations where the current demand is heavy. This is particularly the case where the declared pressure is low, as, owing to the fact that the capacity of the bulb decreases with the voltage, the number of bulbs required would be too great to be practicable.

Mr. S. C. Bartholomew: I had hoped that the author would have told us what steps are being taken to avoid interference with Post Office communication circuits. I was pleased, therefore, to hear Captain

Donaldson raise the question. The use of mercury rectifiers for supplying current to the tramway system on a certain route in Birmingham has resulted in very serious disturbance to trunk circuits between that town and other towns in the West of England. The engineers of the Corporation have in hand the provision of remedial measures, but inductive effects are causing at the moment considerable inconvenience to the Post Office and to the public.

(*Communicated.*) The author in his verbal reply stated in effect that, as the disturbance had not come under notice until 12 months after the mercury converters were introduced, the interference could not be very serious, although the Post Office cables run close to the tramway track for some distance. It is true that complaints of disturbance were not received until the middle of June of this year, and the more serious complaints on the 1st August. The explanation is that the increases in the trouble were apparently due to extensions of the tramway system along the road on which the Post Office wires are overhead and not in cable, and the accentuation of the disturbance coincided with the opening of a new substation by the Corporation at the beginning of August. Overhead telephone wires are much more likely to be disturbed than those in underground cables, and this, coupled with the working of substations in parallel, no doubt accounts for the late appearance of the trouble.

[The author's reply to this discussion will be found on page 186.]

North Midland Centre, at Leeds, 25 November, 1924

Mr. C. I. Shuttleworth: I am glad that the author stated at the commencement that he had no brief for this system on a periodicity of 50, as I also have not been able to make out a case on this frequency. In the first case the cost is considerably higher than that of any other form of converting plant. I have taken out comparative figures of the relative cost per kW and, for practical purposes, if 250 kW is taken as the standard the costs per kW are approximately £1 for a static transformer, £5·8 for a rotary converter, and £8 for a rectifier. In addition, the static transformer gives no trouble due to back-firing, and possesses none of the other drawbacks inherent to the use of mercury-vapour rectifiers. On a new installation there is absolutely no case (at least I cannot see one) for a mercury-vapour rectifier. There is, however, a case for such apparatus in certain outlying districts where a d.c. supply is already established and the problem of either changing over to alternating current or augmenting the existing supply has to be considered. We in Hull have been looking to the mercury rectifier to get us out of a certain amount of difficulty primarily on account of the noise produced by rotary converting plant. With the development of modern rotary converters and the various forms of automatic gear, I cannot see that there is a case for such a small mercury-vapour rectifier plant except (on the plea of absence of noise) in the residential districts, and for that particular reason we have been considering an experimental substation in similar circumstances to those that have arisen at Birmingham, i.e. the supply to outlying residential areas. In addition to the cost, considerably more ground space is required. In a substation not very much larger than the one shown as containing 600 kW of mercury-arc rectifying plant we are accommodating 2 000 kW of rotating converting plant. I agree with the author that the ideal is to use high-tension distribution as much as possible. I think that substations have in the past been made too large and that too much money has been sunk in copper in the attempt to centralize them. We in Hull have limited our standard substations in the centre of the town to four 500-kW sets. Comparatively small units are put down where they are required to suit local conditions. In ordinary towns, however, the difficulty of getting sites, and various other difficulties, make it impossible to have a considerable number of substations and one is obliged to centralize to a certain extent. Whilst the adoption of mercury-vapour rectifiers on a fairly extensive scale at Birmingham may have met present difficulties, I think that in the future it will be found that the units are too small to cope with the growing load. We have been developing a system of central control that would enable a whole town to be run on unattended substations. We have had a considerable amount of success, and I feel quite sure that within the next few years we shall have a complete centralized control system of supply, all the converting plant being controlled by means of pilot wires from the various substations. This, in my opinion, is superior to a number of automatic substations in which no one knows what is happening. The load can be directed at will by one controlling brain governing the whole of the town area. I do not think that the author would claim that his system is equally suitable for a heavy industrial town load, its special application being for rural areas and primarily for non-standard periodicities. The maintenance costs given in the paper are considerably higher than we have experienced in Hull. Our plant capacity is approximately 30 000 kW; half of this is in rotary converters in various sizes from 250 to 1 000 kW, and the remainder in static transformers. We have approximately 20 rotary-converter substations and 35 static substations and the total charges—including the foremen and all the attendance and cleaning—are about £2 100 per annum, apart from salaries. This is equivalent to £0·07 per kW of plant installed. Our charges are therefore about one-tenth of those indicated in the paper for a rotary-converter substation, and about one-third of the charges for a mercury-vapour rectifier substation. From our point of view, therefore, one of the strongest claims made by the author is not justified. There is no saving in attendance or on capital cost for the plant alone—apart from the feeders. I agree that a considerable saving can be shown on low-tension feeders by putting down smaller substations. The ripples on a supply system raise a very serious difficulty and there is something

to be said for the plain rotary converter which does not give such pronounced ripples as the mercury-vapour rectifier does. With regard to the rectifier generally, it certainly simplifies the automatic control gear, although in the system we have evolved we have no more relays than are required for the rectifier plant. The operating engineer is kept in close contact with the machine through instruments during the whole time the plant is running. He can stop it at any part of the process of running up. He has an indication of the load and the voltage and he can adjust these to suit the prevailing conditions. He can shut the machine down and close or open the low-tension circuit breakers at will. With the exception of not being able to see the machine, he can in fact perform all the functions of a manually operated substation. These developments rather lessen the scope for the mercury-vapour rectifier. With regard to the reliability of rotating plant, we have run unattended stations for over 20 years. During the whole of that time we have lost only two bearings: one due to a fractured sight-glass on the oil pump and the other due to a misjudgment on the part of the attendant as to the height of the oil in the well. These difficulties have been overcome by a different type of bearing which dispenses with sight-glasses and allows the rings to dip further in the oil well. All unattended rotating plant should be fitted with pump lubrication in addition to rings. Our experience proves that the risk of running unattended substations is very little greater than it is with manually operated substations or with mercury rectifiers. It may in fact be less, as it seems to me that eventually when the bulbs get impaired there is certain to be a dead short-circuit. I should be glad if the author would indicate how the regulation would be effected in order to ensure that each unit took its proper share of the load in a substation having an aggregate capacity of, say, 2 000 kW.

Mr. W. A. A. Burgess: The author appears to have made out a good case for the mercury-vapour rectifier for loads up to 250 kW at 25 periods. Beyond that I cannot see any case for the mercury-vapour converter in its present state of development. I am fully in agreement with Mr. Shuttleworth on the question of costs, and in Appendix 2 I do not think that the author is quite fair in his estimate as regards rotary plant. He has installed three 500-kW rotary converters to take the load that is dealt with by four 276-kW rectifiers. Two 500-kW units would apparently have sufficed. If he had made these completely automatic or, cheaper still, if the cost of pilot cable is ignored, made them remote-controlled on the principle successfully adopted by Mr. Shuttleworth, the cost would have been at least £8 000 or so cheaper and somewhere about £1 600 per annum would have been saved. It will be seen from the comparison between estimates (2) and (3) of Appendix 2 that there would then be very little difference, if any, in favour of the mercury-vapour converter. That of course assumed that he was able to obtain three suitable sites and put one 500-kW set on each in order to save a proportion of the low-tension feeder cost as in the case of the mercury-vapour equipment. On the question of buildings I agree with Mr. Shuttleworth. The buildings illustrated are certainly ample for the job, and I should be prepared to put forward an equipment which would provide fully 1 000 kW in two 500-kW sets in one of the 276-kW substations. The roof for rotating plant would have to be higher, and the foundations heavier. I think the estimates for building are unduly liberal. As regards the actual value of the mercury converter, I can foresee a very good future, in spite of its present inherent disadvantages, for stand-by plant in the form of a mobile unit capable of being moved from station to station. As a stand-by for rotating plant it should be an excellent thing. It is a light equipment, it can be easily moved, and transformers could quite well be designed for rotary converters with suitable tappings to supply mercury converters. Further, with the type of control equipment put forward by the firm with which I am associated, the modification of the switchgear and control gear would be extremely small, and such as could be provided for in advance at very little cost. I am rather impressed by the author's remarks regarding the severity of the short-circuit on both types of mercury arc. There seems to be no way of countering this, except on the a.c. side, with complete suppression of the arc and the necessity for restarting. One cannot use the d.c. high-speed reactance form of circuit breaker which has proved so effective in preventing flash-over on rotary plant. This type of circuit breaker definitely limits the short-circuit current to some 7 or 8 times full load and clears within 0·03 sec., compared with the more usual 18 to 20 times full load for a much longer period, and completely saves the brushes and prevents flash-over. The author raises a new point when he mentions the forming period required by the Brown-Boveri type of mercury-arc rectifier; both the preliminary period and the periodical one after being out of service for 24 hours appear to constitute a real drawback. It reminds one of the periodic charging required by the "aluminium arrester" on which so much faith was placed when it was first introduced into this country and in which American engineers apparently still have faith. The charging process with this apparatus was distinctly uncertain and a short-circuit was possible. The author seems to think that there is some risk in adopting totally automatic rotary-converter equipment, but after the risk voluntarily undertaken in the development of mercury arcs I think he need have no fear on that score. It is true that the original completely automatic rotary-converter equipments were rather complex, but I think it will be agreed that the latest types, particularly the type manufactured by Messrs. Reyrolle and demonstrated by them at the British Empire Exhibition, are as simple as anything that could be shown to us; certainly much simpler in arrangement than the panels and equipment shown on the lantern slides exhibited by the author. The complete diagram is no more complex than that of the author's own mercury-vapour equipment, with the exception that some 4 or 5 more relays are required for synchronizing and other purposes. The equipment has been proved in service to be as stable as manually operated plant, and more dependable in emergency. Mr. Shuttleworth's equipment also

tends to prevent operators' mistakes, as the operator only has to manipulate a simple selector device and press a button in his distant control room. I have seen the equipment supplied to Mr. Shuttleworth, although I have not had an opportunity of examining it on the site, and I could see no cause for apprehension. With regard to the author's final remarks on ripples, with rotary converting plant the ripple effect is practically negligible. The author states that the Post Office is already complaining of ripples due to his mercury converters, and I am afraid that his colleagues in charge of fault protection will also be likely to complain of high voltage induced in neighbouring pilot wires. Cases have been known of breakdown of pilot cables due to high voltage induced by external high-frequency currents, and I am of opinion that a heavy d.c. fault on a circuit supplied by mercury-vapour equipment of considerable size will prove to be a parallel case. The figures given in the paper appear to contain no provision for loading the rectifier when the d.c. circuit breaker opens on a fault. I suppose that that is merely an omission, and that there is actually a loading resistance in case all feeder circuit breakers are out at the same time. In such a case it would appear that the arc would be extinguished unless a loading resistance were provided. Again, one of the figures shows a connection to the pressure-lowering equipment from the d.c. shunt. When the load reaches a certain minimum value the circuit breaker opens, but connections are also shown to the pressure-lowering equipment. Apparently at a predetermined excess current the pressure is definitely reduced to a certain value. What is that value, and what would happen when supplying an isolated network? Would there still be such a connection to the pressure-lowering equipment, and, if so, how much would the pressure be reduced before the "low-volt" condition on the network caused a balance between the "raise" and "lower" coils of the controlling relay? If on a network in parallel, the other stations would pick up when the mercury arc lowered the pressure. Nothing would happen if the pressure fell, but unless there is a limit to the pressure-lowering with an isolated system it appears that the maximum-current relay should be left out or at least not connected to the voltage regulator.

Mr. W. H. N. James: Some 20 years ago a distinguished foreign electrical engineer, M. Leblanc,* made the statement that, so far as epoch-making inventions were concerned, the electromagnetic principle was played out and that attention must be paid to the vacuum tube. The accuracy of this prophecy has been largely borne out by the discoveries concerning the vacuum tube which have been made during the intervening period, and by the many commercial applications of this device not only to light-current engineering but also, as this paper shows, to power work. In nearly all d.c. circuits fed from electromagnetic machines, ripples are very noticeable and may arise from the effect of slots, the effect of eccentricity of the rotor and, in an irregular form, from sparking at the commutator. Can the author give some idea of the relative magnitudes of the ripples commonly met with in such circuits and of those commonly met with in circuits supplied from rectifiers? Information concerning the relative magnitudes of the ripples in circuits fed from glass-bulb rectifiers (with three anodes) and in circuits fed from Brown-Boveri rectifiers (with six anodes) would also be of interest. Another point in which I am interested is in connection with parallel running. In the early days of the mercury-arc rectifier I believe it was necessary to have a special balancing transformer on the a.c. side when tubes were run in parallel, presumably on account of the differing characteristics of the several tubes. I should like to know if this precaution is still necessary and also if rectifiers run well in parallel with rotary converters connected to the same d.c. busbars. The process called "forming" is, I understand, a means of getting rid of occluded air rather than any more material change in the surface of the anodes, and I should like to know, in the case of Brown-Boveri rectifiers, if re-formation is necessary after a short period of idleness if the vacuum has been maintained in the interval.

* See *Journal I.E.E.*, 1913, vol. 51, p. 710.

Mr. T. B. Johnson: I should like to ask whether this method has been tried in places other than Birmingham, and, if so, to what extent. The Post Office Telephones Department used small mercury rectifiers to a fairly considerable extent in comparatively small centres, Harrogate for instance, for charging secondary cells. We had a good deal of trouble, owing partly to transformer faults but chiefly to the failure of the mercury-arc rectifier; consequently the maintenance was troublesome and costly. We have replaced them by "Tungar" rectifiers, which are similar in form to the ordinary amplifiers used in wireless work. In that way we have entirely eliminated the troubles. The mercury arc, if it stops, must be started again by someone on the spot. With the bulb any stoppage is merely for the period of the fault, and the bulb comes into use quite automatically as soon as that is overcome. Does the author think that it would be practicable to develop this "Tungar" rectifier in such a way that it would be suitable for electrical stations of the size he has described? I assume that the large saving in first cost, of which the author speaks, in laying high-tension cables with automatic rectifiers at the distant end, as compared with low-tension cables with static transformers at the principal station, is entirely due to the smaller amount of copper used. If so, I should have thought that it would be necessary for the lines to be of considerable length in order to wipe out the large cost of the apparatus at the substation. I should be glad if the author would give us some information on the important point of the extent to which the duration of the faults has been increased by installing these substations.

[The author's reply to this discussion will be found on page 186.]

SOUTH MIDLAND CENTRE AT BIRMINGHAM, 3 DECEMBER, 1924.

Mr. F. Forrest: I suggest that the description of the apparatus referred to in the paper should be "Mercury-Arc Rectifier" and not "Mercury-Vapour Rectifier." The author uses both terms in the paper, and I think that the correct description should be standardized and always used when referring to this particular apparatus. The very brief reference made to the 225-kW Brown-Boveri rectifier which has been in regular service in Birmingham for over 3 years, hardly does justice to a piece of apparatus which has given extremely satisfactory service in connection with both low-tension lighting and traction supplies. The fact that this type of rectifier cannot at present be obtained in small units has militated against its more general adoption in Birmingham. The steel-clad water-cooled rectifier is, in my opinion, a much better type than the glass bulb cooled by an air blast from a fan. The glass-bulb type is not shielded from external magnetic fields, which may deflect the arc and cause internal short-circuiting, whilst the cooling cannot be uniform over the surface of the glass bulb. I believe that certain experiments have been carried out in Germany with the glass-bulb type of rectifier immersed in a steel tank filled with oil. It seems to me that this experiment may give very good results, increase the output and lengthen the life of the bulb. It will lead to more uniform cooling of the bulb, shield it from external magnetic fields and further assist in maintaining the high vacuum required. The descriptions of the protective relays used in connection with the rectifier, rather mask the fact that the control relays required are few in number and simple in the operations they have to perform. In this respect the rectifier has an immense advantage over the automatically controlled rotary converter. I should be glad if the author would state the number of relays normally required for the control of the glass-bulb rectifier, as compared with the number required for the complete control of a rotary converter for the same class of service. The successful use of these rectifiers for developing the outlying parts of the City of Birmingham on the low-tension direct-current system, which, as the author points out, is on the whole the best system from the consumer's point of view, is one further reason why the present methods of generation and distribution of electricity should not be too rigidly standardized, as it is certain that further improvements along the lines described in the paper may substantially alter what is at present regarded as standard practice in most parts of the country.

Mr. R. G. Jakeman: In connection with the automatic voltage regulator, the author uses a regulating transformer with tappings and sliding contacts. Has the question of using an induction regulator been considered, and, if so, how does it compare? Has the author considered the use of condensers on the h.t. side to improve the power factor? Is it necessary to use a high-speed circuit breaker in case of a short-circuit just outside the substation? It is possible to be troubled with telephone interference both with mercury rectifiers and with rotary converters. I have just obtained oscillograms from a large 25-period rotary converter which show that the tooth ripple on open-circuit is so small that it is difficult to read its value, while the sixth-frequency ripple on full load is only about $\pm \frac{1}{2}$ of 1 per cent.

Mr. J. T. H. Legge: The one point on which I find myself in disagreement with the author is his statement in the third paragraph of the introduction to the paper, where he says that a frequency of 25 periods per second is unsatisfactory for domestic purposes, and that it becomes necessary either to convert to direct current or to change the frequency. Within 10 miles of the City of Birmingham are several thousands of houses lighted by electricity at 25 periods per second, and I can safely say that up to the present time not a single complaint has been received as to it being unsatisfactory owing to the low frequency. I should like to remind the author that the entire supply of current from the Niagara Falls stations, on both the American and the Canadian side, amounting to a total plant capacity of 1 000 000 kW, is generated, transmitted and distributed at 25 periods per second. The area covered is many hundreds of square miles, in which is situated the City of Buffalo with over half a million inhabitants, and every lamp is operated at 25 periods per second. I am sure, however, that the field for conversion of alternating current by means of mercury-vapour rectifiers is rapidly widening where such change is necessary.

Mr. C. W. Goodman: Operating engineers, both in this country and abroad, will particularly welcome this paper as it shows in detail how a particular problem was attacked and the results which were obtained. It is not often that a paper such as this gives both the advantages and disadvantages of the method adopted and the comparative costs of alternative schemes in such detail. It is, perhaps, a pity that the question of using frequency-changers and a low-tension 50-period network instead of direct current has not been dealt with more fully in the paper. The reason for this is made more apparent by the author's supplementary remarks. Frequency-changers are reliable machines and very easy to operate, and being installed in a generating station would not require any extra supervision. Sets rated at about 1 500 kVA could be purchased for about £4 per kVA complete with starting gear, and as modern frequency-changers have a good efficiency it would appear that the overall efficiency of the system would be higher than is the case with small rectifier substations, dealt with in the paper. I should like to know whether the author considers that on a system where no commitments had been made in the outer area, this alternative would not be the best to adopt. It would appear from that part of the paper which deals with the steel-cylinder rectifier, that if it is desired to keep a special rectifier standing by, as would be necessary in the case of important traction substations, the set would have to be kept on a light dead load in order to prevent the half-hour delay before it could be put on the line. This seems to be a serious matter, as the stand-by losses would be a big item in a year's run. The ripple present in these

rectifiers is mentioned in the paper. On the higher voltages and frequencies generally met with in railway electrification, the amplitude and frequency of the ripple would be much greater, and one wonders whether the resultant heating on unlaminated magnetic circuits in d.c. apparatus connected to the system would not be serious. Turning now to the question of regulation, it would appear from other published matter on these rectifiers that the voltage characteristic from full load to 1/10th load is comparable with that of other electrical machines. Apparently, however, below 1/10th load the voltage rises considerably and to a very high value on open-circuit. It would be interesting to know how this is dealt with, as one can conceive that should a heavy consumer throw off his load from a substation, leaving only a few lamps in circuit, these might be damaged due to over-voltage. Reference is made in the paper to the important question of the design of substation buildings, and I feel that very often more attention should have been given to this matter on systems where the inhabitants have complained of unsightly substation buildings being situated in better-class residential areas. As the subject of noise has been mentioned, I should like to say, on behalf of the rotary converter, that a good deal can be done in the design of the substation building towards eliminating noise altogether, without excessive increase in cost. In Appendix 3, the cost of the e.h.t. switchgear, consisting of seven 5 000-volt panels, some if not all of which would be electrically operated, is £323, or £46 per panel. On the other hand, in Appendix 2 the figure for e.h.t. switchgear in a manually operated rotary-converter substation where five 5 000-volt panels are required, is £800, or £160 per panel. I should like to know the reason for this discrepancy, as if a more expensive switch is necessary on rotary converters one would assume that it is also necessary for the rectifiers.

Dr. C. C. Garrard: From the psychological point of view I think that the employment of attendants in substations is to be deplored. Generally speaking, they have very little to do, and I am sure that to spend any length of time as a substation attendant must have a very bad effect on young electrical engineers. I, myself, am a believer in automatic working, and am convinced that it will come more and more into use. As the author has shown, a rectifier appears to be ideal for automatic working, and the gear required is certainly simpler than that necessary for automatic rotary converters. As regards the system of electrical distribution to be adopted in the future in this country, I believe that this will remain direct current in the great majority of cases. The author's case is, of course, based upon a 25-period system, where the advantages of d.c. distribution are certainly greater than if the standard frequency of 50 had been adopted, but if distribution is to be by direct current I take it that a good case could be made out on a 50-period system. I should be glad if the author would state what, in his opinion, is the largest size of rectifier which is commercially practicable at the present day, and when he would begin to install automatic or non-automatic rotary converters. The reports available regarding the operation of large rectifiers are certainly very variable. The conclusion I have arrived at is that their reliability is not so great as that of a modern rotary converter. It would, I think, be most valuable if the relative reliability of the largest practicable size of rectifier, compared with that of the corresponding rotary converter, were thoroughly explored.

Mr. R. A. Chattock: When the question of giving a supply to the outlying residential districts of Birmingham had to be considered, the following decisions were arrived at. An a.c. supply at 25 periods per sec. was considered to be unsuitable, owing to the slight flicker that is noticeable. The proposal to install frequency-changers to change the frequency from 25 periods to 50 periods and to supply the districts with 50-period alternating current was carefully gone into and compared with the proposal to use rectifying plant and to distribute direct current on a three-wire network. The drawbacks to the frequency-changer scheme, which was admittedly cheaper than the rectifier scheme, were: (1) a much lower efficiency of transformation; (2) the impossibility of linking up the distributing networks with the existing d.c. networks in the city, which are all provided with a battery stand-by; (3) the greater suitability of direct current for heating, cooking and the small power apparatus used in private houses; and (4) the less risk of shock with direct current compared with alternating current. The Birmingham undertaking had already obtained experience with a Brown-Boveri steel-cylinder rectifier, which had been in use at one of the substations running by itself, and also in parallel with rotary converters and a storage battery. The excellent results obtained with this piece of apparatus prompted a very careful inquiry into the use of the glass-bulb rectifiers which, it was felt, were more suitable for small power substations which it was proposed to install for feeding into d.c. networks, with a view to eliminating the heavy cost of long low-tension feeder mains, and manually operated rotary-converter substations. As a result of these inquiries it was decided to adopt the glass-bulb rectifier plant, and it is gratifying to know that these have proved to be highly satisfactory. Their use has been extended also for tramway traction purposes. For substations of larger capacity it will probably be found that the automatic rotary converter is more suitable, but in residential districts the rectifier is preferable on account of the greater simplicity of the automatic controls, and also because of the silence with which it runs, the latter being particularly important in a residential district. The experience in Birmingham with these glass bulbs has been highly satisfactory. Not a single failure of a 230-volt bulb has occurred, and there have been very few failures on the higher voltages. It is a very simple matter to take out a bulb and replace it if it does happen to fail. It should be remembered that apparatus of this kind is of fairly recent development for capacities of 25 to 100 kW, and that in all new apparatus a certain amount of pioneering work must be done and experience obtained before the various little difficulties that always arise can be overcome. The question of interference with telephone circuits, owing to the high-frequency ripple in the direct current supplied from these rectifiers, has been mentioned. So far, we have only had one complaint of this effect on the traction route that has been referred to in the paper, where the currents are fairly heavy and the overhead trolley wire

is of course at a distance from the return rail. Continental experience indicates that the insertion of a resonant shunt in the circuit will completely remove this trouble, and this apparatus is now being installed. As regards the Brown-Boveri steel-cylinder rectifier, this has also given us entire satisfaction as regards its operation. At the present time, however, the apparatus is more expensive than the automatic rotary converter, which for larger sizes is quite suitable. It is also manufactured abroad, a fact which, under present conditions, rules it out so far as Birmingham is concerned.

Mr. A. E. Angold: I should be glad if the author would give some information on the following points:

(1) The cost of upkeep (per kW output) of a rotary converter, compared with that of motors for cooling fans and voltage regulators used with Hewittic rectifiers.

(2) Does a rotary converter need (per kW output) any more "minding" than the fan motors and voltage regulators mentioned above?

(3) Which creates the more noise (per kW output)—the rotary converter or the above-mentioned fans?

(4) What is the percentage voltage ripple between outers and middle wire with 3-anode and with 6-anode rectifiers, and what would be the extra cost of effective chokers in the middle wire and voltage regulators supplied to each side of the middle wire in connection with 3-anode rectifiers?

(5) What are the percentage extra costs of transformers and the percentage extra loss in the same for 6-anode and for 3-anode rectifiers, as compared with rotary-converter transformers of equal capacity?

[The author's reply to this discussion will be found on page 186.]

Mersey and North Wales (Liverpool) Centre, at Liverpool, 15 December, 1924.

Mr. P. J. Robinson: The author has produced a d.c. distribution from a 25-period supply, and, whilst appreciating that his difficulties are very real, I cannot agree with some of the statements which he makes when trying to justify his particular method. He states that direct current has distinct advantages over alternating current for the supply of the domestic and cooking load. If he is referring to a 25-period supply I am bound to agree with him, but if the supply is at 50 periods I wholly disagree. Some hundreds of houses in Liverpool are supplied with alternating current, and of the two, from the point of view of distribution and supply, I prefer alternating current. We find it is far more flexible. I admit that the direct-current supply has an advantage in power work in regard to speed regulation, but this disadvantage has to a large extent been overcome by means of cascade motors, by pole-changing and by commutating a.c. motors where wide variation of speed has been called for. This slight disadvantage is, in my opinion, far outweighed by the advantage of the flexibility of the a.c. distribution. With regard to the general power supply, I do not think that the author has put forward any case which justifies the use of rectifiers. With regard to automatic stations, I agree with the author that these have their use, not for feeding long and lightly loaded distributors, but for the purpose of maintaining the pressure in congested areas over periods of peak load. It would not be advisable to deal with a new district by means of a low-tension d.c. distribution, an efficient a.c. distribution being far preferable, and I think that the author adopted the present system more by force of circumstances than because he is strongly in favour of it. We, in Liverpool, have had some experience with fully automatic stations, and during the time that they have been in operation (one has been working since August 1922, and another since September 1923) there have only been two mishaps that might be called breakdowns; in both these cases the supply was not interfered with but the automatic station refused to operate. On the first occasion the trouble was due to a flaw in the metal of the brush-raising gear, and in the second case to a pilot brush sticking in the holder. The author states in col. 2 of page 165: "The method of starting up and shutting down the set as required is comparatively simple, and follows the practice adopted for automatic rotary converters. It is, however, much simpler and requires a smaller number of relays." I have carefully studied the author's Fig. 11, and, comparing the number of relays and fuses with that of an automatic rotary station, I find that there is little to choose between them. In fact the automatic station with the same amount of protection has actually fewer relays, but in the case of the automatic station put forward in my paper * the safety of supply and plant is looked after in a far more efficient way than in the station put forward by the author, so that the actual comparative number of relays depends largely on the care taken in giving the supply. The author states that the life of a bulb is very long. I do not consider that 8 000 hours (which is less than a year) is a very long life for any piece of electrical apparatus, and I would suggest that where he is opening up d.c. distribution in new districts, i.e. where he is using two bulbs across a three-wire 460-volt supply, the consumers would be subjected to a periodic shut-down, more especially if the substation in question were not coupled up to its neighbour. It would also appear that when supplying consumers from two bulbs in series on a three-wire system, the middle wire, or neutral, would have to be of the same section as either of the others.

Mr. T. W. Ross: The steel-cylinder or Brown-Boveri type of rectifier is, for several reasons, not very well adapted to automatic control, and the author states that one of the drawbacks is that the anodes have to be re-formed after each shut-down of 24 hours' duration. This seems to be a decided disadvantage as, although the forming operation can be done in 30 minutes, it seems desirable to be quite sure that it has been successfully performed before switching on. The main trouble, however, is the vacuum in the

* "The Maintenance of Voltage on a D.C. Distribution System by Means of a Fully Automatic Substation," *Journal I.E.E.*, 1923, vol. 61, p. 417.

cylinders. For successful operation this must be maintained to the extent of somewhere about 0·1 mm of mercury. In looking into the question of automatic control for these rectifiers some two or three years ago, I found that the measurement of the vacuum was a most difficult matter when, in addition to measuring the vacuum, it is necessary to operate a contact device to initiate the operation of the automatic switching apparatus. The vacuum gauge supplied with this rectifier has to be operated by hand in order to obtain a suitable scale reading. It seems to me, therefore, that unless the author has some suitable means of automatically measuring the vacuum and initiating switching sequence at the correct moment, there is a grave possibility of short-circuits or flash-overs taking place. I note that it is not necessary to run the exhaust pump unless the load is greater than 50 per cent, but this will no doubt mean running the pump all the time, as one can never be sure what load may be demanded from the rectifier. This also means that the vacuum-measuring device must be in service all the time the rectifier is on load, and ready to shut it down if and when the vacuum fails. Referring to Fig. 1, I notice that there are no fuses between the transformers and the rectifier. Are fuses no longer used? The last time that I examined a rectifier equipment, each anode circuit was carefully fused. I suppose that these fuses are to take care of the heavy short-circuits which can take place if the vacuum fails, or for any other reason. The glass-bulb type of rectifier is much more suitable for automatic control and offers very little difficulty in that direction. The greatest drawback to this type of rectifier seems to be the comparatively small size of the converting unit and the delicate nature of the glass bulbs. The question of simplicity of the automatic control gear is very often raised by operating engineers and is a point which at times is very much over-stressed. To say that the control gear for these glass bulbs is more simple than that for an automatic rotary converter is to my mind of very little importance from an operating point of view. The manufacturing undertaking that sells automatic substation control gear has to provide such protective apparatus as will give protection to the converting plant under all conditions and, moreover, must discriminate between faults inside and outside the substation building, so that the converter will not be locked out of service unless absolutely necessary. That is where most of the so-called complication comes in and gives rise to the necessity for most of the relays used. The actual control gear for an automatic rotary converter is very simple and, in comparing the two schemes, this fact must not be lost sight of. In any automatic control scheme a certain amount of development is very often brought about by the process of evolution, and I believe that the author will find, if he has not already found, that certain additions to the control apparatus are desirable in order that certain conditions may be taken care of. For instance, I see no means of disconnecting the bulb if the cooling fan fails, and I presume that it will be necessary to do this as a safeguard against damage to the bulbs. In comparing the cost of a converting plant with rotary converters against that of rectifiers, I think that it is only fair to take into account the overload capacity of the two equipments, and I should be glad if the author would give the overload capacity of the two types of rectifiers mentioned. The manufacturer of rotary converting machinery is continually being asked to increase his overload guarantees, and one must not overlook this fact when the rating of the plant is considered. It is also very difficult to compare the cost of switchgear. The breaking capacity of oil switches, the number and type of auxiliary apparatus used, etc., all give room for considerable difference without affecting the actual switching operations. If, therefore, we compare the cost of an automatic rotary converter equipment with that of an automatic rectifier equipment, it would be more accurate to leave out any switchgear or control gear common to both. Taking the figures given by the author in Appendixes 2 and 3, I find that without this common switchgear the prices of automatic rotary converters will compare very favourably with those of rectifiers, showing a decided balance in favour of rotary converters. The cost of the d.c. switchgear given in Appendix 3 seems very low, as apparently this includes five automatic reclosing circuit breakers, knife switches, meters, slate panels, angle iron, copper busbars and connections, and all auxiliary apparatus. I feel that some mistake has been made here and I should be glad if the author would state exactly what gear is included in this price. No mention is made in the paper of the limitation of the mercury-arc rectifier station and I am sure that there must be some point where it is desirable to install rotary converters instead of rectifiers. This is more or less proved by the fact that the Birmingham Corporation sometimes order rotary converters, and it would be interesting to know under what conditions these are found to be more suitable than mercury rectifiers. In conclusion, I think that the schemes outlined by the author are probably more suitable to the particular conditions existing at Birmingham than to the general problem of converting plant.

Mr. J. H. Williams: The author gives the cost of the rotary converters on page 172 as £6 per kW, and of the rectifiers as £8, therefore it would seem that the difference in cost is mainly due to the type of switchgear used. In the case of rotary converter installations already running, practically the maximum number of protective relays have been put in, whereas the Birmingham Corporation, who have themselves provided the switchgear, have approached the problem with the idea of having the minimum number of relays, a frame of mind not usually found in purchasers. The efficiency of the mercury rectifier on 230 volts is low; also it seems questionable whether it would not pay to put in a 300–500 kW rotary converter at the start rather than put in a 46-kW mercury rectifier and then have to keep adding to it as the load grows. The mercury rectifier cannot claim to take up less space than the rotary converter. I should like to know whether the author is prepared to give the cost of the bulbs, and also the average life; both of these items would be of interest. I gathered from the author's opening remarks that the overload capacity of the bulbs is limited to something like 4 to 5 per cent.

Mr. L. Breach: On one lantern slide exhibited by the author there appear to be some oil circuit breakers controlling the d.c. supply. I should like to know whether any trouble has been experienced with these switches and whether the carbonization which takes place on opening circuit has had any ill effects. Has frequency any effect on a flash-over, that is to say, is the risk greater or less at 50 periods than at 25 periods? Speaking of telephonic disturbances, the author appeared to be rather anxious about the results that he would obtain from the insertion of reaction and resonant shunts, but I can assure him that if he has taken the same values as we have in Liverpool his troubles with the Post Office will cease, as we have been fortunate in eliminating all disturbances. I should be glad if the author would say whether any loading resistance is left across his rectifier when operating on a traction load; this would appear necessary, otherwise the bulbs will require tilting each time the load on the line drops to zero. Also, has he found the reclose breaker satisfactory on traction, and is there a limit to the number of times it operates? It seems to be a dangerous proceeding to leave a breaker to close as soon as the fault is removed, as it is of course equivalent to clearing a fault with pressure on. Referring to the designs of substations adopted by the author, I should like to describe the method by which we have solved the question of ventilation in Liverpool. In all cases we introduce cold air into sealed ducts under the transformers. Through the floor under each transformer is a 12 in. pipe, and as there is no other inlet into the substation all cold air must pass round the transformer and out through a large ventilator in the roof. The inlet ventilator is above ground-level outside, with a duct built into the wall and into the transformer air-duct. We have found this cheap to construct and the results have been most satisfactory, all short-circuiting of air having been done away with. In Figs. 4 and 5 there appears to be one transformer for four rectifiers, and in Fig. 5 there is apparently no switchgear between the transformers and the rectifiers. Apparently if one rectifier develops a fault the only protection is the oil switch controlling the transformer, and if this operates all four rectifiers will be shut down. It is, of course, possible that some switchgear is inadvertently left out of the figure.

[The author's reply to this discussion will be found on page 186.]

North-Western Centre, at Manchester, 16 December, 1924.

Mr. H. A. Ratcliff: It is evident that the choice of a direct-current system of suburban distribution has been influenced by the comparatively low frequency of the Birmingham high-tension alternating-current supply system, and to that extent it is perhaps permissible to say that the author is making a virtue of necessity, since he admits the conveniences and advantages of a three-phase, four-wire distribution network—provided that the frequency is suitable for a lighting load. The occasion is not opportune for a discussion of the relative merits of a.c. versus d.c. systems of distribution, but it is significant that the author refers to the advantages of direct current for domestic loads, and as there are still a few advantages attaching to a d.c. system of distribution it would be helpful if he would amplify his reference to the domestic load. Assuming that the only cure for a low a.c. frequency is a d.c. system of distribution, the case appears to become largely one of substations versus feeders, and undoubtedly, within reasonable limits, a gradual increase in the number of substations is the correct policy—it is, in fact, the policy which is being carried out in Manchester, although not quite on the extensive scale advocated by the author. It follows as a natural corollary that small substations must be either fully or semi-automatically controlled, if they are to be commercially successful. Manual control is, of course, quite out of the question, even in the case of substations of much larger capacity than those described in the paper. Without a more intimate knowledge of the Birmingham conditions, it is not possible to criticize either the schemes referred to by the author or the figures relating to costs which are given in the appendixes. Substations having a total capacity of only 230 to 276 kW appear to be unduly restricted and, moreover, it is not evident whether these capacities include any margin of spare plant. Experience has shown that such small plant capacities are of very little use for dealing with the rapidly growing domestic heating and cooking loads. Such very small substations are only justified when they are connected directly to the distributing network without any feeders at all, and, as soon as feeders become necessary, the stations are approaching a size for which rotary converting machinery would be more satisfactory and probably more efficient. In one of the appendixes a comparison is made between feeders and 276-kW rectifier substations, but, provided that it is not unduly long, a 1 sq. in. 460-volt feeder has a much greater capacity than 276 kW. There are one or two real advantages attaching to the use of feeders of moderate length. The loan period for feeders is very much longer than that for plant of the same equivalent capacity, and consequently the capital charges are correspondingly lower. Suitably disposed feeders enable the total load capacity of a substation to be increased, with the result that the cost per kW of plant and the proportionate operating costs are both very appreciably reduced. The maintenance of feeders is an almost negligible item and, in the case of new districts, provision can be made for them when laying the distributors. A much more uniform distribution of the pressures, and balance of the load, on a three-wire network are possible when feeders are employed, and the location and isolation of network faults is greatly simplified. The author appears to have experienced very little trouble in obtaining suitable sites for substations; that is very fortunate, because it is essential that small stations connected directly to the network should be located within the confines of a fairly restricted area. In some districts it is extremely difficult to obtain suitable sites, and land-

owners frequently object and even refuse to sell land for the erection of substations. It is possible, however, that the prejudice against substations would largely disappear if they conformed more closely with the architectural amenities of the district, and, therefore, I quite agree with the author that they should be designed by architects. Taking everything into consideration, rectifiers appear to furnish the only means suitable for carrying out the schemes referred to in the paper. The cost of automatically controlled rotary machinery for such small sizes is quite prohibitive. There is, however, some prospect for the employment of small self-automatically controlled machines, particularly in view of the unduly high cost of rectifiers. The author is to be congratulated upon his very effective and comparatively simple automatic control arrangements. Unfortunately, it is a common mistake to make automatic equipments far too complicated. The manufacturers of automatic control gear appear to have a poor opinion of the plant which the gear is to control, and consequently they introduce a variety of devices to meet more or less imaginary troubles. Such a multiplicity of protective devices is quite unnecessary, and the ultimate development of successful automatic gear will be along the lines of gradual elimination of all unessential features. It is an inherent advantage of mercury rectifying plant that it lends itself more or less to simple methods of control, since the rectifiers are non-reversible and there are no synchronizing difficulties. The voltage-control scheme illustrated in Fig. 8 is very ingenious and, so far as can be judged from the description, it should be quite free of any tendency to hunt. One very interesting point is the critical nature of the first few days' life of the bulbs, and therefore presumably the manufacturers allow a reasonable proving period, during which they accept full responsibility for the satisfactory behaviour of the bulbs. In estimating the ultimate life of the bulbs, however, some allowance for possible accidents appears to be desirable, since the residual value of a broken bulb must be very small, if not entirely negligible. The outstanding advantage of the glass-bulb type of rectifier for use in residential districts, and possibly also for boosting purposes in the centres of large cities, is the complete absence of noise. Another advantage is the division of the load between several bulbs, since in the event of one bulb breaking there is every prospect that the load will be carried on the remaining bulbs. Rectifiers of this type should also be very suitable for relieving the load on feeders and distributors in large cities where the cost of additional feeders is very heavy and where it is frequently very difficult, if not impossible, to find room for them, owing to the congested condition of the ground under the streets.

Mr. D. S. Paxton: The reason why in the author's case it is necessary to run the vacuum pump continuously when operating the rectifier at more than half-load, as I understand is the case, is probably the fact that the load conditions are such that the rectifier has never run continuously on full load for any length of time, so that the cylinder has not been fully formed. The final forming of the cylinder is not attained until a number of full-load runs of some duration have been made. In the ordinary way it is found that the rectifiers when fully formed will run on full load without the vacuum pump just as well as they will on partial load. The author has referred to the reduction in the time required for forming. The process has been rather altered since the rectifier was installed in his case, so that a great deal of time is saved. The necessity for re-forming after a plant has been shut down is also entirely overcome, and the rectifier can be put on full load however long it has been standing, provided the vacuum is right. Provision has been made that the vacuum shall always be kept up to the correct figure by the latest type of constantly indicating vacuum gauge, which can be arranged to control the vacuum pump automatically, even if the rectifier is out of service. In such cases if the vacuum drops, the pump can be arranged to start up from an auxiliary supply and thus bring the vacuum back to the correct value, so that the rectifier is always ready to take up its load. The author assumes that the frequency of the ripples in the d.c. supply is six times the fundamental frequency, which is, of course, correct where there is a six-phase connection, but in the three-wire diagram (Fig. 5), showing a first instalment of plant in a small lighting substation, apparently there is one bulb only on each side of the system, to each of which only three phases of the six-phase transformer are connected, so that presumably the ripple in this case will be three times the fundamental frequency of 25 periods per sec., viz. 75. When extensions are made, however, the phase connections to the new bulbs will doubtless be arranged in the reverse manner so that there will be a six-phase connection on each side of the three-wire system. I am not quite clear about the exact arrangement of the special regulating transformer, but I presume that it is on the low-pressure side between the six-phase winding and the bulbs, unless the main transformer itself is tapped and brought out to the regulating switch. I should be glad if the author would give some further explanation on this point. Tappings are not very desirable on a six-phase transformer winding. With three or four tappings per phase there are a large number of connections to bring out, and this is to be avoided if possible. In the comparative estimates of three alternative schemes for dealing with the conditions that arise in Birmingham, I see that in No. (2)—a manually operated substation with low-tension feeders—the allowance for the maintenance of plant is £150, and in alternative No. (3) the same allowance is made for the maintenance of bulbs and plant. I should like to know whether this is purely an estimated figure or whether it is based on any definite tests. In the case of a scheme of this size—four substation buildings each containing a 276-kW rectifier equipment—it appears to me that, to come within this figure of £150, one must assume the life of a bulb to be five or six years. Has this period been definitely taken as a basis?

Mr. A. E. Clarke: I should be glad if the author would say (1) what is the recorded number of shutdowns in twelve months for the best installation of which he has had experience, and (2) what the figure is for the worst installation. Given these two extreme conditions, we shall be able to form some idea of the

relative reliability of this form of conversion. The author mentions that short-circuits are very severe. What does he mean by that? Is it that the bulb is shattered and the mercury distributed over the contents of the cubicle, or is it that the bulb remains intact but the rush of current is so severe as to tax the breakers or fuses installed in circuit therewith? I should also like to know the average life of the high- and low-voltage bulbs under actual working conditions; also whether any warning is afforded before a short-circuit occurs, so as to give an opportunity of changing the bulb before trouble eventuates. The author states that his substations have a capacity of 92 kW, and that provision is made to increase this to 230 kW. Do these substations supply a calculated unit area and, if so, what is that area, or what is the average number of domestic consumers served per substation? On page 161 the author states that the substations are connected to ring mains by means of non-automatic oil switches. It would appear to be questionable practice to link them thus solidly, owing to the danger of shutting down large areas—and so losing one of the greatest advantages of small substations supplying small areas—by trouble which might occur either on any part of the ring main or in any substation. In Fig. 8 the author shows four rectifiers and says that "the supply to the motor is so interlocked with the excitation relay (8) of each rectifier bulb that a failure of a.c. pressure or a failure of any one bulb opens the motor circuit." The correctness of the procedure outlined in the last alternative seems debatable. Assuming that all the rectifiers were carrying 2/3rds full load and one failed, then the other three would presumably take up each 8/9ths of their respective full loads, with the result that the voltage on the line would immediately fall and, in the absence of automatic regulation, would remain low. Thus, just when regulation is most required, it is absent. I should be glad if the author would say whether there is some reason for this. I am rather in doubt whether the mercury-arc method of rectification would ever have been adopted had not the periodicity of the Birmingham supply been the inconvenient one of 25, and in this connection it is interesting to compare the cost of this method with that of changing over from direct current to three-wire single-phase at 50 periods. Recently such a change-over has been effected in this district, the transmission being at 6 600 volts, three-phase, the transformation being effected by means of Scott-connected transformers, each transformer giving a supply to a three-wire system at 460 volts between outers and 230 to neutral. Satisfactory arrangements were made to effect adequate balancing of the transformers. The eventual capacity of the substation is 900 kVA, and the present capacity 300 kVA. The building costs per kVA were approximately the same as those quoted in the paper. The total cost with the present plant (300 kVA) including low-tension gear and connections thereto was nearly £3 000. The capacity of the substation can be increased to 900 kVA for an additional expenditure of £1 200, making a total for 900 kVA of £4 200 and demonstrating that this is a very much cheaper method of effecting distribution than that carried out by the author. Needless to say, the efficiencies and regulation we obtain are better than the mercury-arc method can show, and further, as the distribution system consists of old vulcanized-bitumen mains laid solid, there has been a gratifying diminution in the number of faults which have developed since the change-over to alternating current was effected.

Mr. R. Townend: In considering the glass-bulb type of rectifier, the actual bulbs would appear to be the only parts of the equipment liable to give trouble, and it would be useful to know the approximate cost of a bulb and also its average life, based on the total bulb failures experienced by the author. Also, if a bulb should fail due to any cause excepting mechanical damage, is it possible to have it repaired, or is a new bulb necessary? In comparing the glass-bulb and steel-cylinder types of rectifier, it would appear that the former is more suitable for small outputs. In view of this it would be interesting to know why this type was adopted for the traction substations having the comparatively large output of 660 kW. Has the author any information as to the advantages of air-cooling the bulbs, as compared with immersing them in a tank of oil, which latter method would appear to be simple and effective? In comparing the estimated costs of alternatives (2) and (3) in Appendix 2, it should be noted that the total capacity in alternative (2) is 1 500 kW, as against 1 104 kW in the case of alternative (3).

Mr. W. J. Medlyn: There is one point in connection with the paper which I think is of general interest, and that is the liability of the mercury-arc rectifier to cause disturbances in neighbouring telephone lines, when it is used in connection with ordinary electricity supply purposes. The author touched but lightly on that point when he was referring to current ripples in his description of one of the figures. Fortunately, it is possible to overcome this difficulty, and the method of doing so was described by Prof. Marchant in the appendix to Mr. Bartholomew's recent paper.* I trust that electricity supply undertakers will bear this point in mind if they decide to introduce the system recommended by the author, and plan their arrangements accordingly. Our experience is that supply undertakers are ready to co-operate with us in meeting the difficulties which we know are bound to arise from time to time. This spirit is, of course, as it should be where great public services are concerned. In the matter of electrical design, however, I think that prevention is better than cure, and in the long run it is less costly to all the parties who may be affected. Mr. Ratcliff, in his remarks, rather deprecated meeting trouble half way, but I think that this is perhaps a case where we might make an exception, as we know the trouble is already there.

Mr. G. F. Sills: With reference to the question of prices, in Appendix 3 £5 692 is given as the cost of a 660-kVA rectifier plant. An automatic rotary substation would, however, not cost more—in fact not as much. I should like to suggest that when referring to the rectifier type of plant it should not be called a "static" piece of machinery. I believe I am right in stating that in some types of rectifier plants there are six pieces of rotating machinery, and it was claimed

* *Journal I.E.E.*, 1924, vol. 62, p. 817.

that this particular rectifier plant was a piece of static machinery. Surely a rectifier plant with all these rotating auxiliaries is more likely to break down than a rotary converter plant. With reference to Mr. Medlyn's remarks regarding telephonic interference, it it interesting to note that rotary converters can now be obtained to meet the requirements of the Post Office in this respect.

Mr. G. G. L. Preece: I presume that those who were responsible for installing the 25-period supply in Birmingham were afraid that they could not get rotating converting machinery good enough for a 50-period supply. They did not look far and were of little faith. There *were* good types available even then, I think. It is evident from the paper that the present staff at Birmingham are bolder spirits and they deserve success of their pioneering enterprise. Although I am particularly interested in rotating converting plant I am bound to say that there appears to be a distinct field for mercury-arc rectifiers in certain conditions, and the author has by his enterprise proved that such conditions exist at Birmingham. I do not think, however, that makers of rotating converting machinery need feel any apprehension, as it appears to me that the conditions are at the moment limited to such conditions as exist at Birmingham. The steel type of rectifier has yet to prove itself thoroughly, at all events in this country. I do not know, of course, how far the author will go as to the size of the substations which he will equip with these mercury rectifiers, but if the load grows I rather think that when it gets over 500 kW he will find it necessary to consider installing rotary converter plant and use these mercury rectifiers for other districts where the load is small. In common with Mr. Clarke, I am rather interested as to the result of a short-circuit with this type of apparatus. Has it any bad effect on the mains?

Mr. H. Wilkinson: I should like to give a few particulars relating to the installation of mercury rectifier plant of the Hewittic type for the purpose of boosting up a rather outlying section of d.c. three-wire network. The rectifier consisted of two bulbs in series across the outers and was switched in and out daily by means of a time-switch control on the solenoid-operated e.h.t. switch cubicle. The automatic voltage regulator mentioned in the paper was used to maintain a constant voltage at the substation. The experiment proved highly successful in this instance and the operation of the plant generally was found to be extremely flexible, with comparatively wide e.h.t. and l.t. voltage variations.

Mr. G. A. Cheetham: This paper is another proof of the fact that automatic control has passed through the experimental stage and is now quite a reliable method. Those of us who have imagination have long expected that conversion and even generation would be carried out by some means with static apparatus. I think that the mercury-arc rectifier is a step in the direction which we all expect to be taken in the future. Both automatic rotary converters and automatic rectifiers are established as successful engineering propositions, and it is necessary, therefore, to compare them commercially. In comparing various methods of automatic operation, it is very necessary to consider how many possible contingencies have been provided for. Many supply engineers—for example, Mr. Ratcliff—appear to wish to take some risks, and if they prefer to take those risks it is obviously easy to cheapen the gear. For example, many supply engineers do not consider the automatic protection of bearings to be necessary. They consider that, from their experience, it is quite a legitimate risk to take, but most manufacturers when tendering for apparatus of this kind prefer, for obvious reasons, to cover all the contingencies which in their experience have arisen, even though they may be remote. Supply engineers who are considering and comparing quotations and prices must take these facts into account; if they are willing to take some risk the manufacturers are equally willing to cut out these devices and so cheapen the apparatus. As an example, the author appears to consider it unnecessary to provide for the failure of cooling water or for the failure of the vacuum pump, and it is probably quite the correct thing to do; but some supply engineers would not take that risk, and their gear would be more expensive. For an output of 100 kW the rectifier substation would, I think, be possibly a cheaper proposition, but beyond that output I think that the author's own figures prove otherwise. If the high-tension gear and the d.c. switchgear are assumed to be the same for an automatic rotary converter as for a mercury rectifier, then we can compare them on the same basis; and if we do so an automatic rotary-converter equipment, as suggested in scheme (2), would be £700 cheaper, and scheme (3), with automatic rotary equipment, would be 15 per cent cheaper. The cost of maintenance—£150 a year—seems to be very high and, I think, would not be regarded by an engineer with rotary equipment as anything like a reasonable figure. I expected to find some saving in space with the rectifier equipment, but apparently there is no advantage in that respect. I should like to ask the author whether when the bulbs are maintained continuously on full load he experiences much trouble due to flash-over. One other small point—though to some supply authorities it is very important—is that the advantage of power factor correction cannot be obtained with mercury rectifiers.

Mr. A. Manighetti: Regarding the question of flash-overs, I would point out that these troubles have occurred only in the case of the high-voltage bulbs. It has taken some time to obtain sufficient data as to the conditions under which these bulbs have to operate. The flash-over occurs when the vapour tension has passed a critical point, which point is determined by the cooling of the bulb. This bulb vapour tension or internal pressure is dependent on the cathode temperature, and it is a simple matter to cool a bulb sufficiently to enable it to give its maximum output at a point well below that of the critical vapour tension. It should be remembered that manufacturers of the rotary type of plant have had many years in which to perfect their gear, and in the comparatively short time the mercury-vapour rectifier has been supplied for heavy duties it has been found wanting in only small matters which are easily remedied.

Mr. H. C. Lamb: The author is in the fortunate position of having experience of both the Brown-Boveri

and Hewittic mercury-arc rectifiers, and it would be of interest if he could give some information about the advantages and disadvantages of each type. Referring to the last page of the paper, why is it necessary to provide 50 per cent spare plant for the rotary substation and no spare for the rectifier substation? Does that really represent the relative reliability of the two types of plant? If spare plant were necessary for a rectifier substation the figures of cost would be very different from what they are. Why is high-tension switchgear so cheap for rectifiers and so comparatively dear for rotary converters?

The Author's Reply to the Discussions at London, Leeds, Birmingham, Liverpool and Manchester.

Mr. G. Rogers (*in reply*): Many points have been raised at nearly every Centre, and I propose to deal with these first.

Many speakers have drawn attention to Appendix 2 (2), pointing out that allowance has been made for three 500-kW rotary converters, whereas in the alternative scheme outlined in Appendix 2 (3) only four 276-kW units are provided. To make this matter quite clear, it is necessary to point out that the problem involved feeding into the existing networks at four points. The existing networks at these points were fed from three distinct sources of supply, and could not be linked together. With a new substation, therefore, it would be necessary for the four new feeders supplied from this station to pick up entirely distinct networks and to be linked through to the existing network at one point only, i.e. to only one of the existing sources of supply. Obviously, therefore, it was necessary to have spare plant in the station, as the load to be picked up was over 1 000 kW. By having four distinct and separate substations close to the network, as suggested in the alternative scheme, each unit would start up automatically and feed into the network, and take its full load when required. If a short failure occurred at any time, it would only involve a drop in pressure. Further, it was not practicable to supply the larger station with three 500-kW rotary converters from an existing ring-main feeder, and the proposal involved the laying of new high-tension feeders to the station from the nearest generating station, whereas in the alternative scheme a ring-main feeder in each case was in close proximity to the site of the small substation and simply had to be looped in.

Another point raised by many speakers is the low cost of the high-tension switchgear for the small rectifier substations, as compared with the cost for the rotary substation. For the small substations no instruments of any sort were required on the high-tension side, whereas for the rotary converters it is obvious that many instruments and much gear would be required. Further, the larger units with the new high-tension feeders would involve switchgear of greater capacity than the small units supplied from the existing ring mains.

Mr. Bartholomew and others raise the question of interference with Post Office telephones due to induction caused by the ripples. I admit that in one particular case where the traction supply from the rectifier substations runs parallel with the Post Office trunk lines, some interference is being caused. Steps are being taken to obviate this by installing suitable inductances and resonant shunts in each of the substations to eliminate the ripples causing the trouble. This apparatus has now been tried out in one substation and found to be quite satisfactory. I have no doubt that as soon as we can install the complete apparatus the interference will be entirely eliminated.

Another point mentioned at many Centres is that justice has not been done in the paper to the steel-cylinder rectifier made by the Brown-Boveri Co. The reason this rectifier was not dealt with at greater length in the paper was that full technical details have already been published at various times in the technical Press. Mr. Chattock points out that our experience of this type of rectifier is quite satisfactory, but its high cost has prevented its more general use. A further objection is that the apparatus is made abroad. I feel certain that there is a good future for the Brown-Boveri rectifier for converting to direct current, particularly for traction work at high voltages. In situations where the absence of noise is a big factor, there can be no question that the large unit rectifier can and will be used for converting to direct current.

Corrections have been made in the paper with reference to the "forming" which up to the present has been necessary on the set in Birmingham, and also in respect of the large units that can now be supplied by the Brown-Boveri Co.

Many speakers raise the question of the high cost of the small three-wire rectifier substations, and compare it with that of simple static transformer substations. Assuming, however, that a satisfactory case has been made out for a d.c. supply instead of an a.c. supply, then such comparisons should obviously be made between different methods of conversion to direct current. The rectifier will certainly have the advantage over other plant for the small units. Above capacities of 500 kW it would probably be cheaper to install automatic rotary converters. The cost of the buildings, however, would be considerably more if this were done.

Captain Donaldson points out that the cost of the small rectifier substation works out at approximately £20 per kW, whereas a small static transformer substation of about the same capacity would work out at about £4 per kW. On any large distribution scheme, however, such as the one described in the paper, I would point out that the cost of the substations, whether a.c. or d.c., forms only a small part of the total cost of such a scheme, the greater part being absorbed in the distribution mains. I agree with Captain Donaldson that the overload capacity of a static transformer substation is more than that of the mercury-arc rectifier substation. The explanation of the low efficiency of the three-wire lighting unit, namely 85 per cent, is due of course to the two sets being in series, but

this efficiency compares favourably with the overall efficiency of a small rotary-converter substation with a battery.

All the efficiency figures given in the paper were obtained experimentally, the meters used being indicating instruments. In one particular case, integrating meters were also installed for the test, and it was found that both sets of instruments gave practically the same results. The only error that could creep in would be in the current transformers used in the primary circuit, and it is possible that the distortion in the wave-shape might, to a slight extent, affect the readings obtained from them.

The voltage-regulating device described consists simply of a regulating transformer in series with the main transformer secondary windings, with tappings brought out to the contacts of a sliding switch, the arrangement being very similar to that of the well-known end-cell battery-regulating switch.

Mr. Highfield points out that any form of rectifier introduces a harmonic into the primary. In most cases in Birmingham the plant runs in parallel with the rotary converter substations, and no effect of this nature has yet been noticed.

Mr. Taylor suggests that the method devised by Mr. J. R. Beard might have been used with advantage instead of developing a d.c. supply. It has, however, many disadvantages. If Mr. Taylor's static frequency-changer had a better power factor it is possible that the whole scheme of development to the outlying areas might have been on different lines.

Mr. Brazil points out that it was not necessary to run all the rectifier plant in a substation in series to give a three-wire supply. After the initial set has been installed, subsequent units could be connected across the outers only, with an efficiency of approximately 94 per cent.

Mr. Forrest points out that the correct title of this apparatus should be "Mercury-arc rectifier," and I agree that this is so. The exact number of relays and contactors required to operate a completely automatic mercury-arc rectifier as described in the paper is 8, whereas the number required to give the same control on a rotary converter set is approximately 30.

In reply to Mr. Jakeman, it would be possible to use induction regulators instead of the regulating device described, but the cost of this apparatus prevents its adoption for the small stations. The actual method used and described is comparatively cheap. The use of condensers would no doubt improve the power factor of rectifier units, but the additional cost is not warranted, since the power factor actually obtained is quite good.

Mr. Legge states that low-tension 25-period a.c. supply is being largely used in this country and abroad, and is considered quite satisfactory. Nevertheless, it cannot be said to be as good as direct current and, where the circumstances warrant the use of the latter, it is better to have direct current than alternating current at 25 periods for lighting. No doubt Mr. Legge and others who are giving a low-tension supply at 25 periods will welcome later a change to 50-period supply.

I agree with Mr. Goodman that 50-period supply by means of frequency-changers would be quite satisfactory in a case where there was no particular reason to convert to direct current. Mr. Goodman also raises the question of the voltage-rise on open circuit. This applies to the Brown-Boveri rectifier, and a special loading resistance is provided which is automatically switched in when the d.c. breaker opens. In the glass-bulb type of rectifier, however, this rise in the pressure does not, except in the case of traction units, take place at no load, and loading resistances for the purpose of preventing a rise in pressure are not required. In the case of the traction rectifiers no loading resistance is provided, because the stations run in parallel with rotary converters, and this prevents a no-load rise in pressure. It has, however, been decided to provide additional cathode chokes in all the traction rectifier plant, which chokes, together with small loading resistances to be switched in automatically when the load falls below 5 amperes, will prevent any rise of pressure at light loads.

Dr. Garrard is quite correct in stating that where a d.c. supply is required, an equally good case could be made out for converting from a 50-period supply. The largest size of a single rectifier unit is now stated to be 1 500 amperes at 600 volts, and is, of course, of the steel-cylinder type. I understand that developments are being made in the size of the glass-bulb type, but at present the unit of 150 amperes at 600 volts is the limit for commercial use. Unless there is some very special reason for using rectifiers, it will probably be found better and cheaper to use rotary converters for units above 500 kW. On the question of reliability Dr. Garrard is probably correct in stating that the rotary converter is on the whole more reliable than the mercury-arc rectifier, but more experience will probably make the rectifier plant equally as reliable as rotating plant.

Mr. Chattock explains more fully the reason for developing the outlying areas in Birmingham on d.c. lines instead of adopting special means for commencing a 50-period supply.

In reply to Mr. Angold, the fans and regulators require little attention, whereas a rotary converter necessarily does require a considerable amount of attention. The noise made by a bank of fans in a small substation seems rather loud inside the station, but, whereas the note of a rotary converter travels a considerable distance, the noise of the cooling fans cannot be heard a few feet outside the station.

Mr. Shuttleworth's remarks are extremely interesting. The decentralization now being carried out in Hull will be watched with great interest by engineers. A system of remote control of the various substations from one central point is on the right lines. His cost for maintenance and attendance of £0·07 per kW of plant installed is interesting, but further details would be required to enable a correct idea to be formed of the value of this figure. The glass-bulb type of rectifier would hardly be used in a substation up to 2 000 kW capacity, but in a substation of this capacity equipped with the steel-cylinder type of rectifiers there would be no difficulty in ensuring that the units took up their proper share of load.

In reply to Mr. Burgess, I would point out that the maximum-current relay for lowering the pressure is only

used in connection with the completely automatic booster sets which run in parallel with another supply.

Mr. James raises the question of ripples in the circuits fed from mercury-arc rectifiers, and I agree that the ripples have a greater amplitude than those from a rotary converter plant. Without giving oscillograph records it is difficult to supply full details of the amplitude of the ripples. The amplitude of the ripples varies with the load, but the ripples obtained from the glass-bulb rectifiers are comparable with those obtained with the Brown-Boveri steel cylinder. Reactances are provided in the anode circuits to enable two or more rectifier sets to run satisfactorily in parallel with each other. The experience in Birmingham shows that both the steel-cylinder rectifier and the glass-bulb rectifier run satisfactorily in parallel with rotary converters in the same substation.

In reply to Mr. Johnson, rectifiers are now being used in many places in this country and to a larger extent abroad. I should imagine that the "Tungar" rectifier is hardly likely to be used for heavy service work.

I find myself largely in agreement with Mr. Ratcliff's summing up of the general question.

Mr. Paxton mentions the interesting fact that the Brown-Boveri Co. now supply for use with the steel cylinder an indicating vacuum gauge which can be arranged to control the vacuum pump automatically, even if the rectifier is out of service. I have already dealt with the point raised by Mr. Paxton in regard to the connections for the regulator. Many speakers, including Mr. Paxton, have raised the question of the nature of the ripples in the three-wire rectifier circuit. The ripple in the circuit across the outers, in the case where two bulbs only are in service in the small three-wire substations, is six times the fundamental frequency of 25, viz. 150. Across one bulb only, i.e. 230 volts either positive or negative, the ripple is still practically six times the fundamental, and this is obtained by means of choking coils in the cathode circuit. Any current in the neutral, i.e. "out of balance" current, has a ripple of three times the fundamental. By cross-connecting when additional bulbs are added, a ripple of six times the fundamental frequency can be obtained as suggested by Mr. Paxton.

In reply to Mr. Clarke, failures of supply from any of the 25 substations now in service have been comparatively few in number. Many of the three-wire lighting substations have been in service for over 18 months without a single shut-down. The traction substations have given the most trouble, yet the supply has failed on but few occasions, and then only for a short period. Most of these interruptions have been due to the failure of parts of the installation other than the rectifiers, and the remainder have been due to faulty bulbs. When a short-circuit occurs in a bulb the bulb does not break, but the circuit breaker or fuses clear the fault. I am not in a position to give any information in regard to the life of the bulbs other than that already stated in the paper. A careful "life" record is being taken of all bulbs in service. No warning is given when a bulb is about to fail, but experience may show whether any warning signs may be found. It is obvious that some risk must be run in this connection. An interesting point is raised by Mr. Clarke in regard to the voltage regulator and its interlock with the excitation circuit of each bulb. In the case mentioned, it would be better if the voltage regulator continued to function, but in other cases there would be a danger of overloading the other bulbs. The details given of a change-over from direct to alternating current by using the Scott-connected transformer method is very interesting.

In reply to Mr. Townend, the glass-bulb type of rectifier was used for traction purposes because it was much cheaper, and also because duplicate plant was not necessary, owing to the plant being made up of a number of small units.

Mr. Sills states that an automatic rotary converter would have cost less for the 660-kW traction substation. This may be so, but spare plant would have to be provided, as any little trouble on the rotary converter or its transformer might have put the whole set out of commission for some time. In any case the cost of the building to house the plant would have been very much greater. It is true that the cooling fans—one for each bulb—constitute rotating plant, but the risk of breakdown is very small. For all intents and purposes it is correct to term the plant a static converter.

Mr. Preece suggests that in the early days the choice of 25 periods for the Birmingham supply was a mistake; nevertheless, rotary converters were not satisfactory at that time on a 50-period supply. I have a lively recollection of certain 50-period rotary converters the cost of repairs to which was at least three times as much as the maintenance costs of the rotary converters of the same period running on a 25-period supply.

Mr. Wilkinson gives his experience of plant of similar type to that described in the paper. It is very interesting and particularly pleasing to me to hear that other engineers are having satisfactory experience with this type of plant.

Mr. Cheetham endorses the opinion expressed in the paper in regard to the natural and inevitable development of automatic control gear for all types of electrical plant. He suggests that even generators may come later into the field of automatic control. He also raises the question of flash-overs in the glass bulbs. We have experienced no flash-overs in the 230-volt bulbs, but the higher-voltage bulbs have given some trouble in this respect. This has been due apparently to insufficient cooling of the bulbs.

Mr. Manighetti deals with the question of flash-over and points out the cause and the remedy. I feel confident that this apparent weakness will be entirely eliminated, and that the higher-voltage bulbs will be equally as reliable as the lower-voltage bulbs.

The various points raised by Mr. Lamb have already been dealt with.

Mr. Robinson agrees with the opinion expressed in the paper that a d.c. supply is preferable to a 25-period supply. He considers, however, that the automatically controlled rectifier unit as described in the paper is little less complicated than a rotary converter. I must differ entirely from Mr. Robinson in this matter. A comparison of Fig. 11, which is a complete wiring

diagram for the control gear, with the diagrammatic representation of the control gear for rotary converters (as for instance in Mr. Robinson's paper) will clearly indicate the greater simplicity of the rectifier control gear. The fact that less protection is provided for the rectifier plant than for a rotary converter is due to the plant itself requiring considerably less protection, and herein lies its great advantage. He would be a bold engineer who undertook to buy and connect up the control gear and relays necessary for the automatic operation of a rotary converter, yet this is what has been done in Birmingham, not for one automatic rectifier unit, but for several. On the question of the life of bulbs, the 8 000 hours mentioned in the paper has now been increased to over 12 000 hours, and there is no sign of the bulbs giving out.

I do not agree with Mr. Ross that the steel-cylinder Brown-Boveri type is not very well adapted to automatic control. On the contrary, a set in Birmingham has been so controlled with entire satisfaction for nearly three years. True, I pointed out in the paper the drawback caused by the necessity to reform under certain conditions, but this is not now necessary in the later plant. The other drawback mentioned by Mr. Ross has also been removed by the means mentioned by Mr. Paxton.

The Brown-Boveri Co. do not now provide fuses between the transformer windings and the rectifier anodes, but rely on the main oil switch and d.c. circuit breaker to clear a short-circuit in the cylinder. Mr. Ross draws attention to the low cost of the d.c. switchgear for the traction station described in Appendix 3. Actually the d.c. panel consists simply of angle-iron framework carrying three automatic reclose circuit breakers which control the supply to three outgoing feeders. There are no ammeters or knife switches in the feeder circuits. The apparatus was bought and erected on the angle-iron framework. This accounts for the low cost of this gear. The later substations, however, were equipped with a d.c. board having slate panels and a knife switch and ammeter in each feeder circuit. It is true that we now have in hand a number of automatic rotary converter substations for both traction and lighting supplies. Above a capacity of 500 kW and where the question of noise need not enter into consideration, the rotary converter is likely to be used in preference to glass-bulb rectifiers.

In reply to Mr. Williams, the overload capacity of the glass bulbs has not yet been fully determined. From experience it is known that an overload of 25 per cent for two hours will be carried satisfactorily. An overload of 50 per cent has been noted on the traction bulbs for short periods.

Mr. Breach points out that in one of the slides shown, illustrating an installation of mercury-arc rectifiers, an oil circuit breaker is shown controlling the supply to a d.c. distributor. This happens to be the only case where an oil breaker is used, and in this case it was used because at the time a suitable air-break totally-enclosed breaker was not available. The standard practice is now to use switch fuses (as described in the paper) or air circuit breakers for this purpose. The particular breaker referred to has not opened in practice, but it is guaranteed to be satisfactory for its present duties. We are adopting a similar method to that successfully used in Liverpool for removing the interference—due to induction—on the Post Office telephone circuits. I am hoping for similar satisfactory results in our particular case.

The question of loading resistances on the traction sets has been dealt with already. The reclose circuit breakers on the traction circuits can open an indefinite number of times and reclose when faulty conditions have been removed. Before handling a faulty cable or overhead line which may have fallen, the practice is to open the section switch in the street pillars controlling the faulty line. The breaker will not reclose until this has been done, unless of course the fault has cleared itself in the meantime. Mr. Breach's description of the method adopted in Liverpool for substation ventilation is very interesting and well worth consideration. I regret that in the advance copies of the paper, the fuses in circuit between the transformer secondary and the bulb in Fig. 5 were omitted. These have now been added. A fault on one bulb does not necessarily affect other bulbs in circuit with it.

THE CURRENT RATING OF SINGLE-CONDUCTOR, LEAD-COVERED, LOW-TENSION CABLES ON SINGLE-PHASE ALTERNATING-CURRENT CIRCUITS.

By S. W. MELSOM, Associate Member, and W. E. BEER, Student.

[FROM THE NATIONAL PHYSICAL LABORATORY.]

(*Paper first received 29th April, 1924, and in final form 21st January, 1925; read before the* NORTH-EASTERN CENTRE *24th November, 1924.*)

SUMMARY.

Single-core cables in single-phase systems are bonded to annul the high voltages that would otherwise exist between the lead sheaths when the latter are open-circuited, but bonding brings into being induced currents which may reach high percentages of the conductor current and reduce the safe current-carrying capacity.

In this paper some theoretical considerations of the losses of energy occurring in single-core cables on alternating-current circuits are given, and their effect on the line characteristics are noted.

In the first portion of the paper the results of measurements carried out on a single-phase system in air to determine the loadings for a given temperature-rise are tabulated and represented graphically. In a series of experiments the following factors were varied one at a time:—

(1) Current flowing in the system.
(2) Spacing of conductors in an iron-free neighbourhood.
(3) Spacing of conductors with iron interposed.
(4) Cable cross-section.

It is noted that, taking into account the mutual heating effect of two cables in proximity and the heating due to alternating currents flowing in the system, there is an arrangement of the cables in a horizontal plane which gives the maximum value of permissible current loading.

It is generally accepted that temperature-rise is the most important limiting factor in power-cable operation, and the recent Report on the Research on the Heating of Buried Cables * has been based on this assumption. Any study of cable characteristics must therefore take account of heating, and these notes have for their object the consideration of the heating, and consequent limitation of the current loading, of cables in single-phase systems.

Modern practice requires that the lead sheaths of single-conductor cables laid underground must be continuous throughout and bonded across at intervals; for installing in a building the lead sheaths must again be continuous, being connected at every joint, with the possibility of bonding across at intervals in the length by means of joint boxes, structural metal-work to which the cables or joint boxes are attached, or the metal clips used to support the cables.

The practical case, therefore, on which any limitation of the use of such cables must be based, is that in which the sheaths of a pair of cables are bonded at frequent intervals.

In addition to the core and sheath losses which occur in alternating-current circuits there is the mutual heating effect when the cables are in proximity, which arises in all cases. This effect is greatest with the lead sheaths in contact, and rapidly decreases until it becomes negligible. This occurs when the distance between the cable axes is approximately five times the diameter of the lead sheath. On the other hand, the losses in the lead increase rapidly as the distance between the cable axes increases. Hence for any single-phase power system there is a critical distance between the cable axes for which the total heating effect is a minimum and which therefore gives the maximum permissible loading.

* *Journal I.E.E.*, 1921, vol. 59, p. 181, and 1923, vol. 61, p. 517.

EXPERIMENTAL WORK.

The limit of heating has been taken as 35 deg. C. rise of conductor temperature, but this figure is simply taken in order to afford a basis of comparison and not necessarily as a final value of permissible temperature-rise for operating conditions.

In general, the temperature-rise of the conductor in an iron-free neighbourhood varies very nearly with the square of current intensity.

As a preliminary experiment with the object of providing a reference, a series of tests was carried out to determine the permissible direct-current loadings for the low-tension lead-covered cables considered in detail below.

The arrangements of the tests were, in the case of cables laid in a neighbourhood free from iron, designed to approximate to practical conditions. The other experiments described later, in which the proximity effect of extraneous metal is taken into account, involved conditions in some cases possibly more severe than those occurring in practice.

In the series of experiments the results of which are given in Tables 1 to 12, two lengths of cable of each size tested, forming the lead and return, were laid straight out on the wooden floor of an evenly ventilated, draught-free, constant-temperature room, and in an iron-free neighbourhood. A transformer T (see Fig. 1) fed through an adjustable series regulator AR from an alternating-current supply at 50 periods per sec. (wave-shape ordinary), supplied the cores through a change-over switch and a current transformer CT; the latter, in combination with an ammeter A, measured the conductor current. By throwing over the change-over switch the cable was fed with direct current from

a heavy-current battery, a standard resistance being included in this circuit for measuring purposes. In this way it was possible to supply the cable system with either alternating or direct current of any desired value.

The ends of the lead sheaths were bonded by copper bars of $1\frac{1}{4}$ in. $\times$ $\frac{3}{8}$ in. cross-section (the contact resistance

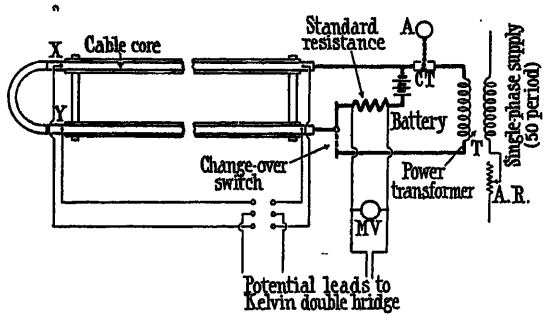

FIG. 1.—Diagram of connections for current loading.

being negligible) at right angles to the cable axes, whilst the ends X and Y of the cable were joined by a copper conductor loop of cross-section equal to that of the core, in order to ensure that there should be no extraneous heating or cooling.

METHODS OF MEASUREMENT.

The temperature-rise of the cables was determined by measuring the increase of conductor resistance by means of a Kelvin double bridge, and the surrounding air temperature was observed by means of a number of thermometers placed at the same level as the cable but about 3–4 ft. from it. The temperature coefficient used in calculating the rise of temperature was taken from B.S.S. No. 72 (1917).

Other investigators of losses in single-phase cable systems have determined them by means of voltmeter, ammeter and wattmeter, but the thermal method of test employed is well known and the principle of measuring the relative amounts of heat produced when the test length is traversed by two types of current is used in the determination of the resistance of wires to currents of high frequency, and, as here used, consists in comparing the direct and alternating currents necessary to produce the same temperature-rise of the conductor of the cable under test.

Having established a steady state in which, with the testing current maintained constant, a constant temperature-rise is obtained; then for equal heating in the two cases

$$I_1^2 R_1 = I^2 R$$

where I_1 = alternating-current loading in amperes,
R_1 = resistance of cable to alternating current,
I^2 = direct-current loading in amperes,
R = resistance of cable to direct current.

I_1, I and R can all be accurately determined; the first two by precision ammeters, and the last by the Kelvin double bridge. R_1/R is therefore immediately determinable.

The heating is brought about by actually loading the cable, and therefore in the experiments the same distribution of heat is obtained as in actual working. The true permissible loading is accurately ascertained and the only measurements involved are those of current, resistance and temperature. In the heating method slight differences may arise under slightly different conditions of ambient temperature, a lower initial room temperature tending to cause a slightly higher temperature-rise, but such differences do not appreciably affect the general results and under proper conditions a high degree of accuracy is obtainable. Among the advantages of the method it is to be noted that the observations made refer only to that part of the circuit in which we are interested, and so render corrections for the remainder of the circuit unnecessary. The observations, however, require a considerable time, and have, moreover, to be made under special conditions which are often not available in practice.

In the case of the tests with alternating current, the measurement of resistance was made by changing over to direct current immediately before making an observation, the time taken being about 20 seconds.

The temperatures of the lead sheath were determined by means of thermo-couples, the hot junctions being embedded in the sheaths. The mean temperature coefficient of lead at 20° C. was taken as 0·00385. This is based on a large number of observations on cable sheaths.

The effect of iron in the immediate vicinity of the cables was investigated by laying the conductors alongside lengths of iron of different cross-sections, as shown in Figs. 9 and 10, the axial distance being varied and the temperature-rise of the cable cores being determined as before. Three sizes of cable of sections 0·1 sq. in., 0·3 sq. in., and 0·5 sq. in. were tested under these conditions, both with direct current and with alternating current at 50 periods per sec.; the comparison in all cases refers to a temperature-rise of 35 deg. C., whence the ratio R_{eff}/R follows immediately.

Then, with the testing apparatus arranged as described, a series of experiments was carried out varying the following factors one at a time:—

(1) Current flowing in the system.
(2) Spacing of conductors in iron-free neighbourhood.
(3) Spacing of conductors with iron interposed.
(4) Cable cross-section.

The usual precautions were taken to avoid end-effects.

RESULTS.

For a given temperature-rise, say 35 deg. C., the conductors of a given single-phase system with lead sheaths short-circuited will carry various loadings according to the proximity of the return cable, and also according to the proximity of the system to neighbouring masses of iron. Under certain conditions the losses in the sheath and extraneous iron may be greater than the copper loss. The variations of the loadings with direct current from those given in the Report already referred to are due to the individual characteristics of the various cables and to the conditions under which they were laid.

The largest cable on which a full series of tests was

carried out was a low-tension single-conductor paper-insulated plain lead-sheathed cable having a cross-section of 0·5 sq. in.

Here the number and diameter of wires comprising the conductor = 61/0·101 in.

Maximum number of component wires on a diameter = 9.

Overall diameter of complete strand = 0·909 in. = 2·309 cm.

Actual copper area = 0·4885 sq. in. = 315 sq. mm.

Diameter over paper insulation = 2·86 cm.

Thickness of lead = $\frac{1}{2}$ × 0·5 cm = 0·25 cm.

Diameter over lead = 1·322 in. = 3·36 cm.

Resistance of conductor per 1 000 yards at 15·6° C. = 0·0497 ohm.

Resistance of lead sheath per 1 000 yards at 15·6° C. = 0·81 ohm.

Approximate age = 12 years.

A single cable.—Typical heating curves corresponding to various steady d.c. and a.c. loadings for a single

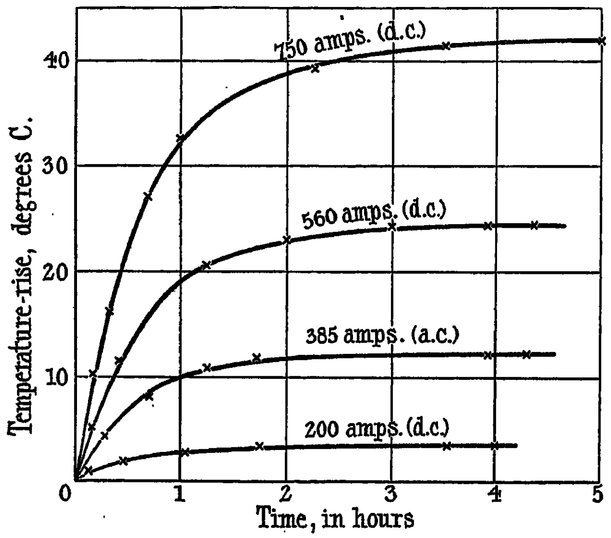

FIG. 2.—Curves showing temperature-rise of a 0·5 sq. in. single low-tension cable tested in air.

cable in air and obtained by running until a final maximum temperature-rise above that of the surrounding air was established, are given in Fig. 2. It will be observed that the time required for each test was between 4 and 5 hours.

The series of values of final temperature-rise and their corresponding current loadings are plotted in Fig. 3, from which the loading for a single cable in air * for any temperature-rise can be obtained by interpolation. It will be seen that the points all lie on the same curve, showing that under this particular condition there is no appreciable difference between direct current and alternating current at 50 periods per sec.

Two cables laid side by side.—The results of the experiments made to determine the mutual heating effect of two such cables in air are shown in Fig. 3.

* By "in air" is to be understood that the cable is lying on the wooden floor of a room.

Summary of results.—Assuming 35 deg. C. to be the permissible temperature-rise of the conductor :—

For a 0·5 sq. in. cable laid singly under the conditions stated above, current loading = 678 amperes direct current, or alternating current at 50 periods per sec.

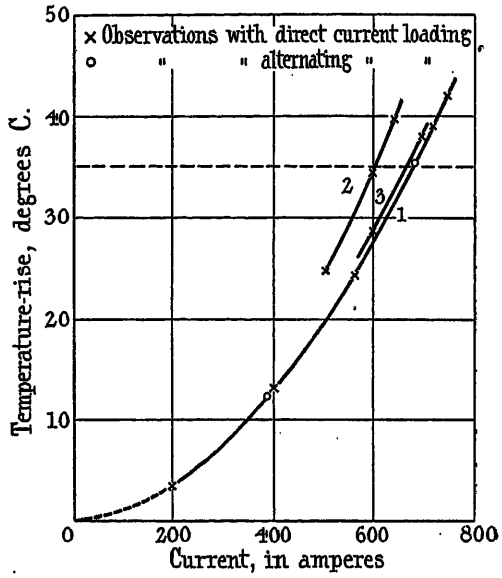

FIG. 3.—Curves showing temperature-rise of various arrangements of 0·5 sq. in. single-conductor cable tested in air.

Curve 1 refers to a single cable.
Curve 2 refers to two single-core cables laid side by side with axes 3·36 cm (1·3 in.) apart and loaded with direct current.
Curve 3 refers to two single-core cables with axes 9 cm (3·5 in. apart and loaded with direct current.

For a pair of 0·5 sq. in. single cables in air laid parallel throughout their length and under the same conditions as the above, the values given in Table 1 apply.

TABLE 1.

Distance between axes		D.C. current loading	Pair d.c. loading / Single d.c. loading
in.	cm	amps.	per cent
1·3*	3·36*	604	87·8
3·5	9·0	670	97·5
4·75	12·0	673	99·3
8·25	21·0	678	100
12·0	30·4	678	100

* Cables touching.

The first and last columns of this table are shown by curve A in Fig. 4.

The calculation of the mutual heating effect of a pair of cables in air is not simple when it is remembered that the problem is one of a single cable in an infinite medium together with a local disturbance. Further, a solution would be only of theoretical interest and the experimental curves in the paper relating to the problem of mutual heating are included solely on this account. It may be noted that at distances between axes of about 5 diameters, the effect is negligible.

The problem of the mutual heating of buried cables is of course of great interest, but this has been fully dealt with elsewhere. In general, the effect will be to give a curve of the same type as that obtained in air but with the initial portion increasing at a much lower rate.

Two single-phase cables (lead and return) laid up together.—The results of the tests corresponding to the practical case where the two 0·5 sq. in. single-phase cables carrying alternating current and having their sheaths bonded are laid up together or fairly close to each other, are given in Table 2 and are summarized in Fig. 4, curve B.

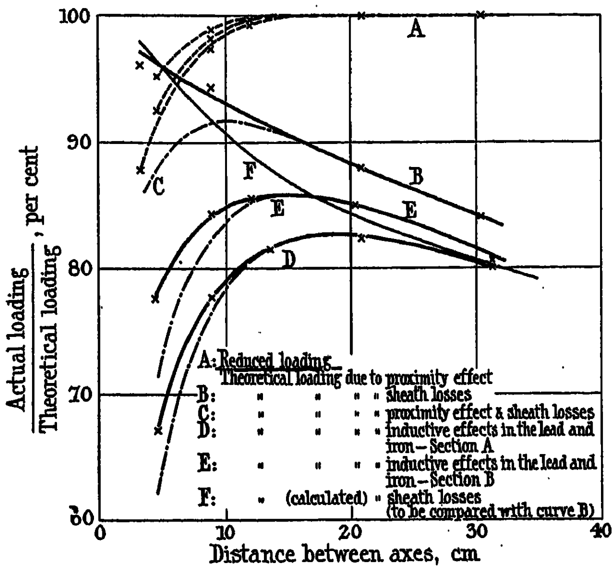

FIG. 4.—Curves showing the relation between (actual loading)/(theoretical loading) and axial spacing for a 0·5 sq. in. single-phase cable system tested in air.

TABLE 2.

Distance between axes		Current loading at 50 periods per sec.	Temperature-rise	
			Copper	Lead
in.	cm	amps.	deg. C.	deg. C.
1·3	3·36	500	26·3	—
1·3	3·36	600	37·3	28·5
1·3	3·36	650	43·1	—
3·5	9·0	600	31·56	23·4
3·5	9·0	660	37·7	—
8·25	21·0	600	35·4	—
12·0	30·4	600	38·25	28·9
12·0	30·4	520	29·4	—

Reducing these to the common value of a temperature-rise of 35 deg. C., the results given in Table 3 are obtained.

The results given in Table 3 are represented graphically by curve B in Fig. 4. The last column gives the ratio of the effective resistance to the ohmic resistance of the conductor.

Curve C in Fig. 4 represents the effects due to mutual heating and lead-sheath losses combined. The shape of this curve is interesting as giving an indication of the variation of permissible loading with distance between axes, and it is to be noted that the maximum possible loading occurs when the axes are separated by about 10 cm. But, as has already been pointed out, curve A applies to cables laid along the wooden floor of a room; for the case of buried cables the ordinates would be rather different. Curve B, however, will apply equally well to buried cables.

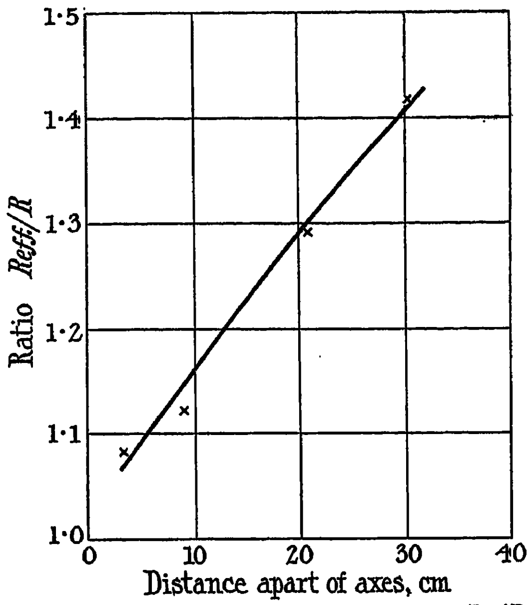

FIG. 5.—Curve showing the relation between $R_{eff.}/R$ and axial spacing in cm for a 0·5 sq. in. single-phase cable system tested in air and in an iron-free neighbourhood.

Considering curve B, it is seen that the effect of lead-sheath losses increases as the conductors get further apart, resulting in a decreased loading of the cable for a given temperature-rise. For the case of the lead sheaths bonded at both ends the induced current is a maximum. Fig. 5 shows how the effective resistance offered to alternating current at 50 periods per sec. increases with the spacing (with lead sheaths bonded),

TABLE 3.

5·3	13·5	704	574	81·5	1·49
8·25	21·0	704	580	82·4	1·47
12·5	31·6	704	564	80·1	1·56

The values for direct current given in Table 5 are not quite the same as those in Table 3. This difference is due to the cable being supported off the floor, and to the proximity of the iron. In order, however, to determine the magnitude of the inductive effects the comparison is made with values of both alternating and direct current obtained under identical conditions of laying.

(2) *Employing section of steel girder* (*see section B, Fig.* 10).—This is a type of girder commonly employed in building construction, weighing approximately 8·2 lb. per foot length.

8·25	21·0	711	605	85·1	1·38
12·5	31·6	711	574	80·6	1·53

The results given in Tables 5 and 7 respectively are shown in Fig. 4, curves D and E.

From the graphs it is seen that the current loading is greatly reduced owing to the strengthening of the field by the iron. The curves are somewhat similar in shape, the distance between the axes corresponding to the maximum loading increasing as the mass of iron per foot run increases. Also, with spacings greater than 30 cm the curves tend to coincide and run parallel to the corresponding curve for the system in an iron-free neighbourhood. With ordinary cable spacings, however, the reduced loading does not appear to follow any simple law, and it is clear that the losses and consequent heating will depend largely on the configuration of the neighbouring iron, and therefore, if the installation of a single-phase system in the vicinity of magnetic material is contemplated, each case should receive careful and separate attention with a view to the determination of its probable characteristics when working.

In connection with the tests employing section A, an experiment was carried out with the cable embracing the steel rail, and axes 31·6 cm (12·5 in.) apart, but with the lead-sheath circuit open. No difference was observed between the heating with alternating current and direct current, though on bonding, while the alternating current was flowing, a heavy spark showed the presence of dangerous induced sheath voltages.

Low-tension single-conductor paper-insulated plain lead-sheathed cable of 0·3 *sq. in. cross-section.*

Number and diameter of wires comprising conductor = 37/0·1038 in.

Maximum number of component wires on a diameter = 7.

Overall diameter of complete strand = 0·7266 in. = 1·847 cm.

Actual copper area = 0·3126 sq. in. = 202 sq. mm.

Diameter over paper insulation = 0·92 in. = 2·34 cm.

Thickness of lead = 0·24 cm.

Diameter over lead = 1·11 in. = 2·82 cm.

Resistance per 1 000 yards at 15·6° C. = 0·078 ohm.

A series of observations was made similar to those carried out on the 0·5 sq. in. cable in an iron-free neighbourhood, and in general the same order is followed.

A single cable.—As in the case of the larger cable, there is no appreciable difference between direct and alternating current at 50 periods per sec. Current loading (a.c. and d.c.) for a rise of 35 deg. C. = 512 amperes.

Mutual heating effect of a pair of cables.—With direct current for a temperature-rise of conductor of 35 deg. C. the values are given in Table 8.

TABLE 8.

Distance between axes		D.C. current loading	Pair d.c. loading / Single d.c. loading

12·5	31·7	512	456	89·0	1·26

* Cables touching.

The results are plotted in Figs. 6 and 7, and these curves show that the performance of a 0·3 sq. in. cable in an iron-free neighbourhood is not radically different from that of a 0·5 sq. in. cable under the same conditions of laying. As would be expected, the inductive effects are less pronounced than with the 0·5 sq. in.

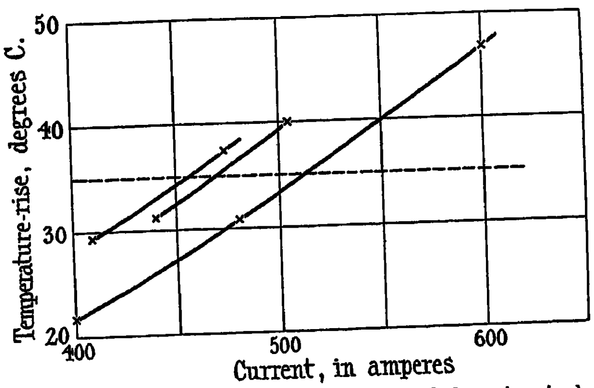

FIG. 6.—Curves of temperature-rise for a 0·3 sq. in single-phase cable system tested in air.

cable. The maximum loading for a cable of this size in air occurs with a spacing of about 9 cm. In Fig. 7, curves A and B refer to the measured and calculated values respectively. There is close agreement over the practical range of spacings, the greatest discrepancy occurring when the cable sheaths are touching and also at the largest spacing.

The ratio R_{eff}/R increases with the distance between the axes, as in the previous case.

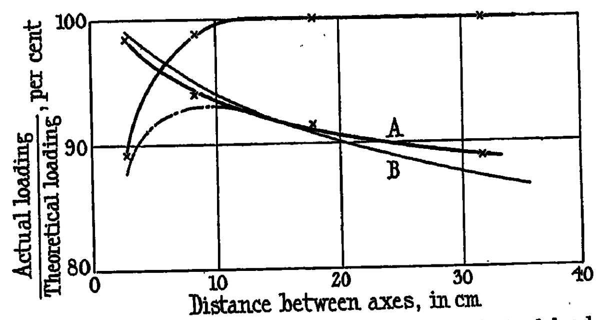

FIG. 7.—Curves showing the relation between (actual loading)/(theoretical loading) and axial spacing for a 0·3 sq. in. single-phase cable system tested in air.

The corresponding figures for a 0·1 sq. in. vulcanized-rubber plain lead-sheathed cable are as follows :—

Number and diameter of wires comprising conductor = 19/0·083 in.

Maximum number of component wires on a diameter = 5.

Overall diameter of complete strand = 0·425 in. = 1·08 cm.

Actual copper area = 0·103 sq. in.

Diameter over rubber insulation = 0·582 in. = 1·48 cm.

Thickness of lead = ½ × 0·15 in. = ½ × 0·38 cm.

Diameter over lead = 0·732 in. = 1·86 cm.

Resistance per 1 000 yards at 15·6° C. = 0·25 ohm.

A single cable lying along the wooden floor of a room.—Current loading (a.c. 50 periods, and d.c.) for a rise of 35 deg. C. = 245 amperes.

Mutual heating effect of a pair of cables.—With direct current for a temperature-rise of conductor of 35 deg. C. the values are given in Table 10.

TABLE 10.

Distance between axes		D.C. current loading	Pair d.c. loading / Single d.c. loading

The above results are graphically represented in Fig. 8, in which A and B indicate the measured and

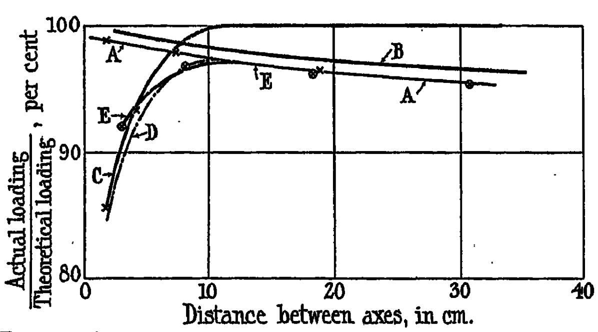

FIG. 8.—Curves showing the relation between (actual loading)/(theoretical loading) and axial spacing for a 0·1 sq. in. single-phase cable system tested in air.

calculated values respectively. In this case the difference between the two curves is practically constant, the experimental values indicating a rather lower … Curve C refers to mutual heating in air with … rent, and D is the resultant of A and C, giving a maximum loading in air corresponding to an axial spacing of about 12 cm.

The effect on the current-carrying capacity when the iron section A (Fig. 9) was interposed throughout the whole of the test lengths of cable was investigated as in the case of the 0·5 sq. in. cable. The results obtained are given in Table 12.

TABLE 12.

Distance between axes		A.C. loading / D.C. loading
in.	cm	per cent
1·23	3·13	92·0
3·2	8·2	96·7
7·25	18·37	96·3
12·2	30·9	95·4

The values in Table 12 refer to a temperature-rise of conductor of 35 deg. C., the lead sheaths being bonded, and are shown graphically by curve E in Fig. 8.

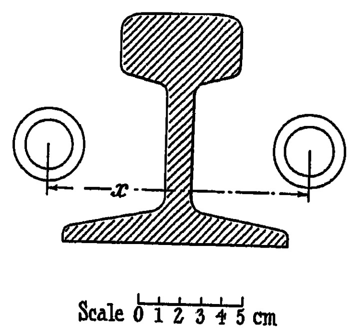

FIG. 9.—Section A.

Permissible current loading for various conditions of laying.—The composite effect of spacing the cables apart and the induction effects with and without iron are shown in Tables 13 and 14, in which the loading under the different conditions is expressed as a percentage of the standard value for two cables laid up

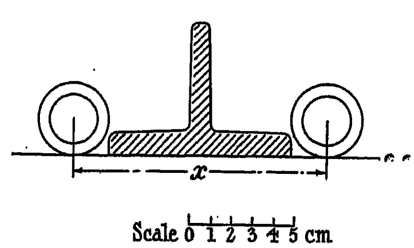

FIG. 10.—Section B.

close to and touching each other as is given in the I.E.E. Wiring Rules tables (7th edn.).

It will be noted that with the 0·1 sq. in. cable the current-carrying capacity is in most cases increased by increase of the spacing and by clamping the cable to iron. In the case of the 0·5 sq. in. cable, however, the loading with alternating current is in most cases substantially

reduced and, in particular, under the not unusual condition of two cables being clamped to an iron girder, the rating is only 72 per cent of the standard. Attention should be drawn to the fact that if a cable laid under these conditions were run at the standard rating, this temperature-rise would be 96 deg. F. instead of the 50 deg. F. allowed by the I.E.E. Wiring Rules.

TABLE 13.

For a Pair of 0·5 sq. in. Cables (Go and Return).

Condition of laying	Type of current loading	Current loading in terms of standard value in I.E.E. Wiring Rules (7th edn.)
Cables touching without iron	D.C.	100
	A.C. (50 periods)	96

	A.C. (50 periods)	91

TABLE 14.

For a Pair of 0·1 sq. in. Cables (Go and Return).

Condition of laying	Type of current loading	Current loading in terms of standard value in I.E.E. Wiring Rules (7th edn.)
Cables touching without iron	D.C.	100
	A.C. (50 periods)	99
Cable axes at 1·23 in. apart without iron	D.C.	106
	A.C. (50 periods)	105
Cable axes at 12·0 in. apart with and without iron	D.C.	117
	A.C. (50 periods)	111
Cable axes at 1·23 in. apart with iron	D.C.	113
	A.C. (50 periods)	105

The above refers only to comparison with the standard rating. Actually, as shown by Figs. 4, 7 and 8, in which the whole of the results are given, the comparison between alternating and direct current for any one condition is more unfavourable to alternating current. Reference to these figures shows that there is a critical spacing for a particular size of cable and method of laying that will give the maximum loading. This is approximately 10 cm (4 in.) where there is no iron, and increases up to 20 cm in the proximity of a heavy section of iron.

The values in Tables 5, 7 and 12 and in Figs. 4 and 8 are for cables laid on an iron girder, where the rating will, of course, be affected by the extent to which the cables are in intimate contact with the iron. They must therefore be regarded as being only approximate. It is, however, satisfactory to find that the cables of 0·1 sq. in., and less, can be used up to the standard rating under all conditions, but it is clear that special precautions must be taken for cables larger than this.

LOSSES IN LEAD SHEATH.

The calculation of the induced E.M.F.'s in the lead sheaths of single-core cables carrying alternating current is facilitated by considering the system as a transformer in which the primary is the copper conductor and the secondary is the lead sheath, each of one turn.

The conception of a single-phase system as being equivalent to a transformer with short-circuited secondary, and with zero reactance in the secondary, was elaborated by Clark and Shanklin.* The appendixes to that paper deal very fully with the characteristics of single-conductor cable.

For a discussion of the magnetic interlinkage between two circuits, "Theory and Calculation of Electric Currents," by J. L. La Cour and O. S. Bragstad (translated by S. P. Smith, D.Sc.) should be consulted. On page 116 the authors state: "In electromagnetic machinery, we have nearly always to deal with a main flux and a stray flux, or with corresponding magnitudes, viz. the coefficients of mutual and of stray induction. This is due to the fact that these fluxes are actually present in the machine, whilst the fluxes corresponding to the coefficients of self-induction do not as a rule exist, and consequently are not easy to calculate. Moreover, the former method of calculation has the advantage that all machines can be analytically replaced by equivalent electric circuits. On the contrary, the reactance $2\pi cL_1$ (where c = frequency and L_1 = coefficient of self-induction of the primary winding) is not at all confined to one electric circuit, but is distributed over two circuits in which different currents flow. Consequently, with machines, it is not convenient to work with the reactance due to self-induction. In the case of mains or other similar circuits, however, where little or no iron at all is present, the conditions are different. Here the reaction of the currents in neighbouring conductors is often so small that the stray flux is larger than the main flux. In such cases it is best to use the coefficients of self-induction, and estimate as nearly as possible, by approximate calculations and experiments, the damping effect of secondary currents in the neighbourhood or in the conductors themselves."

Clark and Shanklin,† Capdeville ‡ and other investigators have, for the purpose of extending the treatment to certain polyphase systems, considered one cable and the neutral. In the present paper attention is confined to single-phase lines consisting of a pair of cables, go and return.

The question of single-phase lead-sheathed cables can be conveniently approached by a consideration of the various coefficients of induction involved, and this is the course adopted in the present case.

* Bibliography, item (2). † *Ibid.*, item (2). ‡ *Ibid.*, item (1).

In considering the losses in the lead, let Fig. 11 represent a single-phase system. Let the distance between the axes of the two cables be denoted by D, and let the conductors of length l be traversed by a current i_a (absolute units).

The magnetic field at any point P is the resultant of the two magnetic fields at point P due to the currents in the two conductors.

To take into account the effect of the various linkages we must therefore use an expression of the form $\Phi_x I_x$, where Φ_x is the flux linking the current I_x.

In this treatment there are three inductances to be determined, viz.,

(1) The inductance of the copper circuit comprising the two conductors;
(2) The inductance of the lead circuit comprising the two lead sheaths; and
(3) The mutual inductance between the copper and lead circuits.

Taking these in order:—

(1) In Fig. 11 let r_1 be the radius of the conductor, and r_2 and r_3 respectively the internal and external

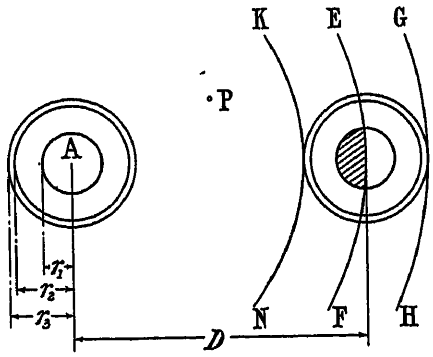

FIG. 11.—Single-phase circuit of a pair of single-core lead-covered cables lying parallel to one another in a horizontal plane.

radius of the lead sheath. It is assumed that the length of the line is great compared with the axial spacing.

The field H outside conductor A at a distance x from the centre of A is $2i_a/x$. Consider a length of 1 cm.

$$\text{Then flux} = d\Phi = (2i_a/x)dx \quad \text{and} \quad \Phi = \int_{r_1}^{D}(2i_a/x)dx$$

It should be noted that in connection with the upper limit D we ought actually to take the mean between GH and KN, which is EF (Fig. 11), and therefore the shaded area is involved. But the usual assumption in these calculations is that the core diameters are small compared with the distance apart of the axes. With such assumptions D is quite sufficient. It is interesting also to note that the result obtained by these limits is strictly correct, the slight apparent discrepancy being compensated for by the distortion of the magnetic whirl axes due to the proximity of the two conductors.

Hence
$$L_{c_1} = 2\log_e x\Big]_{r_1}^{D} = 2\log_e\frac{D}{r_1}$$

Now consider the flux inside conductor A.

Remembering that the magnetomotive force = work done in carrying unit pole once round the circuit we have:—

At distance x_1 from centre

$$H \times 2\pi x_1 = 4\pi i_a\frac{x_1^2}{r_1^2}$$

Therefore
$$H = 2i_a\frac{x_1}{r_1^2}$$

If $d\Phi'$ is the flux traversing an element comprised between the cylinders of radii x_1 and $(x_1 + dx_1)$, then

$$d\Phi' = \frac{2i_a}{r_1^2}x_1 dx_1$$

The current linked by $d\Phi'$ is $\frac{x_1^2}{r_1^2}$

$$\text{Therefore linkages due to } d\Phi' = \frac{2}{r_1^2}x_1 dx_1 \times \frac{x_1^2}{r_1^2} \times i_a = \frac{2x_1^3 dx_1 i_a}{r_1^4}$$

Hence
$$L_{c_2} = \frac{2}{r_1^4}\int_0^{r_1} x_1^3 dx_1 = \frac{2}{r_1^4} \times \frac{r_1^4}{4} = \tfrac{1}{2}$$

Hence total inductance per cm due to the flux of conductor A is

$$L = \left(2\log_e\frac{D}{r_1} + \tfrac{1}{2}\right) \text{ abs. units}$$
$$= \text{effective inductance of one wire.}$$

Since the currents in the two conductors are in opposite directions, the total fluxes produced in each are added.

Hence total inductance per cm due to both conductors

$$= \left(4\log_e\frac{D}{r_1} + 1\right) \text{ abs. units.}$$

If the conductor has an inner hemp or other non-conducting core of radius r_4 the total inductance per cm due to both conductors is given by

$$L = \left[4\log_e\frac{D}{r_1} + \frac{r_1^2 - 3r_4^2}{(r_1^2 - r_4^2)} + \frac{4r_4^4}{(r_1^2 - r_4^2)^2}\log_e\frac{r_1}{r_4}\right] \text{abs. units.}$$

For a length l cm each expression is multiplied by l.

(2) For the second coefficient of self-induction with

which we are concerned the argument is as before, and for the lead system we therefore have :—

Total inductance per cm due to the double line

$$= L_s = \left[4 \log_e \frac{D}{r_3} + \frac{r_3^2 - 3r_2^2}{(r_3^2 - r_2^2)} + \frac{4r_2^2}{(r_3^2 - r_2^2)^2} \log_e \frac{r_3}{r_2}\right] \text{abs. units.}$$

As before, this expression is multiplied by l for a length l cm, and its reactance

$$x_s = \omega L_s = 2\pi f L_s.$$

(3) The mutual inductance between the copper and lead circuits will be denoted by M.

The field at a point Q distant x from the centre of A is $2i_a/x$. If $d\Phi_1$ is the flux traversing an element comprised between the cylinders of radii x and $(x + dx)$, then $d\Phi_1 = (2i_a/x)dx$ per cm length.

The current linked by $d\Phi_1 = i_s\left(\frac{x^2 - r_2^2}{r_3^2 - r_2^2}\right)$

Linkages due to $d\Phi_1 = \frac{2i_a}{x} \times i_s \times \left(\frac{x^2 - r_2^2}{r_3^2 - r_2^2}\right)dx$

$$M_1 = \frac{2}{(r_3^2 - r_2^2)} \int_{r_2}^{r_3} \frac{x^2 - r_2^2}{x} dx$$

$$= 1 - \frac{2r_2^2}{(r_3^2 - r_2^2)} \log_e \frac{r_3}{r_2}$$

The field at a point outside the lead sheath of A and distant x from the centre of A is $2i_a/x$.

Flux $d\Phi = (2i_a/x)dx$ per cm length. This flux links the whole of the lead sheath current i_s.

$$M_2 = \int_{r_3}^{D} \frac{2}{x} dx$$

$$= 2 \log_e \frac{D}{r_3}$$

The total inductance per cm due to flux of conductor A is

$$\left[1 - \frac{2r_2^2}{(r_3^2 - r_2^2)}\left(\log_e \frac{r_3}{r_2}\right) + 2 \log_e \frac{D}{r_3}\right] \text{abs. units}$$

Mutual inductance per cm due to both cables

$$= M = \left[2 - \frac{4r_2^2}{(r_3^2 - r_2^2)} \log_e \frac{r_3}{r_2} + 4 \log_e \frac{D}{r_3}\right] \text{abs. units.}$$

It will be assumed that the lead sheath is a complete circuit, the ends being bonded across, and the following symbols will be taken to refer to the long rectangular loop so formed.

I = current flowing in the conductors.
R = ohmic resistance of the copper circuit per cm length of the loop (go and return).
i_s = current flowing in the lead sheath.
l = length of each conductor.
D = distance between the axes of the two cables.
r_s = ohmic resistance of the lead-sheath circuit per cm length of the loop.
V = P.D. applied to the copper circuit.
$\omega = 2\pi f$, where f = frequency in periods per second.
M = coefficient of mutual induction between the copper and lead circuits per cm length of loop.
L = coefficient of self-induction between the copper (or primary) circuit per cm length of loop
= total interlinkage of the copper circuit with the flux produced by unit current in the cores.
L_s = coefficient of self-induction of the lead-sheath circuit per cm length of loop.
S = coefficient of stray induction of the copper circuits per cm length of loop
= total interlinkage of the copper circuit with the copper stray flux produced by unit current in the cores.
S_s = coefficient of stray induction of the lead-sheath circuit per cm length of loop.

Then $L = S + M$ for the copper circuit per cm length of loop and $L_s = S_s + M$ for the lead circuit per cm length of loop, i.e. $M^2 = (L - S)(L_s - S_s)$.

Then for the very long rectangular loop the following equations apply :—

$$V = IR + L\frac{dI}{dt} + M\frac{di_s}{dt} \quad . \quad . \quad . \quad . \quad (1)$$

$$0 = i_s r_s + L_s\frac{di_s}{dt} + M\frac{dI}{dt} \quad . \quad . \quad . \quad (2)$$

Assuming V to vary sinusoidally, Equations (1) and (2) may be solved to give I and i_s, the solution involving differential equations of the second degree. The mathematical problem is well known and the method of solution is briefly as follows*: With the currents I and i_s assumed to differ in phase by θ and following the equations $I = \hat{I} \sin \omega t$ and $i_s = \hat{i}_s \sin (\omega t + \theta)$, the useful results are :—

$$\tan \theta = \frac{r_s}{\omega L_s}; \quad \sin \theta = \frac{r_s}{\sqrt{(r_s^2 + \omega^2 L_s^2)}} \quad . \quad (3)$$

$$\hat{i}_s = -\frac{\omega M \hat{I}}{\sqrt{(r_s^2 + \omega^2 L_s^2)}} \quad . \quad . \quad . \quad . \quad (4)$$

$$V = \hat{I}\sqrt{\left[\left(R + \frac{\omega^2 M^2 r_s}{(r_s^2 + \omega^2 L_s^2)}\right)^2 + \omega^2\left(L - \frac{\omega^2 M^2 L_s}{r_s^2 + \omega^2 L_s^2}\right)^2\right]} \sin (\omega t + \Phi) \quad . \quad (5)$$

$$\text{where} \quad \tan \Phi = \frac{\omega[L - (\omega^2 M^2 L_s)/(r_s^2 + \omega^2 L_s^2)]}{[R + (\omega^2 M^2 r_s)/(r_s^2 + \omega^2 L_s)]} \quad . \quad (6)$$

The current I in the conductor lags behind the voltage by an angle Φ.

Apparent resistance of the copper circuit

$$= R + \frac{\omega^2 M^2 r_s}{r_s^2 + \omega^2 L_s^2} \quad . \quad . \quad . \quad . \quad (7)$$

* S. G. Starling: "Electricity and Magnetism," 4th edn., p. 350.

Apparent inductance of the copper circuit

$$= L - \frac{\omega^2 M^2 L_s}{r_s^2 + \omega^2 L_s^2} \quad . \quad . \quad . \quad . \quad (8)$$

From these equations it is seen that eddy currents in the lead sheath can be regarded as being equivalent to an increase in resistance and a decrease in inductance of the cores, resulting in increased losses. Equations (7) and (8) indicate that the magnitude of the eddy-current effects depends upon (and increases with) the frequency of the current in the conductors and upon the dimensions of the latter.

Vector Diagram for the E.M.F.'s Arising in a Single-Phase Cable Circuit with Lead Sheaths Bonded.

Equations (1) and (2) can be combined in the vector diagram given in Fig. 12, where the vectors OA, AB,

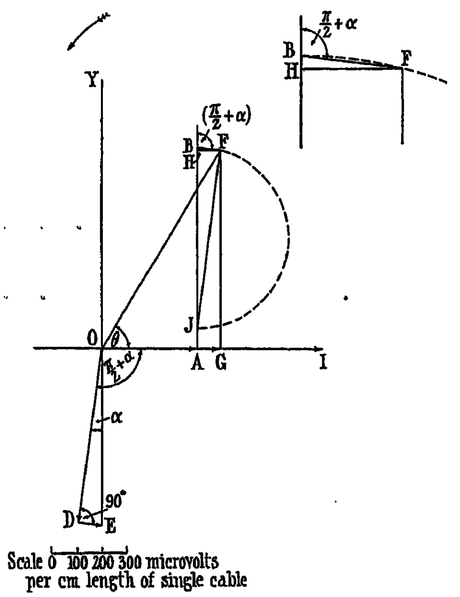

Fig. 12.—Vector diagram for the E.M.F.'s arising in a single-phase 0·5 sq. in. cable circuit with axes 10 cm apart and lead sheaths bonded.

BF, and the vectors OD, DE, OE, correspond to (1) and (2) respectively.*

Let OI be reference vector,

OA $= R\hat{I}$ in phase with the copper current,

AB $= \omega L\hat{I}$ (90° ahead of OA),

OD $= r_s\hat{\imath}_s$ in phase with the lead-sheath current,

$$\hat{\imath}_s = -\frac{\omega M\hat{I}}{\sqrt{(r_s^2 + \omega^2 L_s^2)}}$$

$\angle$ AOD $= (\frac{1}{2}\pi + \alpha)$

DE $= \omega L_s\hat{\imath}_s$, 90° ahead of OD

where α is given by $\tan \alpha = \dfrac{\omega L_s}{r_s}$

* S. G. Starling, *loc. cit.*, p. 361.

OE = vector sum of OD and DE

= E.M.F. induced in the lead due to variation of copper current

$= M\dfrac{dI}{dt}$ (parallel to OY)

$= \omega M\hat{I}$

BF = E.M.F. induced in the copper circuit due to variation of lead-sheath current

$= \omega M\hat{\imath}_s$ (parallel to DE)

$$= \frac{\omega^2 M^2 \hat{I}}{\sqrt{(r_s^2 + \omega^2 L_s^2)}}$$

OF = the resultant of (OA, AB and BF)

= applied P.D. to copper circuit.

Effective Resistance and Effective Reactance of the Copper Circuit.

By suitably altering the scale of the diagram we can make the vectors represent ohms instead of volts, as an air-core circuit is being considered.

Drawing FG perpendicular to OI and FH perpendicular to AB we have the effective resistance of copper circuit represented by OG $= R_1\hat{I}$, say,

$$\text{OG} = \text{OA} + \text{AG} = \text{OA} + \text{HF}$$
$$= \text{OA} + \text{BF} \sin(\tfrac{1}{2}\pi - \alpha) = \text{OA} + \text{BF} \cos \alpha$$

Therefore $\text{OG} = \hat{I}R + \dfrac{\omega^2 M^2 \hat{I}}{\sqrt{(r_s^2 + \omega^2 L_s^2)}} \cos \alpha$

Effective resistance of copper circuit

$$= R_1 = R + \frac{\omega^2 M^2 \cos \alpha}{\sqrt{(r_s^2 + \omega^2 L_s^2)}}$$

but $\cos \alpha = \dfrac{r_s}{\sqrt{(r_s^2 + \omega^2 L_s^2)}}$

therefore $R_1 = R + \dfrac{\omega^2 M^2 r_s}{r_s^2 + \omega^2 L_s^2}$

The effective reactance of the copper circuit is represented by

FG $= \omega L_1 \hat{I}$ (say)

FG = AB − BH = AB − BF sin α

$$= \omega L\hat{I} - \frac{\omega^2 M^2 \hat{I}}{\sqrt{(r_s^2 + \omega^2 L_s^2)}} \times \frac{\omega L_s}{\sqrt{(r_s^2 + \omega^2 L_s^2)}}$$

$$= \omega L\hat{I} - \frac{\omega^3 M^2 L_s \hat{I}}{r_s + \omega^2 L_s^2}$$

Therefore $\omega L_1 = \omega L - \omega L_s\left(\dfrac{\omega^2 M^2}{r_s^2 + \omega^2 L_s^2}\right)$

or $X_1 = X - x_s\left(\dfrac{\omega^2 M^2}{r_s^2 + \omega^2 L_s^2}\right)$

The angle FOA $=\theta$ is the angle by which the copper current lags behind the applied P.D. to the core. Thus with the lead-sheath circuit closed and consequently a current of i_s circulating in the lead, the effect, as

already shown, is to cause an apparent increase in the resistance and an apparent decrease in the self-inductance of the copper circuit. In every case a lead-sheath current results in increased power being absorbed by the cable, either by increasing the core current or by altering the phase of the copper current.

OF represents the impedance when the lead circuit is completed, and OB the impedance when the lead circuit is open, showing that the impedance in the first case may be greater than in the second case.

If FJ is drawn perpendicular to BF, i.e. $\angle$ BFJ $= \frac{1}{2}\pi$, we have

$$\begin{aligned} \text{BJ} &= \frac{\text{BF}}{\cos(\frac{1}{2}\pi - \alpha)} \\ &= \frac{\omega^2 M^2 \hat{I}}{\sin\alpha\sqrt{(r_s^2 + \omega^2 L_s^2)}} \\ &= \frac{\omega^2 M^2 \hat{I}}{\omega L_s} \end{aligned}$$

$$\begin{aligned} \text{AJ} &= \text{AB} - \text{BJ} \\ &= \omega L\hat{I} - \frac{\omega^2 M^2 \hat{I}}{\omega L_s} \\ &= \frac{\omega\hat{I}}{L_s}(LL_s - M^2) \end{aligned}$$

Now M^2 cannot be greater than LL_s, since it is impossible for the core and sheath to enclose the whole of the magnetic flux. Hence $1 - [M^2/(LL_s)]$ must have a positive value.

The Case when the Lead Sheath is Open-Circuited.

It is of interest to consider the case where the lead sheath does not form a complete circuit.

We have $i_s = 0$, $r_s = \infty$, $\alpha = 0$.

The vector diagram becomes as shown in Fig. 13.

$$\begin{aligned} \text{OA} &= R\hat{I} \\ \text{AB} &= \omega L\hat{I} \\ \text{OE} &= \omega M\hat{I} \end{aligned}$$

E.M.F. in the lead sheath = OE = $\omega M\hat{I}$.

If the copper resistance (OA) is small, then OE is nearly 180° out of phase with the applied E.M.F. to copper (OF).

$\hat{e}_s = \omega M\hat{I}$, and this is the voltage induced in the lead when the sheath is insulated.

Impedance is represented by OB.

The difference between the open-circuit and closed-circuit conditions may be better realized by imagining that the circuit is completed through a gradually diminishing resistance.

As the resistance of the lead circuit diminishes from infinity (the diagram being of the form shown in Fig. 12), the point F moves over the arc of a circle of diameter BJ in the direction BFJ. Additional power is absorbed by the cable in order to maintain the same current in the core, and, in the limit, the minimum value r_s is reached when the sheath is closed on itself.

Effect on the Permissible Current Loading.

Having determined an expression for the losses we proceed to determine the permissible current loading in the cable for a given temperature-rise. In any such case the procedure is on the assumption that we can express the loss of energy occurring in the sheath in the form I^2R_1, where R_1 represents the resistance by which the ohmic resistance of the core must be increased so that I^2R_1 is equivalent to the lead-sheath loss.

Thus if I = permissible current loading of core,
and R = direct-current resistance of core,
total losses W = copper losses W_c + lead-sheath losses W_s

$$\begin{aligned} W &= W_c + W_s \\ &= RI^2 + R_1 I^2 \\ &= I^2(R + R_1) \end{aligned}$$

Alternatively, we may take I_1 to be the conductor current which, flowing through the ohmic resistance

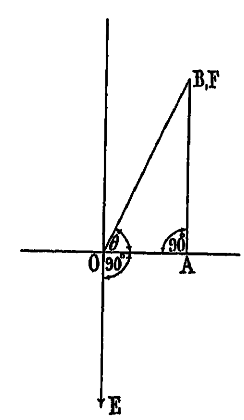

Fig. 13.

R of the copper system, gives rise to a loss equivalent to the lead-sheath loss.

Then, as before, $W = W_c + W_s$

therefore $\quad W = I^2R + I_1^2R = R(I^2 + I_1^2)$.

Then if I_e be the direct current which, flowing through the conductor, produces the same heating as is produced under alternating-current working, we have

$$I_e^2R = R(I^2 + I_1^2)$$

Therefore $\quad I_e^2 = I^2 + I_1^2.$

Now I_e, the intensity of direct current producing a given temperature-rise in the cable, is directly determinable when the conditions of laying are known. In the case of the tests described in the paper, curves are given which enable the value I_e to be read off directly. For cables laid under certain conditions the values of the current for a given temperature-rise of the core can be obtained from other sources.* I_1 is given by $W_s = I_1^2R$. Hence I is calculable.

* S. W. Melsom and H. C. Booth: *Journal I.E.E.*, 1911, vol. 47, p. 711; also S. W. Melsom and E. Fawssett: *Ibid.*, 1923, vol. 61, p. 517.

Returning to the first method where the ohmic resistance of the core is increased by an amount R_1 we have, from the preceding, the lead-sheath loss given by

$$W_s = i_s^2 r_s$$
$$= I^2 r_s\left(\frac{\omega^2 M^2}{r_s^2 + \omega^2 L_s^2}\right) = W_c\left(\frac{r_s}{R}\right)\left(\frac{\omega^2 M^2}{r_s^2 + \omega^2 L_s^2}\right)$$

Also $\quad W_s = I^2 R_1$ and $W_c = I^2 R$.

Therefore $\quad \dfrac{W_s}{W_c} = \dfrac{R_1}{R} = \dfrac{r_s}{R}\left(\dfrac{\omega^2 M^2}{r_s^2 + \omega^2 L_s^2}\right)$

where R = direct-current resistance of the core,
R_1 = resistance by which the square of the permissible current is multiplied to give the lead-sheath loss,
$(R + R_1)$ = resistance by which the square of the permissible current is multiplied to give the total losses under alternating-current working,
and I = permissible current loading under alternating-current working.

This means that lead losses may be expressed in terms of conductor loss and, therefore, regarded as a decrease in the copper cross-section, the loading being correspondingly reduced.

Let $\quad R_f = R + R_1$

If a_f, a and a_1 are the cross-sections corresponding to the resistances R_f, R and R_1

then $\quad \dfrac{1}{a_f} = \dfrac{1}{a} + \dfrac{1}{a_1}$

where a_f is the section of a fictitious conductor carrying the permissible current I in which the direct-current loss is equal to the loss occurring in the actual cable of section a

$$\frac{a_f}{a} = \frac{R}{R + R_1}$$

Proceeding on the assumption that the total heating occurs wholly in the core, we can determine the permissible loading when alternating current is employed.

The relation between the current I in a cable of cross-section a, when only conductor heating is considered, is given by

$$I = f(a)$$

Hence if I = actual current loading, and
I_e = theoretical current loading

then $\quad \dfrac{I}{I_e} = f\left[\dfrac{a_f}{a}\right] = f\left[\dfrac{R}{R + R_1}\right]$

This may also be expressed graphically as in Fig. 14, where curve 1 is given by $I = f(a)$

Now $\quad \dfrac{W_s}{W_c} = \dfrac{R_1}{R} = \dfrac{a}{a_f} - 1 = \dfrac{a}{a_1}$

Hence $\quad a_1 = \dfrac{W_c}{W_s} \times a.$

In the figure, AC is given by $(W_c/W_s) \times$ AB, since B is a point on the curve $I = f(a)$, and AC represents the copper cross-section across which the square of the current OA flows to produce the lead-sheath losses. A series of points can thus be obtained from experiment or calculation, and curve 2 drawn through them will satisfy the equation

$$a_1 = \frac{W_c}{W_s} \times a.$$

To complete the figure we join OC, draw BM perpendicular to the horizontal axis, and join AM cutting OC in P.

Then the ordinate RQ gives the permissible current loading with alternating current.

The section represented by OQ gives with an alternating-current loading (represented by RQ) the same

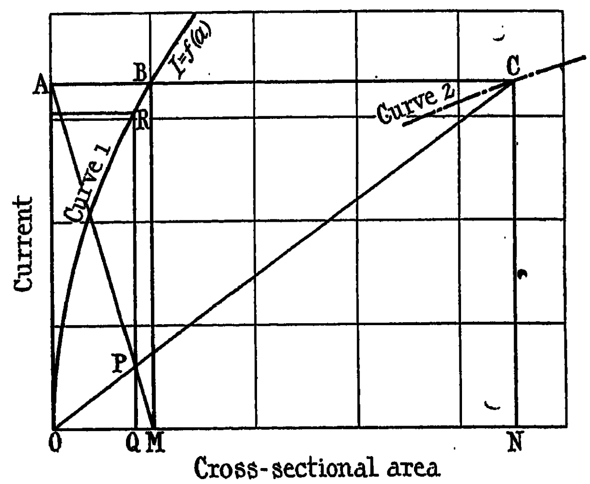

FIG. 14.—Construction for obtaining the permissible loading of a cable circuit on the assumption that the total heating occurs wholly in the conductor.

loss of energy as the section represented by OM gives with a direct-current loading represented by BM.

$$OQ = a_f$$
$$OM = a$$
$$ON = a_1$$

and $\quad \dfrac{1}{a_f} = \dfrac{1}{a} + \dfrac{1}{a_1}$

A similar figure has been given by Soleri* in connection with the dielectric losses in high-tension cables.

The calculated value of the ratio R_{eff}/R is greater than the measured value in the case of the large cable (0·5 sq. in.) working at its normal rating, but the formula is in good agreement with experimental determination for the cables of 0·3 sq. in. and 0·1 sq. in. cross-section.

The maximum difference observed over the range of cables tested was about 4 per cent of the current loading, which is probably near enough for practical purposes.

The differences between actual and calculated values are due partly to small differences of temperature.

* Bibliography, item (6).

Further, in the theory a number of assumptions are made in order that the mathematics may become manageable, but it is evident that some of these do not completely fit the facts. For example, the theory assumes uniform current distribution, whereas the latter is affected by the presence of the return conductor. In this instance, however, formulæ are avilable for estimating this effect, and, for further particulars, "Theorie der Wechselströme" by J. L. La Cour and O. S. Bragstad should be consulted. Also, in the calculation of the coefficients of induction the effect of end-connections is neglected.

The impedance and power were not checked experimentally, but the theory shows that the resistance factor is the important one in the expression for impedance. As pointed out by Atkinson,* it is possible for the impedance of the cable to be greater when the lead is short-circuited than when it is open-circuited.

In considering the experimental work it is important, in order to obtain results of any value from a theoretical treatment, to know the actual values of the resistances of the copper and lead per unit length, more especially the lead. These "constants" should be obtained by measurements on the actual cable, for they are important factors in the theory and it is of little use to assume a resistivity for lead and work from the dimensions to get the losses. Small variations in r_s affect the calculated losses to an appreciable amount. These precautions will be more important when dealing with the larger sizes of single-conductor cable with small spacings, for then the theory is likely to depart still further from practice, owing to the difficulty of accounting for the complex proximity effect.

The fact that even with the largest size of cable tested no measurable difference could be detected between the heating with direct current and with alternating current, and the lead sheaths being open-circuited, indicates that under these conditions the eddy-current effects (skin effect) in sheath and in conductor are negligible. With still larger sizes of cable, however, the skin effect would become appreciable.

DISCUSSION BEFORE THE NORTH-EASTERN CENTRE, AT NEWCASTLE, 24 NOVEMBER, 1924, ON THE ABOVE PAPER AND ON A PAPER * BY MESSRS. MELSOM AND BOOTH.

Mr. E. Fawssett: The paper by Messrs. Melsom and Beer is a very good example of a carefully controlled series of experiments the results of which are compared with theory. I wish, however, that the authors had carried their investigations to greater separations—at least on one size of cable to obtain the characteristic—and had also employed up to at least 1·0 sq. in. cables, as the additional sheath losses rise very rapidly with the size of cable used. The theoretical law of sheath losses versus separation in a single-phase system was shown † by Prof. Cramp and Miss Calderwood to depend on a logarithmic term $\log_{10}[(1 - K^2)/K]$, K being the ratio of the cable radius to the axial separation, and varying from 0·23 with the cables nearly touching to 36 (theoretically) when the return cable is at a nearly infinite distance away, or, say, about 1 to 150. This ultimate figure is, of course, impossible because of the bond resistance then necessary. The curve drawn for the ratio a.c./d.c. loading from this formula, after providing for the proximity effect, comes well below the authors' experimental results at moderate separations, and this is a further reason why they should have shown the effect of separation over a wider range, seeing that it is rapidly increasing at the point where they left off. I consider that the authors were quite right to limit their investigations to a "continuously earthed" system, as this is the usual and also the severest case. While the method of measurement adopted is justified in their case for this particular investigation, it is not one ordinarily capable of great accuracy and requires very specially close control of the current and of the room temperature: at a temperature-rise of 35 deg. C. this ought to be held to within ½ deg. C., which is, I think, scarcely possible. I have not been able to repeat results by this method with such accuracy as would permit me to assert that a 0·5 sq. in. single cable will carry exactly the same current with direct current as with alternating current at 50 periods per sec., and considering the additional losses that there must be in the latter case (sheath eddy currents 1 per cent and skin effect about 1 per cent in terms of copper loss) it would not appear to be rigidly true. More especially does it seem remarkable

* "The Current-Carrying Capacity of Solid Bare Copper and Aluminium Conductors," *Journal I.E.E.*, 1924, vol. 62, p. 909.

† "The Use of Single-Core Sheathed Cables for Alternating Currents," *ibid.*, 1923, vol. 61, p. 477.

that this method could detect no difference between direct and alternating current for a pair of 0·5 sq. in. cables with sheaths not bonded but with iron interposed, when the induced sheath voltage is very much higher than normal and there must be some losses in the iron preventing it having the same cooling effect as on direct current. The equation $I_1^2R_1 = I^2R$ given on page 191 would hold as stated for equal heating in the two cases, but I submit that for a given core temperature-rise the heat-flow conditions with direct and alternating current respectively are very far from equal. With the latter a large percentage of the total watts are expended directly in the sheath and therefore only elevate the core temperature by approximately 75 per cent of what they would if they were expended in the core. Consequently the increment over the copper loss should be increased by 1/0·75 or 33 per cent in order that the resulting effective resistance figure may really represent the watts that have to be supplied. This does not in any way vitiate the experimental results or the conclusions to be drawn from them, provided it is made quite clear that R_1 is the a.c. resistance for thermal considerations only. Seeing that the theory of mutual heating has been worked out, I scarcely think that in Table 1 *et seq.* the term *theoretical* current-loading should be employed for a value which it is known must be wrong, and I would suggest substituting

$$\frac{\text{Pair d.c. loading*}}{\text{Single d.c. loading}}$$

In Fig. 4, curve F seems to agree closely with Prof. Cramp's and Miss Calderwood's figures, curve B showing that the practical result is substantially better. This divergence increases with the size of the cable and if the figures for a 1 sq. in. cable showed the same tendency exaggerated they would be very reassuring. It should be emphasized that Fig. 5, showing the increment of apparent resistance, is applicable to core heating only, since the real effective electrical resistance is considerably higher, the figures to compare with the last column of Table 3 being 1·112, 1·164, 1·39 and 1·557, this last showing a 10 per cent increase over the figure 1·417 in the table. If "proximity effect" curves be drawn from Tables 1, 8 and 10, it is remarkable that the 0·5 sq. in. value starts, when sheaths are in contact, between the values for the 0·3 sq. in. and 0·1 sq. in. sizes. Can the authors account for this? I should like to see an additional figure, similar to Fig. 8, for the case of Table 12. Curve E in Fig. 8 corresponds to curve A for the iron-free condition, but it cannot be combined with C, as the proximity effect with iron interposed is quite different, and a new curve F is required, the resultant of which with E, say G, would then be comparable with D in Fig. 8, giving a different separation, I think, for the maximum loading. There seem to be serious discrepancies in Tables 13 and 14 [since revised for the *Journal*]. The authors state (in the advance copies of the paper) that the relation between the current I in a cable of cross-section a when only the conductor heating is considered is given by $a = KI^2$. If this means "for constant watt loss" I agree, but if, as the curve derived from it in Fig. 14 states, "permissible loading," i.e. constant temperature-rise, is meant, then the watt loss varies as the radius of the cable. Consequently, if the radius be doubled and the area therefore increased four times, the ratio of the squares of the two currents appears to be 1 to 8 for constant temperature-rise, whereas according to the quoted equation it should be 1 to 4. Perhaps I have misunderstood the authors' meaning, but as the construction in Fig. 14 depends on it I should like to hear their explanation. From results on single-core cables in the Report on the Heating of Buried Cables it would appear that, experimentally, $a = KI^{1\cdot5}$. The experimental results in the paper will certainly be of very great value indeed to all users of single-core cables.

* Since substituted in the paper as printed in the *Journal*.

Mr. H. Parry: The cooling-curve method of determining h described by Messrs. Melsom and Booth in their paper published in the November 1924 issue of the *Journal* is very neat, and it is very satisfactory to know that the heat loss can be determined from such simple equations. The method has the disadvantage that the specific heat must be known; this appears to be a variable for copper, as values given in the Smithsonian tables covering the temperature interval 25 deg. C. to 100 deg. C. are 0·0917 to 0·0942 respectively. For busbar purposes the results obtained with dull black paint are chiefly of theoretical interest, as the bars are usually either not painted or painted with the colours red, white and blue for marking polarity, the paints having a glossy surface. I think that it would be of great practical value if the authors would give figures for h under these conditions. The "proximity effect" tests should have included tests with the spacing between the bars equal to the bar thickness, for in multiple-bar busbars this seems to be the usual practice. I think it is worth noting that busbars have not only their own losses to radiate but have to carry away most of the heat from ammeter shunts and such-like apparatus, and allowance should be made for this. I have compared the values for h given in the paper with those given for lead cable sheaths of 1 in. and 1¾ in. diameter in the *Journal* (1923, vol. 61, p. 571), where the average figures are 0·0007 (bright) and 0·0011 (black) at a temperature of 30° C. These values are much higher than those given by the authors. Do they consider that this is due to the lower temperature or to the nature of the surface? I think that the brackets in Equation (3), page 910 (vol. 62), should be deleted.

Mr. T. Carter: With reference to Messrs. Melsom and Booth's paper, it would appear that the regulations specifying that busbars shall be painted with colours to indicate their polarity or their phase relation may have the effect, since bright enamels are often used, of seriously reducing the carrying capacity of the bars, and further comment by the authors on this point is very desirable. The paper states a definite figure for the reduction in carrying capacity due to the placing of two bars near each other with a distance between them equal to their breadth; it is important to know what the effect is of placing bars near each other with a distance between them approximately equal to their

thickness, this being the arrangement commonly met with in bars with interleaved joints, when the parts between the joints are spaced out from each other by the thickness of the interleaved strips. What, for example, would be the effect of using 8 pieces 3 in. × $\frac{1}{8}$ in., spaced $\frac{1}{8}$ in. apart, in place of one solid piece 3 in. × 1 in.?

Messrs. S. W. Melsom and **W. E. Beer** (*in reply*): The separation of the cables was not carried much beyond 12 inches, as this was considered to cover the practical range of spacings. The method of measurement employed is capable of a good degree of accuracy, as pointed out in the paper. The arrangements for steady temperature require special consideration, but are in no way impossible. In the case referred to at the top of page 195 in which no difference was observed between the heating with alternating current and with direct current for a pair of 0·5 sq. in. cables the axes of which were 12·5 inches apart, this result would be expected from theoretical considerations and is in agreement with the observations of other experimenters. Doubtless there are small additional losses with open-circuited sheaths, for the reasons given by Mr. Fawssett, but they are too small to be detected. Such detection would require measurements having an overall accuracy lying within $\frac{1}{2}$ of 1 per cent.

We agree with Mr. Fawssett in the matter of the heat-flow conditions with alternating- and direct-current loadings, and also on his observations with respect to effective resistance. The figures given for R_1 and $\frac{R_{eff.}}{R}$ all refer to a thermal basis, and the values of effective resistance to alternating current on a watt basis, as usually understood, would be greater than those given, owing to the losses in the sheath. These remarks apply also to Fig. 5. The substitution of

$$\frac{\text{pair d.c. loading}}{\text{single d.c. loading}} \text{ for } \frac{\text{actual d.c. loading}}{\text{theoretical current loading}}$$

in Tables 1, 8, and 10 has been made in accordance with Mr. Fawssett's suggestion.

Referring to Fig. 4 wherein the practical result (curve B) is substantially better than the theoretical result (curve F), this is all to the good, but it should be noted that the mutual heating effect is of great importance at the usual spacings, and considerably modifies the permissible loading, taking into account only the sheath losses. In practice the sheath inductive effects, for given dimensions of conductors and for a given spacing, would be governed largely by the bonding resistance introduced, and, further, there is the damping effect of the eddy currents in the lead sheaths, which would introduce a divergence between measured and calculated values. As regards the starting points of the proximity or mutual heating-effect curves, the results given were those obtained by experiment and the difference between the 0·3 and 0·5 sq. in. cable circuits is, in any case, not large.

Mr. Fawssett refers to Fig. 8, in which the curves for a 0·1 sq. in. cable system are plotted. As he points out, curves E and A are comparable, and they show that the presence of iron at the lowest spacing (1·23 in.) decreases the permissible current-loading by about 7 per cent. The mutual heating effect is additional to this and, referred to the case of a single cable in air, is 97·3 per cent at 1·23 in. spacing, 99·8 per cent at 3·2 in. spacing, and 100 per cent at 7·25 in. and greater spacings. Thus the actual loading at 1·23 in. spacing with iron interposed will be reduced to 89·3 per cent of the loading of a single cable in air. The latter has been taken as standard, for this is the value given for all sizes of cables in the Report on the Heating of Buried Cables, whereas the rating of a single cable laid against an iron girder (which might have been used) has no general meaning.

We have to thank Mr. Fawssett for drawing attention to the discrepancies that appeared in Tables 13 and 14 in the advance copies of the paper; these have been revised for the *Journal.*

Mr. Fawssett has also drawn attention to an expression $a = kI^2$ which appeared in the advance copies of the paper. It arises from the procedure of expressing the sheath loss in terms of an increased core loss, i.e. the total energy loss is compared with the loss arising in the conductor only of a cable the section of which is less than the actual cross-section. In the paper the changes in resistance and cross-section are denoted by R_1 and a_1 respectively. For single-core cables $I^2R = k\theta$, where k is a constant for given conditions of laying and given dimensions of cable, and θ is the temperature-rise of the core above the medium in which the cable is disposed. Then for cables having the same overall lead diameter and the same temperature-rise, $k\theta$ is constant, and small changes in I and R will be given by

$$\frac{I}{I_e} = \sqrt{\left(\frac{R}{R + R_1}\right)} = \sqrt{\left(\frac{a_f}{a}\right)}$$

If, however, the extreme case is taken (similar to Mr. Fawssett's example) where the copper area is increased four times, with consequently large changes in the emissivity constant, then the relation $I = f(a)$ should be employed, the function to be determined from the experimental results in the paper, or it may be deduced, as Mr. Fawssett has done, from the recent Report on the Heating of Buried Cables. The last relation is generally true and, to meet Mr. Fawssett's point, has been substituted in the paper. This will, however, make no difference to the method of construction shown in Fig. 14, which is simply a geometrical construction corresponding to the expression

$$a_f = \frac{aa_1}{a + a_1}.$$

Messrs. S. W. Melsom and **H. C. Booth** (*in reply*): Mr. Parry draws attention to an apparent discrepancy between the values of the heat-emissivity constant given in the Buried Cables Report and those deduced from the formula. It should be pointed out, in connection with the values of h which appear in the earlier Report, that Newton's law of cooling was assumed; but as the results now given indicate, the assumption that the rate of cooling is proportional to the 5/4 power of the temperature excess is more nearly correct and has been used in deducing the values of h. If this assumption be followed, the values of h derived from the data quoted in the *Journal* will be found to be closely in agreement with those deduced from Equation (5).

It will also be noticed that the ratio of the emissivities of bright to black surfaces, as derived from the mean of all the results given in the earlier Report, namely 0·00070 and 0·00107, or 1/153, is almost identical with that now deduced, namely 1/154. In deducing the values of h the specific heat of copper was taken as 0·094, which is a fair mean of the specific heat for the range of temperature over which the emissivity was measured, and is in good agreement with the latest determinations.

In reply to Mr. Carter, the effect on the emissivity constant when bars are separated by a distance equal to their thickness, which occurs when a number of strips are interleaved, was not considered, though it is hoped to investigate this problem at a later date. Meanwhile it would be safest to assume that under these conditions the emissivity is approximately equal to that of a solid bar having the same girth. Thus in the case quoted by Mr. Carter the girth of the eight pieces, 3 in. × $\frac{1}{8}$ in. would be $2(3 + 1\frac{7}{8}) = 9\frac{3}{4}$ in. This leaves out of account the heat emission from the inner surfaces of the interleaved strips, but on the other hand it will compensate for the greater temperature-rise experienced by the centre strips as compared with the outer ones. It is probable that where the strips are painted with bright enamels the actual colours have little effect, and the emissivity from surfaces so painted will be very nearly the same as that from surfaces painted a glossy black, which was found to be about 12 per cent higher than that from bright metallic surfaces.

THE LOAD CHARACTERISTIC OF A DYNAMO GIVING CONSTANT CURRENT OVER A LARGE RANGE OF SPEED.*

By J. C. PRESCOTT, M.Eng., Associate Member.

(*Paper first received* 1*st August, and in final form* 22*nd October*, 1924.)

SUMMARY.

A graphical method of predicting the characteristics of a constant-current dynamo, such as the Rosenberg † or Brolt,‡ has been developed and, in the Appendix, the formula derived by the late Dr. Kapp § has been extended to determine the maximum current flowing in the short-circuited paths of the armature, and the steady value of the load current. It is also shown that the maximum value of the short-circuit current occurs when the load current reaches half its final value.

Tests carried out in the Laboratories of Applied Electricity of the University of Liverpool on a non-salient-pole machine are cited to show that the constant-current characteristic of the Rosenberg dynamo may be attained without the use of slotted or salient poles.

§ G. KAPP: "Principles of Electrical Engineering," vol. 2, p. 85.

INTRODUCTION.

The type of dynamo dealt with in this paper is designed for train and automobile lighting and will supply an almost constant current * to a load of constant resistance over a large range of speed, while the polarity of the load brushes is independent of the direction of rotation. When, as is usually the case, a battery is used, floating on the line, arrangements must be made to prevent the battery from being short-circuited when the generator speed is very low and the voltage, therefore, below the normal; an aluminium cell used as a valve is generally placed in series between the armature and the battery. The action of the generator (Rosenberg type) is as follows:—

The shunt field (see Fig. 1) produces in the armature an E.M.F. between the brushes "a" and "b." These brushes being short-circuited, a current passes in the armature conductors and gives rise to a cross field in the line AB at right angles to the line of the load brushes CD. A voltage therefore appears between "c" and "d" which is, for any given speed, proportional to the cross flux due to the short-circuit current in the armature. The load current in turn produces a flux in the line CD, in a direction opposite to that of the main field. At any given speed the short-circuit current must be proportional to the difference between the flux due to the current in the main field winding and that due to the load current in the armature conductors.

* A Rosenberg dynamo may be designed to give a current variation of 12 per cent between speeds of 800 and 2 400 r.p.m. when supplying a load of constant resistance.

Thus the increase in load current which occurs with an increase in speed in an ordinary dynamo, when working on a load of constant resistance, is reduced in the machine under consideration by an automatic weakening of the main field.

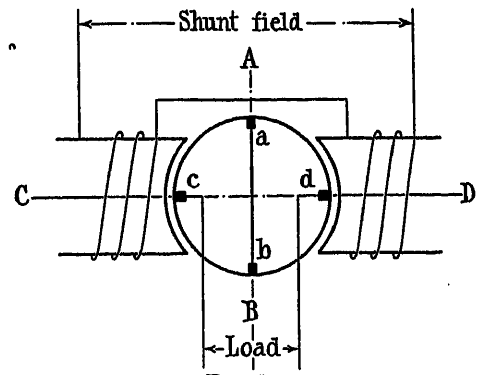

FIG. 1.

GRAPHICAL PREDETERMINATION OF CHARACTERISTICS.

The "speed/load current," and the "speed/short-circuit current" curves of the Rosenberg machine may be determined graphically if the field and armature saturation curves are known for some given speed, it being assumed that the armature resistance is R_a, the total short-circuit resistance R_s, and the load resistance R_l, the total turns on the field t, and the total armature turns T.

The method of predetermination is as follows :—

(1) The curves connecting field current and speed are plotted for various constant values of the short-circuit current.

(2) The straight lines connecting load current and speed are plotted for the same constant values of the short-circuit current.

(3) The field currents in (1) are reduced to equivalent load currents and the curves thus obtained plotted together with the lines from (2), on the axes of speed and load current. The points of intersection of the line and the curve thus obtained for any given value of the short-circuit current give two * points on the load-current/speed curve, while from the speeds corresponding to these intersections and the value of the short-circuit current on whose curve the intersections occur, the short-circuit-current/speed curve may be obtained.

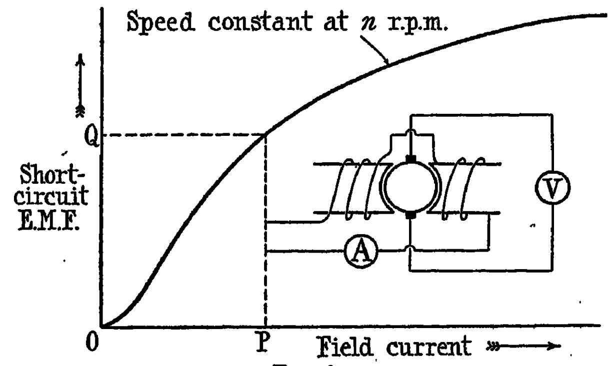

FIG. 2.

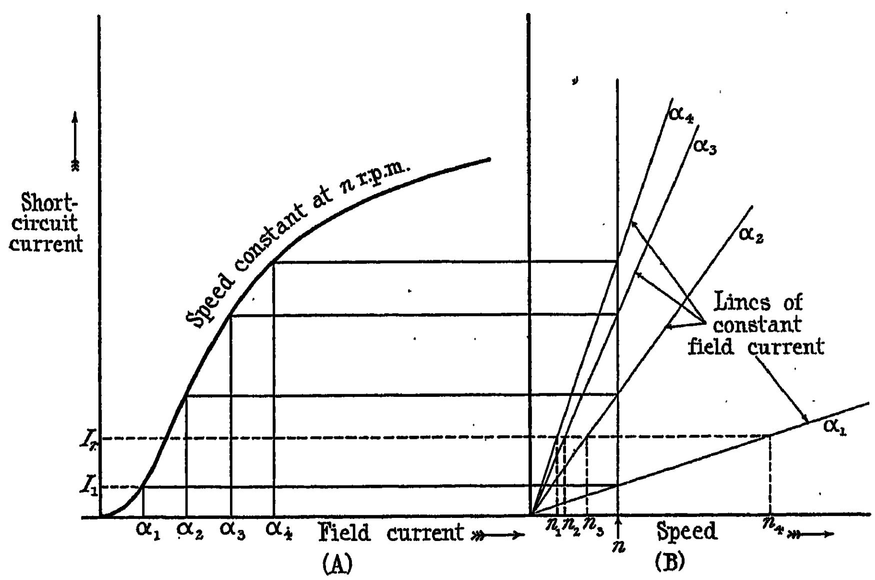

FIG. 3.

(1) *Field current and speed.*—The field saturation curve will give the relation between the field current and the voltage across the short-circuit brushes (the short-circuiting connection being removed). Let this curve represent the conditions at a speed of n r.p.m. (see Fig. 2). At any given field current OP, the short-circuit brush voltage is OQ at speed n, and will be (n'/n)OQ at speed n'. The resistance of the path of the short-circuit current being R_s, the curve may be made to represent the relation between speed and

* Except in the unique case where the curve is tangential.

short-circuit current if the ordinates are divided by R_s. This curve is shown in Fig. 3 (A). A series of straight

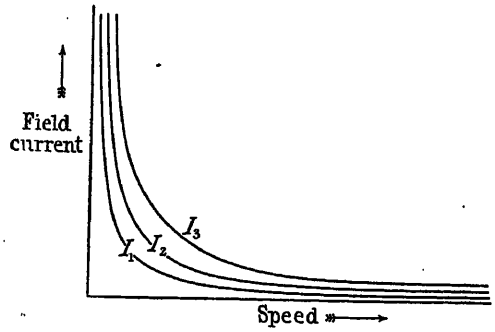

FIG. 4.—Curves of constant short-circuit current.

lines may therefore be drawn on the axes of speed and short-circuit current, each line representing some definite field-current [see Fig. 3 (A)].

constant short-circuit currents I'_1, I'_2, I'_3, etc., I'_1, I'_2, I'_3, etc., being chosen so as to be numerically equal to I_1, I_2, I_3, etc., respectively in Fig. 4.

(3) *Conversion of field current to equivalent armature load current.*—Curves have now been obtained between speed and field current, and between speed and load current, for various constant values of the short-circuit current. These curves must be combined to give the load current/speed characteristic. It has already been pointed out that the armature demagnetizing ampere-turns produced by the load current directly oppose the field ampere-turns (which are constant), the paths of the two fluxes being, of course, identical (neglecting leakage). The ordinates of Fig. 4 should therefore be converted to represent equivalent load currents, since it is obvious that the short-circuit E.M.F. could have been produced by exciting the armature from the load brushes instead of from the field.

If t = field turns and T = armature turns, the

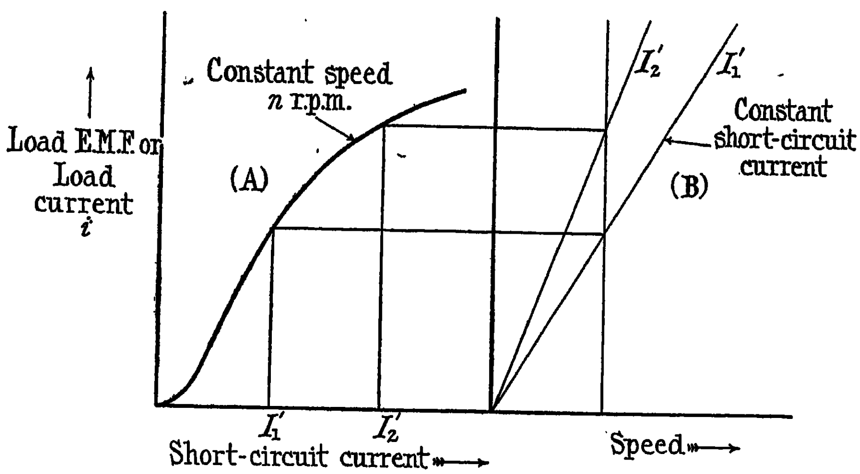

FIG. 5.

For a field current of a_1, the short-circuit current is I_1 for a speed of n, and is proportional to the speed if the field is constant. This gives the line a_1 in (B) which passes through the perpendicular erected at n at a height of I_1. The lines a_2, a_3, etc., are determined in the same way.

From these lines a family of curves may be obtained connecting field current and speed for various values of short-circuit current; for, taking any short-circuit current I_r, this current may be obtained by a_4 at speed n_1, or by a_3 at speed n_2, and so on. The curves are shown in Fig. 4.

(2) *Armature load current and speed.*—The armature saturation curve in Fig. 5 may now be considered. This curve gives the relation between the current in the short-circuit and the voltage on the load brushes. If this voltage be divided by $(R_a + R_l)$ the curve may be made to represent the relation between short-circuit current and load current. This curve is treated in the same way as that between short-circuit current and field current in order to obtain a pencil of lines representing the variation of load current with speed, for

conversion factor is ta/T, where a = number of parallel paths in the armature.

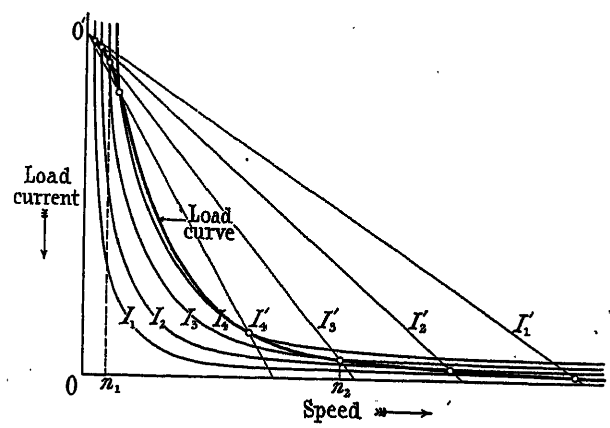

FIG. 6.

Let OO′ (Fig. 6) represent the normal field current in terms of the load current. When the machine is at

rest the resultant field in the line of the load brushes is OO′. As soon as the speed rises the load current flows, demagnetizing armature ampere-turns are intro-

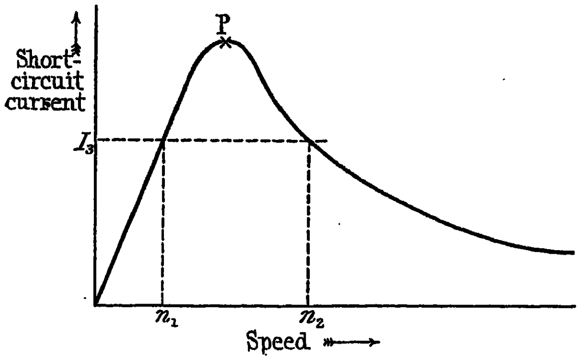

FIG. 7.

duced and the resultant field drops from O′ towards zero. The short-circuit lines [Fig. 5 (B)] must therefore

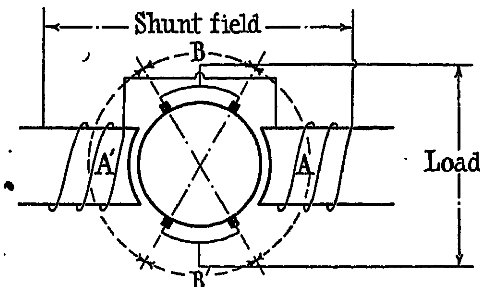

FIG. 8.

be drawn from O′ downwards, and points of stability occur where these lines cut the curves derived from Fig. 4. The load current/speed curve is obtained by join-

instance, the line I_3' cuts the curve I_3 at points corresponding to speeds n_1 and n_2. Thus if I_3 is plotted against speed, two points on the short-circuit-current/speed curve are obtained. This curve has the shape shown in Fig. 7. The value at P, being unique, corresponds to the short-circuit current whose line is tangential to the curve for that same current.

The voltage/speed curve can be calculated from the current curve, since the load resistance is constant.

Brolt machine.—The characteristic of the Brolt machine (see Fig. 8) may be obtained in a similar manner, though in this case the conductors producing the load voltage are contained in the arcs A, A′, and those carrying the short-circuit current in the arcs B, B′.

(2) TEST-RESULTS.

Measurements were made upon a non-salient-pole machine having the following particulars :—

Full-load continuous rating	25 amperes
Resistance of short-circuit path ..	0·37 ohm
Resistance of armature (wave-wound)	0·35 ohm
No. of poles	4
Ratio $\dfrac{\text{field ampere-turns}}{\text{armature ampere-turns}}$ ..	1·2

The rotor and stator conductors are wound in semi-closed slots, the stator winding being contained within 50 per cent of the periphery. The poles are non-salient and the stator iron is laminated. The predicted curves and the curves actually obtained by measurement are given in Fig. 9. It will be seen that above 300 r.p.m. the current is reasonably constant. The distortion of the field on the non-salient poles is probably responsible for the discrepancy between the actual and predicted short-circuit current. Although this distortion may affect commutation it is advan-

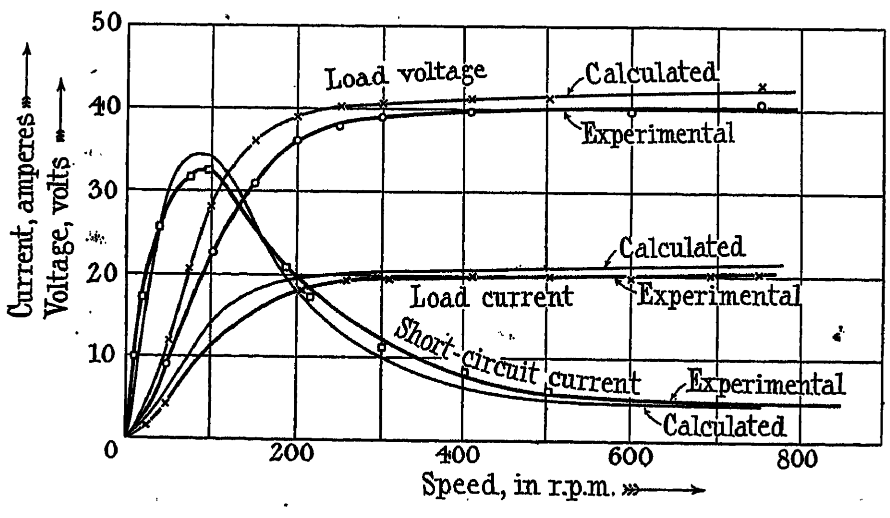

FIG. 9.

ing the points of intersection and is shown in the heavy-line curve of Fig. 6. The origin for this curve is O′.

The short-circuit characteristic.—The short-circuit current itself may also be obtained from Fig. 6. For

tageous in so far as it prevents the rise of the short-circuit current to the theoretical maximum, while the characteristic of the original Rosenberg machine with salient slotted poles is closely imitated.

APPENDIX.

Mathematical Expressions for Load Current and Short-Circuit Current.

If I is the short-circuit current and i the load current, we have

$$I = K'n\,(\phi - Ki/a) \quad . \quad . \quad . \quad . \quad (1)$$

where n = speed in revolutions per minute,
$K' = Zp/[R_s(10^8 \times 60)a]$,
Z = number of armature conductors,
p = number of poles,
a = number of parallel paths in the armature,
ϕ = flux per pole due to shunt field (constant),
R_s = resistance of short-circuit, and
$K = T'/0\cdot 8\rho$, ρ being the reluctance per pole of the main flux path and T' the cross-magnetizing turns per pole on the armature.

The main current i is directly proportional to the speed and to the flux produced by the short-circuit current in the armature.

$$i = K''\frac{In}{a} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where $K'' = ZT'p/[a(R_a + R_l)(10^8 \times 60)0\cdot 8\,\rho']$, ρ' being the reluctance per pole of the path of the short-circuit flux R_l the resistance of the load circuit, and R_a the armature resistance.

Combining Equations (1) and (2) we obtain

$$i = \frac{\phi}{a/(K''K'n^2) + K/a} \quad . \quad . \quad . \quad . \quad (3)$$

Substituting the values for K, K' and K'' this expression becomes

$$i = \phi \div \left[\left(\frac{10^8 \times 60 \times a}{Znp}\right)^2 \frac{(R_a+R_l)R_s a(0\cdot 8\rho')}{T'} + \frac{T'}{(0\cdot 8\rho)a}\right]$$

If a be the shunt field current and t' the number of turns per pole on the shunt field, we obtain

$$i = \frac{at'}{\dfrac{(0\cdot 23 \times 10^{20})(R_a + R_l)R_s\rho\rho' a^3}{(Zpn)^2 T} + \dfrac{T'}{a}} \quad . \quad (4)$$

Writing $T' = Z/(2p)$ this expression becomes

$$i = \frac{at'}{\dfrac{(0\cdot 46 \times 10^{20})(R_a + R_l)R_s\rho\rho' a^3}{Z^3 n^2 p} + \dfrac{Z}{2pa}} \quad . \quad (5)$$

In order that i may be practically independent of the speed (n) the first term in the denominator must be small compared with the second. Thus the number of turns on the armature must be large, as remarked by the late Dr. Kapp, and the speed must be high. The product of the reluctances ρ, ρ' of the main flux path and the short-circuit flux path appears in the numerator of the first term, and, therefore, both reluctances should be small. The reluctance of the short-circuit path may with advantage be kept low, but a low reluctance in the path of the main flux, although desirable at high speeds, will result in a heavy short-circuit current at low speeds when the load current is small. The short-circuit current at any given speed is proportional to the resultant main flux, which is equal to the difference between the flux due to the shunt field and that due to the load current in the armature. Thus at low speeds some means must be found to reduce the resultant flux. This is achieved by arranging that the field-magnet iron when under the influence of the shunt ampere-turns alone is highly saturated. In this way the maximum value of the shunt flux and, therefore, of the short-circuit current is kept within safe limits; while, when the machine is operating at speeds at which the load current is sensibly constant, the resultant flux is small and the reluctance of the main flux path therefore low. That is to say, under operating conditions when supplying load current the machine works on the lower part of the saturation curve.

On the assumption that the reluctances of the main flux path and the short-circuit flux path are constant over the whole range of speeds, an expression may be obtained for the maximum value of the short-circuit current.

Equations (1) and (2) combined to eliminate n give

$$I = K'\frac{ia}{IK''}\left(\Phi - K\frac{i}{a}\right) \quad . \quad . \quad . \quad . \quad (6)$$

Differentiating I with respect to i and equating to zero for the maximum value of the former gives

$$i = \frac{a\Phi}{2K}$$

The limiting value for i is such as to make $(\Phi - Ki/a) = 0$; this occurs when $i = a\Phi/K$. Thus the maximum short-circuit current flows when the load current has reached one-half of its final value. This approximation is justified fairly well by the curves in Fig. 9. Substituting this value $a\Phi/(2K)$ in Equation (6), the maximum value of the short-circuit current is

$$I = 0\cdot 8\frac{a\Phi p}{Z}\sqrt{\left[\frac{R_a + R_l}{R_s}\rho\rho'\right]} = i_{max.}\frac{0\cdot 5}{\rho}\sqrt{\left[\frac{R_a + R_l}{R_s}\rho\rho'\right]}$$

where $i_{max.}$ is the maximum load current which the machine is designed to supply.

In conclusion, the author wishes to express his thanks to Prof. E. W. Marchant, who has put at his disposal apparatus and instruments; to Dr. F. J. Teago, who has helped him with criticism and advice; and to Mr. J. W. Gibson, who has made the actual laboratory measurements.

THE PULLING INTO STEP OF A SYNCHRONOUS INDUCTION MOTOR.*

By H. COTTON, M.B.E., M.Sc., Associate Member.

(*Paper first received* 1*st March, and in final form* 22*nd October,* 1924.)

SUMMARY.

When studying the phenomenon of the pulling into step of a synchronous induction motor from the mathematical point of view, it is usually assumed that the synchronizing torque is a sinusoidal function of the angular distance between the stator and rotor fields. The following research points out that this is erroneous for several reasons, the most important of which is the effect of armature reaction. This sets up a double-frequency component in the synchronizing torque which very considerably modifies the conditions during synchronizing. The synchronizing torque of a salient-pole motor also possesses a double-frequency component but it is produced differently from that of the non-salient-pole motor. It is shown that the operation of the motor when this component is taken into account is amenable to mathematical solution.

An experimental investigation carried out on a small induction motor run as a synchronous motor is also described.

LIST OF SYMBOLS.

T_m = maximum value of synchronizing torque, in pounds-feet;
T_l = load torque, in pounds-feet;
T_i = induction-motor torque, in pounds-feet;
T_n = maximum value of double-frequency synchronizing torque in salient-pole machines;
T_s = total synchronizing torque = $F(\theta)$
$\xi = T_n/T_m$; $\rho = T_l/T_m$;
$\mathrm{I} = mr^2/g$ in pounds, feet and seconds, unless otherwise stated;
t = time, in seconds;
p = number of pole-pairs;
ω = slip, in mechanical radians per second;
$p\omega$ = slip, in electrical radians per second;
θ = angular distance between the stator and rotor fluxes, in electrical radians;
ω_0 = value of ω when $\theta = 0$;
S = synchronous speed, in mechanical radians per sec.;
N = actual speed, in revs. per minute;
E = applied P.D. per phase;
W = power developed per phase, in watts;
w = external load on the motor, in watts;
R = resistance per phase of the stator;
a = base of Blondel diagram;
b = radius of zero power circle in the diagram;
c = length of the back E.M.F. vector with constant excitation;
d = length of current vector;
r = radius of circle of any power;
α = base angle of Blondel diagram;
P = period of phase swing, in seconds.

THE NATURE OF THE SYNCHRONIZING TORQUE.

The most interesting characteristic of the synchronous induction motor is its behaviour during the transition period from induction-motor to synchronous-motor running.* This is essentially a dynamical problem, and in order to investigate the changes of motion that take place during this period it is necessary to establish the equation of slip motion of the rotor. Mathematical investigations of the slip motion have up to the present been made on the assumption that the synchronizing torque is proportional to sin θ, the corresponding equation being that given by Carr,† namely

$$-\rho T_m + T_m \sin\theta + \frac{\rho T_m}{p\omega}\cdot\frac{d\theta}{dt} + \frac{\mathrm{I}}{p}\cdot\frac{d^2\theta}{dt^2} = 0$$

This equation is erroneous for three reasons. First, the motor armature (the stator in most cases) possesses appreciable resistance as well as reactance. The effect of this is, as shown on page 212, to displace the curve of T_s along the θ axis without destroying its sinusoidal form. Secondly, if the speed at any instant is not exactly equal to the synchronous speed the exciting winding will be carrying induced alternating currents of low frequency in addition to the direct-current excitation. Thirdly, there is the effect of armature reaction on the motor back E.M.F. and therefore on the synchronizing torque. The effect of the superposition of direct and induced alternating rotor currents is explained as follows: The exciter gives a very low voltage, usually of the order of 30 or 40 volts in large machines, and its armature resistance is as a result very low. The presence of the armature in one phase of the rotor circuit will therefore make very litt'e difference to the distribution of induced alternating currents whenever the slip speed is not zero. The rotor flux will as a result be a varying and not a constant flux. The variations in exciter terminal voltage due to the slowly pulsating current flowing through its armature will produce additional variations in the exciting current, but these will in all probability be negligible. The effect is at present indeterminate because the equation of motion, even in the simple form it assumes when the rotor direct-current excitation is assumed to be constant, cannot be solved in the general case.

Consider next the effect of armature resistance. This can be deduced from the Blondel diagram shown in

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* The method of running induction motors at synchronous speed by introductory direct-current excitation into the secondary winding appears to have been first suggested by DANIELSON (*E.T.Z.*, 1901, vol. 22, p. 1065) and used for experimental researches by BRAGSTAD and LA COUR (*ibid.*, 1903, vol. 24, pp. 34 and 174).

† "The Pulling into Step of an Induction-Type Synchronous Motor," *Journal I.E.E.*, 1923, vol. 61, p. 692. The derivation of this equation has been given by the present author in the following: "Synchronous Motor Operation," *Electrician*, 1924, vol. 92, p. 220; and "The Synchronous Induction Motor," *World Power*, 1924, vol. 1, p. 329, and vol. 2, p. 45.

Fig. 1. In the triangle OAB, the base AB = applied P.D. (E) per phase, and the slant sides OA = OB = $E/(2R)$, where R is the armature resistance per phase. Circles drawn with centre O are lines of constant power utilized.

Let W = power per phase,
r = radius of power circle for power W.

Then
$$r = \frac{1}{2R}\sqrt{(E^2 - 4WR)}$$

With uniform angular velocity of the rotor and a constant torque the working point P will be fixed. We have from the diagram

PA = stator current,
PB = motor back E.M.F.,
∠ OAP = angle of lag of the current behind the applied P.D.

Now suppose that the excitation is constant and that the rotor is slipping through whole pole-pitches, then

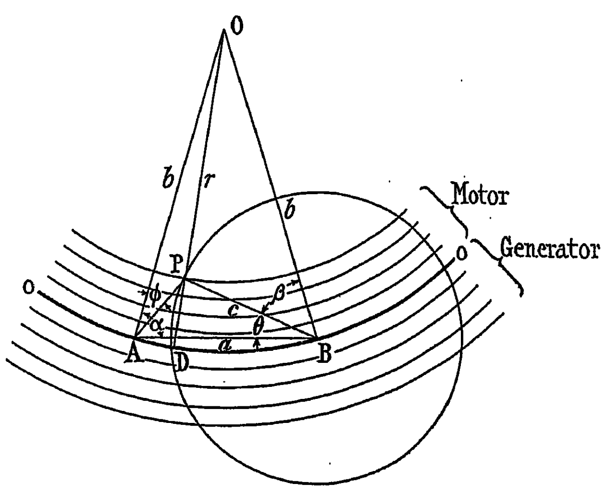

FIG. 1.

the vector BP will rotate about B as centre and will make one complete revolution for each pair of pole-pitches slipped by the rotor. The working point P will therefore pass over a whole family of circles of constant power. So long as P is above the circle of zero power, which passes through the points A and B, the machine will motor, but when it is below this circle the machine will function as a generator. The angle PBA is equal to the angle between the stator and rotor fields for any given position of the working point P; the angles OAB and OBA are fixed, being equal to α, say. Hence for the radius of the power circle for any given position of P we have

$$\begin{aligned} r &= \mathrm{OP} \\ &= \sqrt{(\mathrm{OB}^2 + \mathrm{PB}^2 - 2\mathrm{OB}\cdot\mathrm{PB}\cos\mathrm{OBP})} \\ &= \sqrt{(b^2 + c^2 - 2bc\cos\beta)} \end{aligned}$$

If we put

$$m = \frac{\text{power utilized}}{\text{maximum possible power}}$$

then
$$r^2 = b^2(1 - m)$$

from which it follows that

$$\cos\beta = \frac{c^2 + mb^2}{2bc}$$

or
$$m = \frac{2bc\cos\beta - c^2}{b^2}$$

Hence the power utilized is a sinusoidal function of the angle β, and therefore of the angle θ. This so far agrees with the reasoning of Lindstrom,* who considers a simpler form of diagram than the Blondel diagram. But whereas Lindstrom obtains zero power when θ is equal to 0° or 180°, we see that the angle θ is finite for zero power, its magnitude being then given by

$$\cos(\alpha - \theta) = \cos\beta = \frac{c^2}{2bc} \text{ when } m = 0$$

$$\begin{aligned} \therefore\quad \theta &= \alpha - \operatorname{arc\,cos}\frac{c}{2b} \\ &= \operatorname{arc\,cos}\frac{a}{2b} - \operatorname{arc\,cos}\frac{c}{2b} \\ &= 0 \text{ when } c = a \end{aligned}$$

Hence the motor only gives zero power when θ is zero in the special case in which the excitation is such that the vector c representing the motor back E.M.F. is numerically equal to the vector a representing the applied P.D. In an actual case the base angles of the triangle OAB are so very nearly equal to right angles that the displacement of the curve of T_s along the axis is very small. Experimental results are given on page 217.

The effect of the varying excitation due to the superposition of the direct and alternating currents in the rotor is to modify the motor back E.M.F., the result being that the back E.M.F. is not constant but varies with θ. This obviously causes the curve of T_s to depart from the sinusoidal form, since the path of the working point P as the motor slips two pole-pitches will no longer be truly circular.

Consider now the effect of armature reaction. Let the various lengths and angles be represented by the symbols denoted in Fig. 2. Since the magnitude of the armature reaction is proportional to the current I and therefore to the resultant E.M.F., or the vector AP of length d in the figure, and its magnetizing or demagnetizing effect is proportional to the sine of the internal angle of lag (or lead) ϕ (or $180 - \phi$), we have for the back E.M.F. at any instant

$$\begin{aligned} E_b &= c \pm pI\sin\phi \\ &= c \pm qE_r\sin\phi \\ &= c \pm qd\sin\phi\ \dagger \end{aligned}$$

where p and q are constants which can be determined experimentally for a given machine, E_r the resultant E.M.F. per phase, and c the length of the back E.M.F.

* A. LINDSTROM: "Auto-Synchronous Motors," *Electrician*, 1923, vol. 91, pp. 4 and 64.

† The current always leads the internal E.M.F., whether the machine is motoring or generating, because in the only case that need be considered the internal E.M.F. is greater than the applied E.M.F. Hence the minus sign is used when the machine is motoring, and the plus sign when it is generating.

vector for the given excitation on no load. Hence we have

$$a^2 + d^2 - 2ad\cos(90 - \psi) = (c \pm qd \sin\phi)^2$$

$$\therefore\ a^2 + d^2 - 2ad\sin\psi \qquad = (c \pm qd\sin\phi)^2$$

Put

$$d\sin\psi = x$$

$$d\cos\psi = y$$

and simplify the diagram by making the angles OAB and OBA right angles, which they very nearly are in an actual machine. Then

$$a^2 + x^2 + y^2 - 2ax = (c \pm qd\sin\phi)^2$$

Now

$$\phi = 180 + \psi - \theta$$

$$\therefore\ a^2 + x^2 + y^2 - 2ax$$

$$= \{c \pm qd\sin(180 + \psi - \theta)\}^2$$

$$= \{c \mp qd(\sin\psi\cos\theta - \cos\psi\sin\theta)\}^2$$

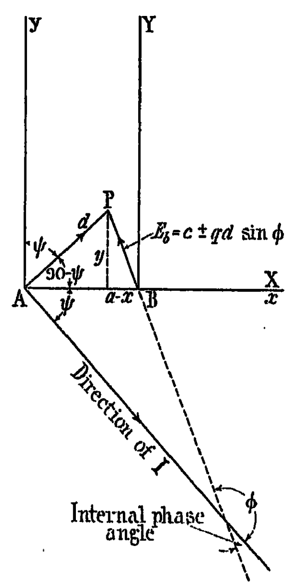

FIG. 2.

Again, to eliminate θ we have

$$\tan\theta = \frac{y}{a - x}$$

$$\sin\theta = \frac{y}{\sqrt{(a^2 - 2ax + x^2 + y^2)}}$$

and

$$\cos\theta = \frac{a - x}{\sqrt{(a^2 - 2ax + x^2 + y^2)}}$$

Substituting these values we have

$$a^2+x^2+y^2-2ax = \left\{c \mp qd\left(\sin\psi \times \frac{a-x}{\sqrt{\{(x-a)^2+y^2\}}} - \cos\psi \times \frac{y}{\sqrt{\{(x-a)^2+y^2\}}}\right)\right\}^2$$

This reduces to

$$\{a^2 + (1 \mp q)x^2 - 2ax(1 \mp q)\} \mp qax + (1 \mp q)y^2 = c\sqrt{\{(x-a)^2 + y^2\}}$$

Now put

$$x - a = X$$

$$y = Y$$

thus transferring the origin from A to B.

$$\therefore\ (1 \mp q)\{a^2 + x^2 - 2ax\} \pm qa^2 \mp qax + (1 \mp q)y^2 = c\sqrt{\{(x-a)^2 + y^2\}}$$

$$\therefore\ (1 \mp q)X^2 \pm qa^2 \mp qa(X + a) + (1 \pm q)Y^2 = c\sqrt{(X^2 + Y^2)}$$

$$\therefore\ X^2 + Y^2 \mp \frac{qa}{1 \mp q}X = \frac{c}{1 \mp q}\sqrt{(X^2 + Y^2)}$$

This is a quartic,* but it can be simplified by converting from rectangular to polar co-ordinates. Remembering that the angle θ is the supplement of the angle included between the rotating vector BP and the positive direction of X, we have

$$X^2 + Y^2 = r^2$$

$$X = -r\cos\theta$$

$$\therefore\ r^2 \pm \frac{qa}{1 \mp q} r\cos\theta = \frac{c}{1 \mp q} r$$

$$r = \frac{c \mp qa\cos\theta}{1 \mp q}$$

Also for the synchronizing power corresponding to any angle we have the perpendicular distance

$$Y = r\sin\theta$$

$$= \frac{c\sin\theta \mp \frac{1}{2}qa\sin 2\theta}{1 \mp q}$$

We see from this that the synchronizing power, and therefore the synchronizing torque, possesses a double-frequency component.

Thus the synchronizing torque is no longer a simple sinusoidal function of θ, the extent of its departure from this form depending upon the magnitude of the constant q. When q is zero we have $r = c$, the locus of P then being the circumference of a circle with centre B and radius equal to the constant motor back E.M.F. An actual experimental case is considered below. If we take the effect of armature reaction into account and put

$$T_s = F(\theta)$$

where F is a function which can be determined either by experiment or from the design data of the motor, then

$$-\rho T_m + F(\theta) + \frac{\rho T_m}{p\omega}\cdot\frac{d\theta}{dt} + \frac{\mathrm{I}}{p}\cdot\frac{d^2\theta}{dt^2} = 0$$

The direct solution of either the approximate or the more exact form of the equation appears to be impossible, so that it is necessary to consider a special case and make use of a step-by-step solution.

EXPERIMENTAL INVESTIGATION.

The whole of the experimental work given in this section of the paper refers to the case of a plain induction

* A somewhat similar problem relating to a salient-pole machine is discussed by E. B. SHAND (*Electric Journal*, 1921 vol. 18, p. 309), who obtains an elliptic locus.

motor synchronized by switching direct current on to the rotor. The specification of this motor is as follows :—

Number of poles	4
Horse-power	2
Voltage	245
Frequency	50

It would have been preferable to have performed the experiments on a larger machine, but unfortunately one was not available. The small size of the machine introduced many difficulties which in all probability would not have existed with a larger machine.

Moment of inertia of the rotor.—The rotor was drawn, and its moment of inertia determined from its time of oscillation in a bifilar suspension was

$I = 4\cdot32$ in ft.-lb. units, or $0\cdot182$ in metre-kg units.

Retarding torque.—In the experiment conducted to

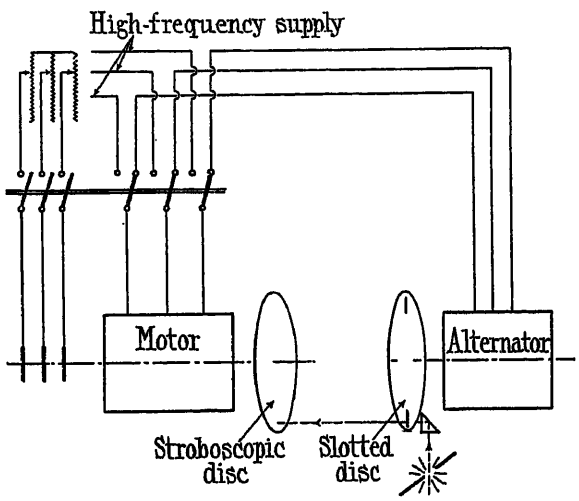

FIG. 3.

determine the changes of slip motion during the process of synchronizing, the motor was run on a small frictional load. The retarding torque at any instant was therefore that due to the iron and total friction losses at that instant. Since the speed of the motor is raised from $S(1 - \sigma)$ to S during the process of synchronizing, the torque corresponding to the mean speed $S(1 - \frac{1}{2}\sigma)$ was used in calculating the value of ρ in the equation of motion. The loss was determined by the retardation method, using a stroboscopic disc of the pattern devised by Robertson. Since the slowing down was very rapid the time was determined by means of a chronograph time marked at 1-second intervals by a seconds pendulum as suggested in an article published * by the author. The losses occurring at a speed greater than the normal induction motor speed were required, and it was therefore necessary to arrange for the motor to run down through synchronous speed. This was done by placing a three-pole double-throw switch in the stator circuit so that the stator could be switched on to either of two independent supplies, one of them of normal frequency and the other with a frequency greater than normal. The motor was run up to full speed on the high-frequency supply and the switch was suddenly thrown over on to the normal-frequency supply. At the same instant the rotor circuit was opened. The stroboscopic disc was illuminated by means of an arc lamp, the light being rendered intermittent by causing it to pass through slits in the periphery of a cardboard disc mounted on the shaft of the alternator giving the normal-frequency supply.* The arrangement of the test is shown in Fig. 3.

The synchronous speed of the rotor was 1 500 r.p.m. The slip speed when running on the small frictional load as a plain induction motor was 38 r.p.m. The percentage slip was therefore $2\cdot53$, and the mean of

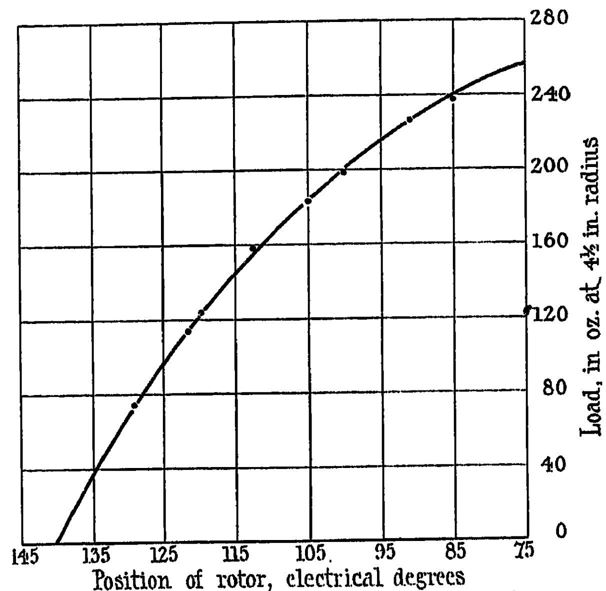

FIG. 4.

the induction motor speed and synchronous speed was 1 481 r.p.m. The rate of deceleration at this speed

$$\frac{dN}{dt} = 122 \text{ r.p.m. per sec.}$$
$$N = 1\,481 \text{ r.p.m.}$$

Hence the load on the motor at the mean speed

$$w = 0\cdot0109\, IN\frac{dN}{dt}$$
$$= 362 \text{ watts}$$

The corresponding retarding torque in lb.-ft. units is

$$T_l = \frac{33\,000}{2\pi \times 1\,481 \times 746} \times w$$
$$= 1\cdot725 \text{ lb.-ft. units.}$$

Pull-out torque when operating as a synchronous motor.—The pull-out torque T_m was determined as follows. The stroboscopic disc on the motor shaft was illuminated

* "The Retardation Method of Determining the Losses in Electrical Machines," *Beama*, 1922, vol. 11, p. 128.

* This method of illumination gives a beautifully clear and steady pattern and is much superior to the Bruckmann method (*Electrician*, 1911, vol. 67, p. 890).

intermittently by means of the slotted disc on the alternator shaft, as shown in Fig. 3. Direct current was switched on to the rotor circuit and the motor pulled into step, the pattern on the disc becoming stationary. The direct-current rotor excitation was kept at 10 amperes for the experimental work. A scale graduated in electrical degrees was placed just behind the stroboscopic disc and it was thus possible to read off the position of any one point on the pattern. The motor was then loaded by means of a band brake and the angular position of the pattern was read off for different values of the retarding torque. The load was gradually increased until the pattern began to be unsteady, indicating that the pull-out torque was very nearly reached. The load was then very gradually increased by hand, but no additional spring-balance readings were taken, and the maximum displacement of the pattern prior to the motor falling out of step was noted. The success of a test of this kind depends entirely upon the clearness and steadiness of the pattern on the disc. With the method of illumination previously described the pattern was almost as distinct as when stationary, flickering taking place only when the position of instability was nearly reached.

The results of this test are given in Table 1 and plotted in Fig. 4. The friction-loss torque as determined by the running-down test was added to the torque due to the brake, and by producing the curve to cut the horizontal axis the position of the pattern for zero retarding torque was found. At this position the poles of the stator and rotor fields were exactly in line and therefore the angle θ in the equation of motion was zero. This point was therefore the zero for the angle θ and was used as such in the synchronizing tests.

From the curve we see that

$$T_m = 6 \cdot 04 \text{ lb.-ft. } (258 \text{ oz. at } 4\tfrac{1}{2} \text{ in. radius})$$

But $$T_l = 1 \cdot 725 \text{ lb.-ft. } (74 \text{ oz. at } 4\tfrac{1}{2} \text{ in. radius})$$

hence $$\rho = T_l/T_m = 0 \cdot 286$$

The variation of the synchronizing torque with the angle θ.—It has been shown previously that the expression $T_s = T_m \sin \theta$ is only approximate, and it is desirable to know what degree of error is involved in the assumption.

It was necessary to adopt an analytical method, making use of the Blondel diagram. In order that the construction of this diagram may be possible, the stator resistance and synchronous impedance when the motor is functioning as a synchronous motor must be determined. The stator resistance R was $1 \cdot 25$ ohms per phase. The synchronous impedance was found both by the

short-circuit (Behn-Eschenberg) method, and by the wattless current method. The motor was belt-driven and run as a synchronous alternator at 1 500 r.p.m., and the rotor was excited from a battery, the range of excitation being from 0 to 15 amperes. Because of the magnetic weakness of the field system (rotor) as compared with the stator—due to the small air-gap and the comparatively small number of rotor turns—it was necessary to make an allowance for the armature reaction. This was determined by putting the machine on a choker load while running as an alternator. The current was kept constant during this test, and was adjusted to be equal to the short-circuit current corresponding to an excitation of 10 amperes (the excitation used in the synchronous motor tests). The experimental results

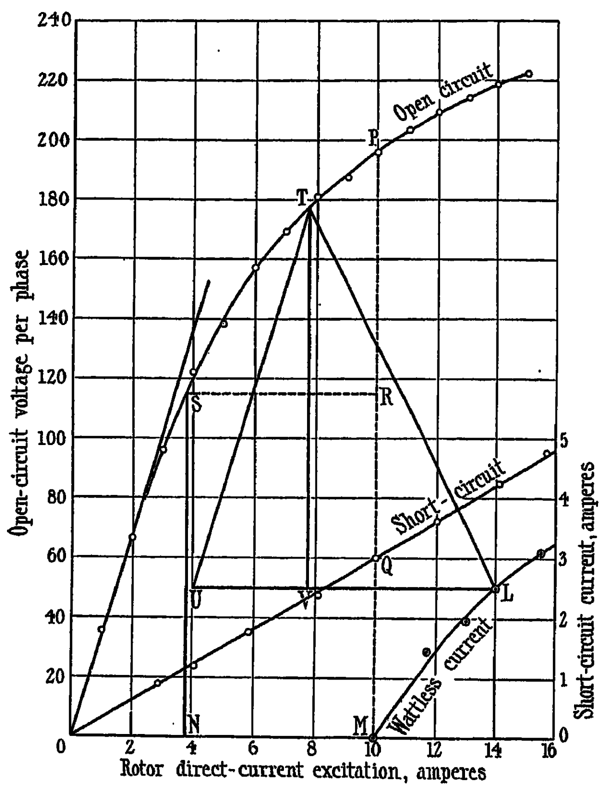

FIG. 5.

for these tests are given in Table 2 and are plotted in Fig. 5. The open-circuit and short-circuit results give very smooth curves, but that for the wattless-current characteristic is rather irregular. This is probably due to the fact that the belt fastener caused the instrument needles to oscillate much more violently during the wattless-current test than in the other tests. It will be noticed that these characteristics are very different from those of a salient-pole alternator because the relative magnetic importance of the armature and field is reversed. This is shown by the fact that the short-circuit current with a rotor excitation equal to the rotor full-load current was less than the normal full-load current.

The terminal voltage on wattless current with 10 amperes excitation was 50, the corresponding point being L in Fig. 5. By the ordinary Potier construction the triangle TUL was obtained, thus giving

Demagnetizing armature reaction, equivalent to LV, i.e. to 6·25 amperes excitation.
Reactance voltage per phase, TV = 128 volts.
Armature current = 3 amperes.
∴ Impedance per phase, $Z = 128/3 = 42\cdot7$ ohms.

In applying the Behn-Eschenberg method we have for the resultant excitation, after deducting that due to armature reaction,

$$\begin{aligned} ON &= 10 - 6\cdot25 \\ &= 3\cdot75 \text{ amperes.} \end{aligned}$$

Corresponding induced voltage per phase

$$SN = 115 \text{ volts.}$$

Short-circuit current with 10 amperes excitation

$$= 3 \text{ amperes.}$$

∴ Synchronous impedance per phase

$$= 115/3 = 38\cdot3 \text{ ohms.}$$

Thus the wattless-current method gave a greater impedance than the Behn-Eschenberg method, the reverse of what is usually found. The reason for this is that owing to the high armature impedance and the very great demagnetizing effect of the armature reaction it was not necessary to apply a reduced excitation when determining the short-circuit characteristic. In fact, as explained above, a current equal to the normal current could only be obtained by applying a considerably increased excitation. It is therefore reasonable to expect the wattless-current method to give the greater synchronous impedance in this case.

In calculating the Blondel diagram the mean value of the synchronous impedance was taken, namely, $Z = 40\cdot5$ ohms.

The normal applied stator voltage was 245 V at the terminals and therefore 143 V per phase. The base line AB of the Blondel diagram (Fig. 1) is therefore made proportional to 143. The base angles of the triangle BOA are each 88° 14′.

The hypotenuse has a length

$$\begin{aligned} OB &= 143 \times \frac{Z}{2R} \\ &= 2\,310 \end{aligned}$$

Now the maximum possible power per phase is given by

$$\begin{aligned} \frac{E^2}{4R} &= \frac{143^2}{5} \\ &= 4\,100 \text{ watts} \end{aligned}$$

Hence the maximum possible power for three phases

$$= 12\,300 \text{ watts}$$

The corresponding power circle is the circle of centre O and of zero radius, namely the point O.

Now, from the figure, the motor back E.M.F. per phase with 10 amperes excitation and zero armature

reaction is 196 volts. Hence the radius of the circle of maximum power developed with this excitation, namely the maximum power of the motor, is

$$\begin{aligned} r &= 2\,310 - 196 \\ &= 2\,114 \end{aligned}$$

Hence if m is the ratio between this power and the maximum possible power of 12 300 watts we have

$$2\,114 = 2\,310\sqrt{(1 - m)}$$

therefore $m = 0\cdot163$

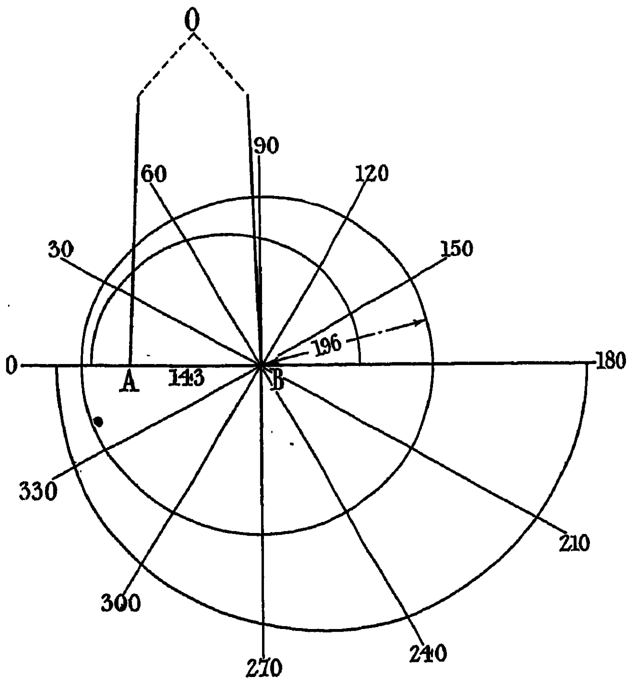

FIG. 6.

Hence maximum power developed with 10 amperes excitation

$$\begin{aligned} &= 0\cdot163 \times 12\,300 \\ &= 2\,000 \text{ watts} \\ &= 2\cdot68 \text{ h.p.} \end{aligned}$$

The pull-out torque of the motor is therefore

$$\begin{aligned} T_m &= \frac{2\cdot68 \times 33\,000}{2 \times 1\,500} \\ &= 9\cdot4 \text{ lb.-ft. or } 113 \text{ lb.-in.} \end{aligned}$$

This is considerably greater than the experimentally determined value of 72·5 lb.-in., but it is obvious that with such a small machine and with such unusual conditions for the determination of the synchronous impedance and armature reaction, close agreement is impossible. In addition the correction for armature reaction has yet to be applied. In determining the changes taking place during the process of synchronizing, the experimentally observed value of T_m was therefore used, but in the investigation of the deviation of T_m from the assumed sinusoidal form the value given by the Blondel diagram was used because the theory of the method is based on the diagram.

The radii of the circles of constant power W are given by the expression

$$\begin{aligned} r &= 2\,310\sqrt{(1 - W/12\,300)} \\ &= 2\,310(1 - W/24\,600) \text{ approx.,} \end{aligned}$$

when m is small. Thus when the excitation is such that the maximum power developed by the motor is a small fraction of the maximum possible power, the circles of constant power for the range of working of the motor are spaced equidistantly.

When the power developed is 2 000 watts we have seen that the radius of the power circle is 2 114. The radius of the circle of maximum power in the generating region of the diagram is

$$2\,310 + 196 = 2\,506$$

for which the corresponding power is

$$W = 2\,200 \text{ watts.}$$

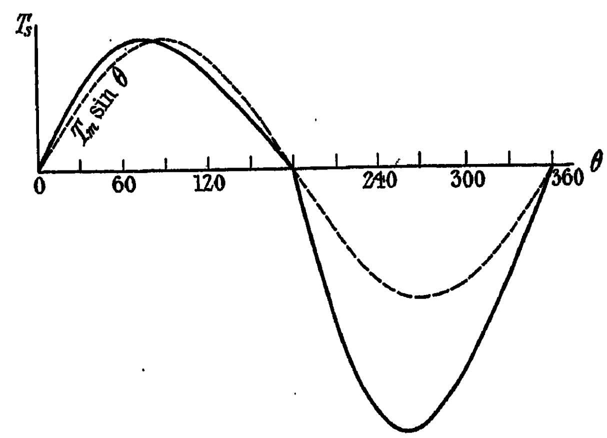

FIG. 7.

If the motor slips two pole-pitches the back E.M.F. vector will make one complete revolution and its extremity will fall in turn on to each of the circles of constant power within the working range. The back E.M.F. vector is drawn in the enlarged diagram in Fig. 6 at intervals of 30°, and the power is plotted as a function of θ in Fig. 7. This curve gives the variation of power and therefore of synchronizing torque on the assumption that the armature reaction can be neglected. It has been shown on page 212 that it is a sinusoidal function of θ, and also, since the base angle of the triangle AOB is nearly 90°, its displacement from the curve of $T_m \sin\theta$ is very small. We have seen that the armature reaction cannot be neglected and it is therefore necessary to make a correction for it. This correction is applied as follows. The vector AP measured on the voltage scale gives the resultant E.M.F. in the armature circuit. Hence it is proportional to the armature current. Now the demagnetizing effect of the armature reaction for a current of 3 amperes lagging approximately 90° was found from the wattless-current test to be equivalent to 6·25 amperes of excitation. Hence for any

armature current I with an internal angle of lag ϕ we have:—

Excitation equivalent to the armature reaction

$$= \tfrac{1}{3}I \times 6\cdot25 \sin\phi$$
$$= 2\cdot08 I \sin\phi$$

In Fig. 8 a portion of the open-circuit characteristic in the neighbourhood of an excitation of 10 amperes is drawn. The mean value of the excitation during one whole revolution of phase-swing was 10 amperes in the experiments, and from the construction we see that a variation of excitation of 2·08 amperes about the mean value (10 amperes) was equivalent to an induced voltage of 14·6. The mean value of the induced voltage was 196 volts.

Expressing by E_r the resultant E.M.F. per phase we have for the current per phase

$$I = \frac{E_r}{42\cdot7} = \frac{d}{42\cdot7} \text{ (see Fig. 2)}$$

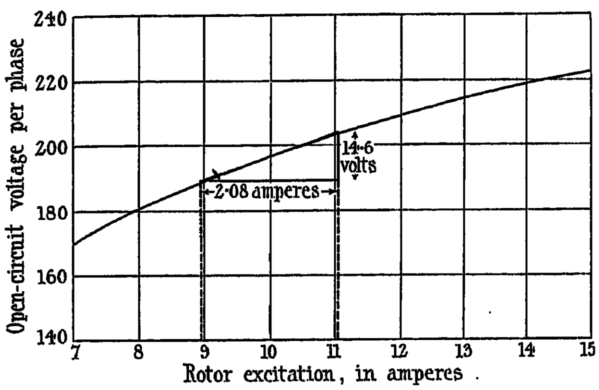

FIG. 8.

The armature reaction was therefore equivalent to a voltage of

$$\frac{d}{42\cdot7} \times 14\cdot6 \sin\phi = 0\cdot34 d \sin\phi$$

from which we see that for the value of the constant q in the equation for the back E.M.F. per phase

$$E_b = c \pm q \sin\phi$$

we have $q = 0\cdot34$.

Hence for the polar equation to the locus of the extremity of the back E.M.F. vector we have

$$r = \frac{c \pm qa \cos\theta}{1 \pm q}$$

Now $c = 196$; $a = 143$; and $q = 0\cdot34$.

$$\therefore\ r = \frac{196 \pm 48\cdot5 \cos\theta}{1 \pm 0\cdot34}$$
$$= 146 + 36\cdot2 \cos\theta$$
or
$$297 - 73\cdot5 \cos\theta$$

This is plotted in Fig. 6, the circle of radius $C = 196$ being drawn for comparison.

The Y co-ordinate of any point on the locus is given by

$$\mathrm{OY} = \frac{c \sin\theta \pm \tfrac{1}{2} qa \sin 2\theta}{1 \pm q}$$
$$= 146 \sin\theta + 18\cdot1 \sin 2\theta$$
or
$$297 \sin\theta - 36\cdot8 \sin 2\theta$$

Now a perpendicular distance of 196 volts corresponds to a torque of 9·42 lb.-ft. using the Blondel diagram. Hence the corrected expression for the synchronizing torque in terms of the angle θ is, when functioning as a motor,

$$T_s = \frac{9\cdot42}{196}(146 \sin\theta + 18\cdot1 \sin 2\theta)$$
$$= 7 \sin\theta + 0\cdot87 \sin 2\theta$$

This is compared with the sinusoidal form

$$T_s = 9\cdot42 \sin\theta$$

in Fig. 7, and it is obvious that there is a very considerable difference between the actual values of the synchronizing torque and those usually assumed. From the equation for T_s we have

$$\frac{dT_s}{d\theta} = 7 \cos\theta + 1\cdot74 \cos 2\theta$$

$= 0$ and corresponds to a maximum when

$\cos\theta = 0\cdot23$

or $\theta = 76\cdot5°$ (approx.)

If the synchronizing torque were a sinusoidal function of the angle the motor should fall out of step when the load has increased to such an extent that θ is equal to 90°. It is well known that a displacement of 90° is never attained. In the case of the 2-h.p. motor under test the displacement was 65° (see Fig. 4). The maximum value of the synchronizing torque from the Blondel diagram corrected for armature reaction is

$$T_m = 7 \sin 76\cdot5° + 0\cdot87 \sin 153°$$
$$= 7\cdot2 \text{ lb.-ft.}$$

This is in reasonable agreement with the experimentally observed value of 6·04.

Phase-swinging subsequent to the excitation of the rotor.—In previous experimental investigations of the variations in current and in speed which take place immediately after the direct-current excitation has been switched on to the rotor, some idea of the rotor position has been obtained from the position of the pointer of the ammeter in the rotor circuit. A complete record of changes corresponding to switching in at θ equal to 0, 20, 40, 60, etc., up to 360 electrical degrees was required for the present investigation. The stroboscopic method was therefore used, the excitation being switched on at the moment the pattern on the disc coincided with a division on the scale. Because of the fairly rapid movement of the pattern it was practically impossible to manipulate an ordinary throw-over switch sufficiently quickly. A special quick-change switch was therefore made by placing a second row of contacts at an angular distance of about 30° from the contacts of an ordinary slow-break three-pole switch. When breaking with one set of contacts the blades were about $\tfrac{1}{8}$ in. from the

second set, the result being that a very quick change-over could be made and the excitation switched on without much appreciable time-lag.

The variations in rotor current are given in the oscillograms of Fig. 9 and show very clearly how the correct moment for excitation depends upon the angle θ.

The variations in speed were next determined. In the case of a large machine having its own exciter the obvious method is to excite the exciter separately and use it as a speed indicator, neutralizing the voltage induced in its armature when running uniformly at full induction-motor speed. The oscillograph then gives the variations of speed only. This method is certainly the most convenient but it suffers from the disadvantage that since the exciters are very low-voltage machines they have a very pronounced commutator ripple which somewhat impairs the clearness of the curve of speed variation. The machine under test had no d.c. machine coupled to it, and therefore after much experiment the following method was adopted :—

A german-silver disc keyed to the induction-motor shaft rotated between the poles of an electro-magnet, and two flexible brass clips were used as collectors. On running at 1 500 r.p.m. an E.M.F. of about 200 millivolts was obtained, the E.M.F. corresponding to slip speed being therefore in the neighbourhood of 6 millivolts. When running steadily the E.M.F. was balanced out by a potentiometer slide, thus leaving the small E.M.F. due to the variations in slip to operate the oscillograph. This E.M.F. was magnified by a thermionic valve (Marconi-Osram type LS 2) which was worked with a plate potential of 400 volts and a filament current of 1·3 amperes. Since the frequency of the variations was so very low, transformers were not used. The amplifying circuit is shown in Fig. 10. When it was found that the valve acted in a

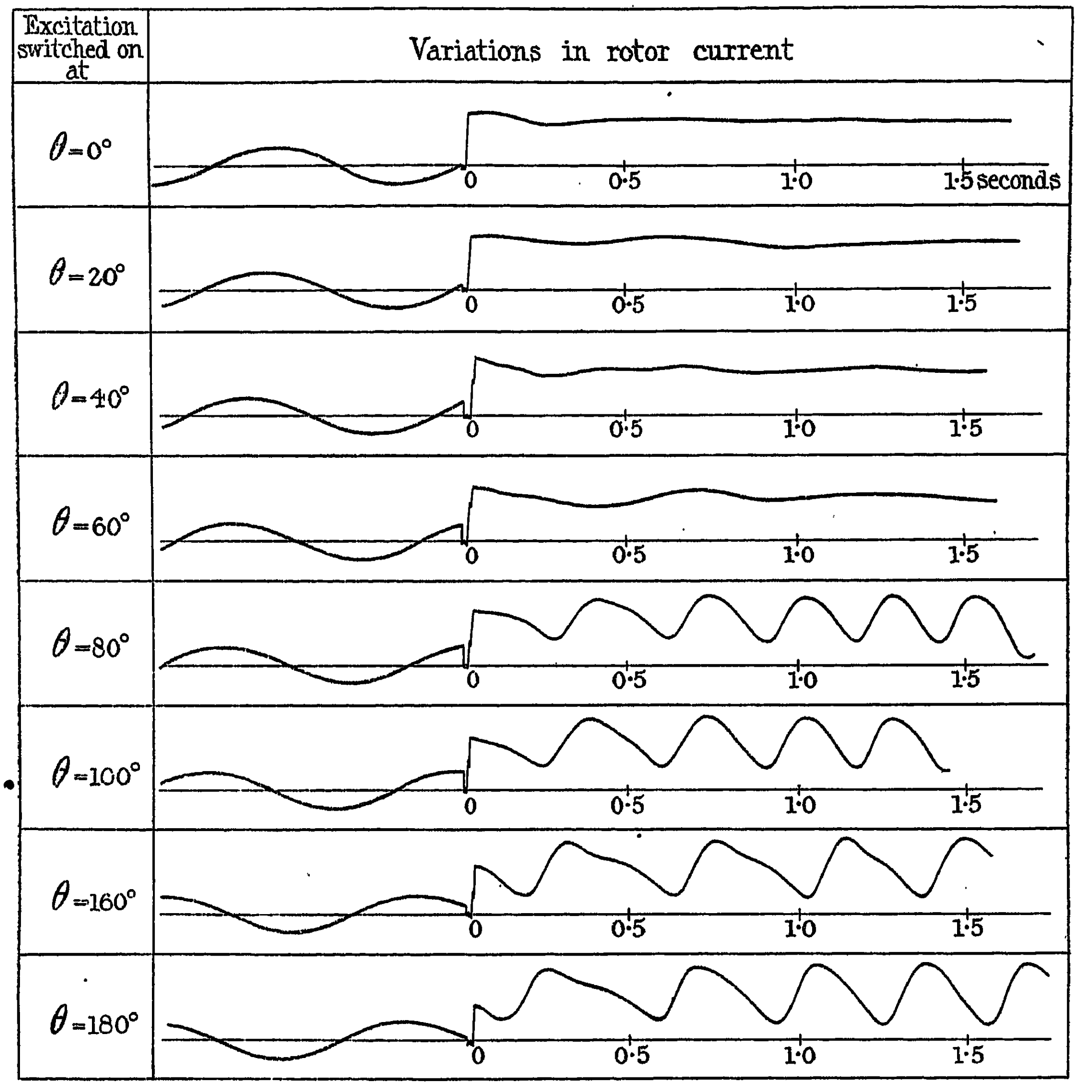

FIG. 9.

satisfactory manner as an amplifier the characteristic was determined in order to ensure that it was worked on the straight portion, thus producing no appreciable distortion.

The slip curves in Fig. 11 show two sets of ripples due to the following causes. First, there is a comparatively low-frequency ripple due to a slight wobble in the rotating disc; and secondly a high-frequency ripple the two horizontal portions on the curves is equal to the slip speed of 38 r.p.m., the curves are automatically calibrated for speed. Time marking was effected by sending through the second vibrator a very small alternating current whose frequency was 45 cycles per second.

The above method has the advantage that it liberates the exciter (in the case of a commercial machine) to

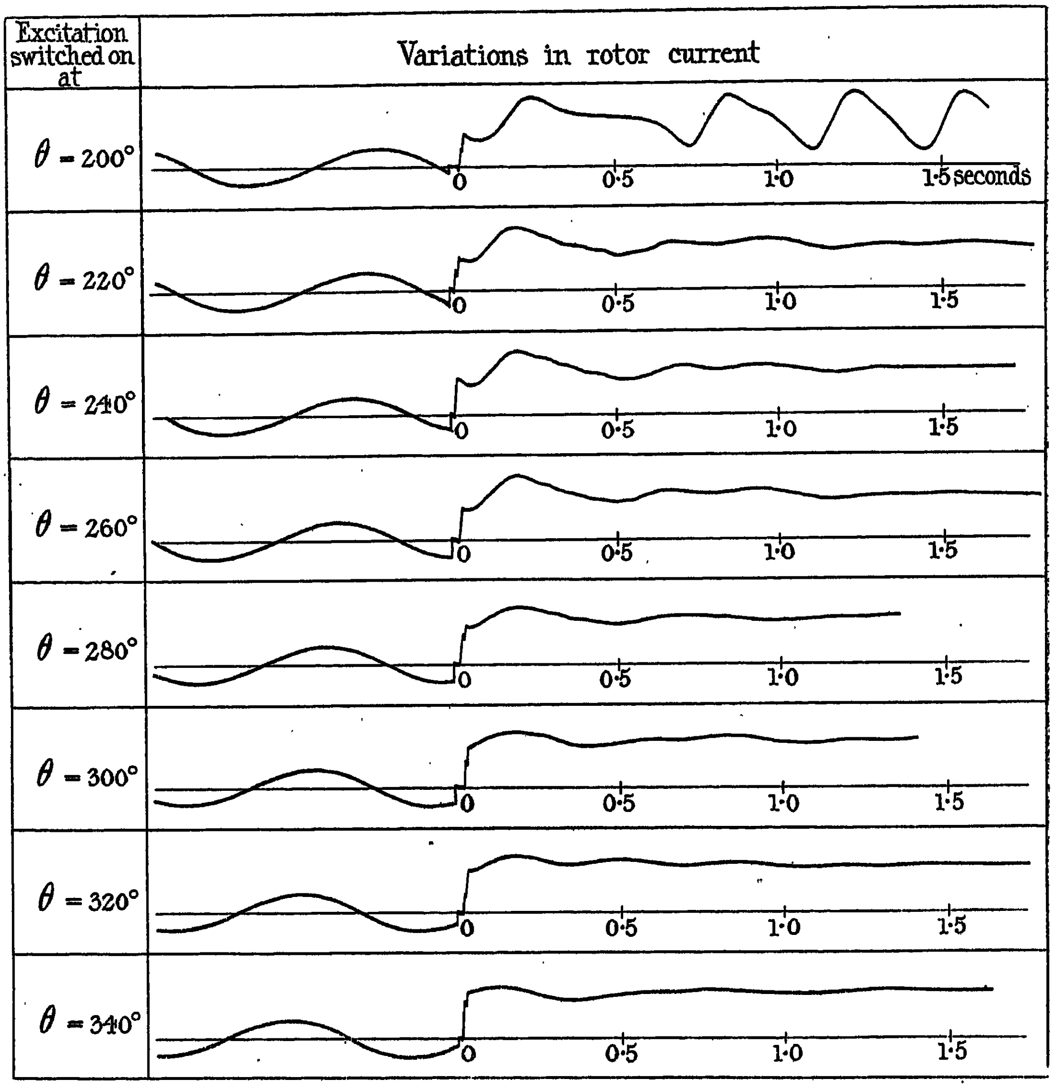

FIG. 9 (*continued*).

due to variations in plate voltage. This was a commutator ripple on the voltage of a d.c. generator used for this purpose as a battery of sufficiently high voltage was not available. It will be seen that it is possible to eliminate these ripples, and the author believes that this is the only method by which the speed variations can be determined experimentally in the form of smooth curves. The amplitude was not very large and therefore the mirror giving the zero line was put out of action in order to avoid confusion. Since the distance between carry out its proper function. This is desirable since, as pointed out on page 224, the variations of exciter voltage must have some influence on the conditions of pulling into step, especially for those values of θ for which the chances of synchronizing or not are almost equal.

The period of whole revolutions of slip.—The equation of motion for no-load conditions is

$$\ddot{\theta} + \frac{T_m p}{I} \sin \theta = 0$$

assuming $T_s = T_m \sin\theta$, and the period for small oscillations is

$$P = 2\pi\sqrt{\left(\frac{\mathrm{I}}{T_m p}\right)}$$

Comparing this with the period for a simple pendulum

$$P = 2\pi\sqrt{\left(\frac{l}{g}\right)}$$

we have for the length of the equivalent simple pendulum

$$l = \frac{\mathrm{I}g}{T_m p}$$

In the case of the simple pendulum, if the angular velocity when the position $\theta = 0$ is greater than $2\sqrt{(l/g)}$ the pendulum will make complete revolutions. Supposing that the angular velocity in this position is numerically equal to the velocity attained by falling

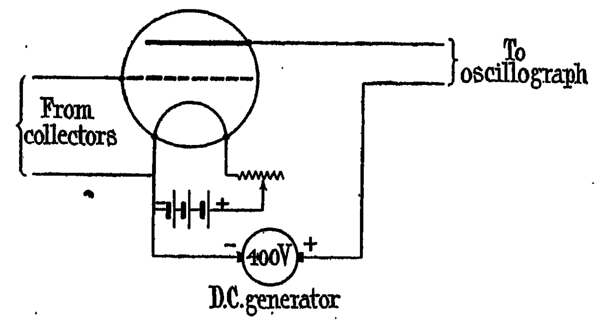

FIG. 10.

freely from a height $2h(>2l)$, then the period of a revolution will be

$$P = \pi\sqrt{\left(\frac{4l^2}{gh}\right)}\left\{1 + (\tfrac{1}{2})^2\frac{l}{h} + \left(\frac{1\,.\,3}{2\,.\,4}\right)^2\frac{l^2}{h^2} + \left(\frac{1\,.\,3\,.\,5}{2\,.\,4\,.\,6}\right)^2\frac{l^3}{h^3} + \ldots\right\}^*$$

In the case of the motor we have for the height $2h$ from which a linear velocity numerically equal to ω_0 will be attained (the radius of the disc in the mechanical model † being unity),

$$\omega_0^2 = 4gh$$

$$h = \frac{\omega_0^2}{4g}\ ‡$$

Hence for the period of one revolution we have

$$P = \pi + \frac{2\mathrm{I}g}{T_m p\omega_0}\left\{1 + (\tfrac{1}{2})^2 \cdot \frac{4\mathrm{I}g^2}{T_m p\omega_0^2} + \left(\frac{1\,.\,3}{2\,.\,4}\right)\left(\frac{4\mathrm{I}g^2}{T_m p\omega_0^2}\right)^2 + \ldots\right\}$$

From the speed curves of Fig. 11 we see that the maximum value of ω_0 is about $6{\cdot}75$ mechanical radians per sec.

$= 13{\cdot}5$ electrical radians per sec.

$T_m = 6{\cdot}04$ lb.-ft.; $p = 2$ and $g = 32$

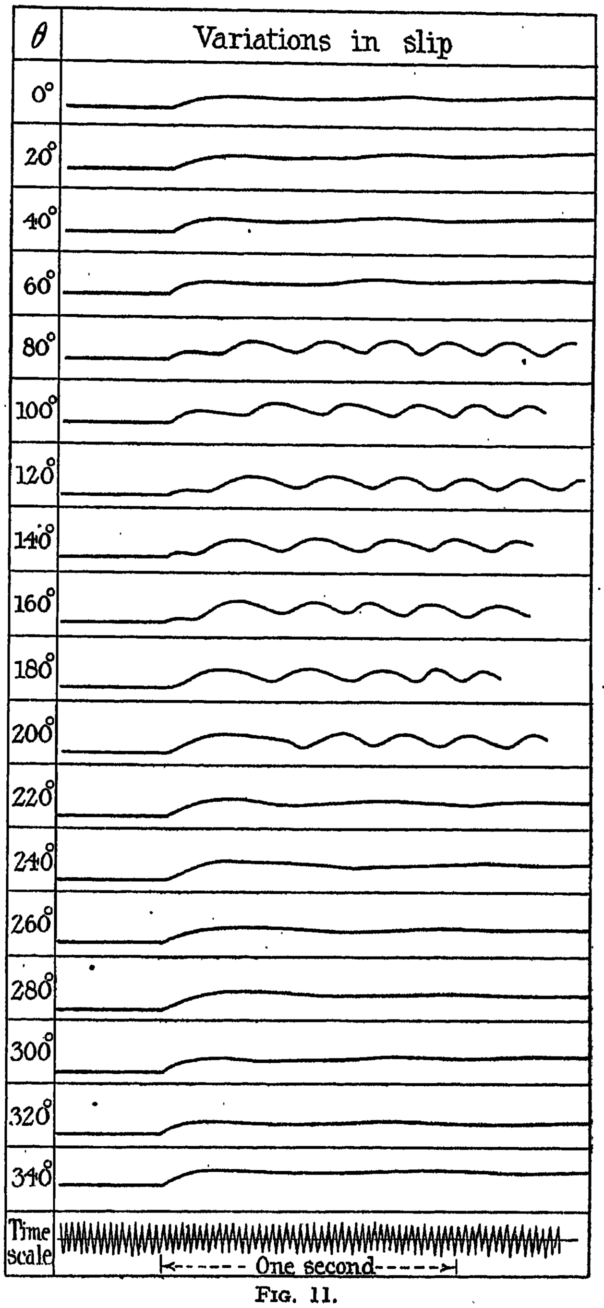

FIG. 11.

Hence $$\frac{2\mathrm{I}g}{T_m p\omega_0} = 0{\cdot}054$$

where I is in ft.-lb.-sec. units, and T_m is in lb.-ft.,

and $$\frac{4\mathrm{I}g^2}{T_m p\omega_0^2} = 0{\cdot}26$$

$$\therefore\ P = \pi \times 0{\cdot}054\{1 + \tfrac{1}{4} \times 0{\cdot}26 + \tfrac{9}{64} \times (0{\cdot}26)^2 + \ldots\}$$
$$= 0{\cdot}182 \text{ second.}$$

* See Greenhill's "Elliptic Functions," p. 19.
† CARR, *loc. cit.*
‡ In this equation ω_0 has the dimensions LT^{-1}.

The curve of current variations corresponding to $\theta = 80°$ is the longest record and from it we see that after the first two or three revolutions, when the motor has settled down, the time of a revolution is 0·25 second. This is the period for a revolution with the motor loaded, whereas the calculation refers to no-load conditions. There is sufficient agreement to show that some idea of the order of the period can be obtained by calculation. This appears to have a very important practical application. Suppose that a synchronous induction motor is working from the same supply as a number of salient-pole synchronous motors or rotary converters. If the load on the motor is increased to such a point that the motor falls out of synchronism and is not immediately disconnected from the system, current surges of definite frequency will be set up. These surges will produce forced oscillations in the other synchronous machines, and if the frequency is of the same order as the natural frequency of oscillation of these machines they will fall out of step. Furthermore, the time required to bring this about may not be more than a few seconds. The property which the synchronous induction motor possesses of continuing to run

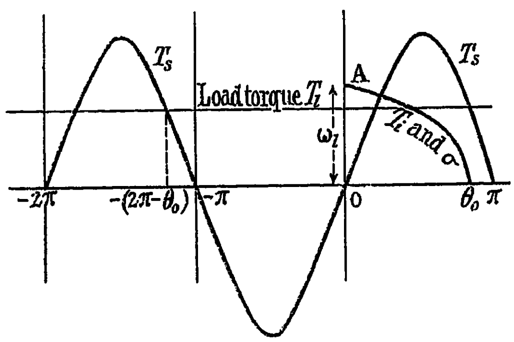

FIG. 12.

under overload conditions may therefore be a disadvantage in such circumstances.

The limiting value of T_m for synchronizing.—The formulæ developed by Carr * and Böhm † are based on the assumption that the work done by what Carr calls the net oscillating torque acting over the angular distance $-(2\pi - \theta_0)$ to $+\theta_0$, i.e. a whole revolution of slip, is equal to the work done in accelerating the moving masses. θ_0 is the angular position of unstable equilibrium with the motor loaded, its position being defined by the intersection in the third quadrant of the curves of T_l and T_s (see Fig. 12).

The synchronizing torque is therefore assumed to exist over the whole of this angular distance, or, in other words, the excitation is assumed to be switched on at the angular position $-(2\pi - \theta_0)$. This method of calculation is based on the worst possible conditions for synchronizing, such conditions never existing in practice because it is not a difficult matter to switch on the excitation in the neighbourhood of the position $\theta = 0$, i.e. the best position for synchronizing. It follows that if the exciter capacity is calculated from the formulæ developed on the above assumption it will be considerably larger than is required in actual practice Again, the formula given by Carr is based on an artificial value for the angular velocity at the position $\theta = 0$. This does not appear to be justifiable, because the angular velocity at the instant of switching on the excitation is the ordinary induction motor slip velocity and is therefore known if the magnitude of the load torque T_l is known. The criterion is the true induction-motor slip angular velocity and not the velocity given by a special solution of the differential equation of motion.

It therefore appears to be more logical to make the calculation on the assumption that the excitation is switched on at the angular position $\theta = 0$, and also to make use of the ordinary slip angular velocity. This method will obviously give the minimum exciter capacity which will enable the motor just to synchronize if the excitation is switched on in the best position.

The slip angular velocity must become zero by the time θ becomes equal to θ_0. Let the slip velocity corresponding to the load T_l be ω_l. Then the slip velocity in electrical radians per second is $p\omega_l$ and the work done in accelerating the moving masses is

$$\tfrac{1}{2} \cdot \frac{I}{p}(p\omega_l)^2$$

The work done against the load torque is obviously $T_l\theta_0$, so that the total work done by the sum of the synchronous and induction-motor torques acting from $\theta = 0$ to $\theta = \theta_0$ is

$$\tfrac{1}{2} \cdot \frac{I}{p}(p\omega_l)^2 + T_l\theta_0$$

When the slip velocity just becomes zero at the position θ_0 the author has found that the slip curve as determined by the step-by-step method is very nearly an ellipse. Since the induction-motor torque is proportional to the slip, this torque can therefore be taken as represented by an ellipse whose semi-axes are θ_0 and T_l. Both synchronizing torque and induction-motor torque are positive over the range considered, so that the work done by the net oscillating torque (assuming the sinusoidal form for T_s) is

$$\int_0^{\theta_0} T_m \sin\theta d\theta + \tfrac{1}{4}\pi T_l\theta_0$$

Hence

$$T_m(1 - \cos\theta_0) + \tfrac{1}{4}\pi T_l\theta_0 = \tfrac{1}{2} \cdot \frac{I}{p}(p\omega_l)^2 + T_l\theta_0$$

Actually the area enclosed by the curve of T_l is rather less than that of a quadrant of an ellipse, so that we can substitute as a fair approximation $\tfrac{3}{4}$ instead of $\tfrac{1}{4}\pi$ for the coefficient of $T_l\theta_0$.* We then have

$$T_m(1 - \cos\theta_0) - 0{\cdot}25T_l\theta_0 = \tfrac{1}{2} \cdot \frac{I}{p}(p\omega_l)^2$$

or $$T_m(1 - \cos\theta_0) - 0{\cdot}25\rho T_m\theta_0 = \tfrac{1}{2} \cdot \frac{I}{p}(p\omega_l)^2$$

* L. H. A. CARR: *Journal I.E.E.*, 1922, vol. 60, p. 165; and 1923, vol. 61, p. 692.
† O. BÖHM: *E.T.Z.*, 1922, vol. 43, p. 429.

* The ratio of the area enclosed by curve A (Fig. 12) to that of a quarter ellipse with equal semi-axes, is almost exactly 3 to π.

Now $\sin\theta_0 = \rho$, and θ_0 is in the second quadrant.

Hence $\qquad \cos\theta_0 = -\sqrt{(1-\rho^2)}$

$$\therefore \quad T_m\{(1+\sqrt{1-\rho^2}) - 0\cdot25\rho\theta_0\} = \tfrac{1}{2}\cdot\frac{\mathrm{I}}{p}(p\omega_l)^2$$

or
$$T_m = \frac{\mathrm{I}p\omega_l^2}{2\{1+\sqrt{(1-\rho^2)} - 0\cdot25\rho\theta_0\}}$$

We see from the form of this expression that since ρ is always less than unity it is quite unnecessary to make any very elaborate calculation in order to determine more exactly the work done by the induction-motor torque.

In the case of the 2-h.p. motor we have $\mathrm{I} = 0\cdot135$; $p = 2$; $\omega_l = 3\cdot98$ radians per sec.; $\rho = 0\cdot286$; and therefore $\theta_0 = 2\cdot85$ radians. Hence the necessary value of T_m for the motor just to synchronize when the excitation is switched on at the most favourable moment is 1·23 lb.-ft. By plotting the slip curves for different assumed values of ρ and using the experimentally determined data it was found that the motor just synchronized for ρ in the neighbourhood of 0·7 when $\theta = +\theta_0$. This is contrary to what actually takes place, because at the moment of switching on the direct-current excitation ω will be equal to ω_l, no matter what the angular position of the rotor may be. The velocity ω_l is a function of ρ, as it should be, but in Mr. Carr's expression the ω used bears no relation to ρ.

Graphical determination of the operation of the motor.—Assuming a sinusoidal form for the synchronizing torque, the equation of slip motion is

$$-\rho T'_m + T_m\sin\theta + \frac{\rho T_m}{p\omega}\cdot\frac{d\theta}{dt} + \frac{\mathrm{I}}{p}\cdot\frac{d^2\theta}{dt^2} = 0$$

or say

$$a + b\sin\theta + c\frac{d\theta}{dt} + d\frac{d^2\theta}{dt^2} = 0$$

For the 2-h.p. motor $a = -\rho = -0\cdot286$; $b = 1\cdot0$ $c = 0\cdot036$; $d = 0\cdot012$. A step-by-step solution was adopted.

Since it was required to determine the positions of switching on the d.c. excitation for which the motor would synchronize under actual working conditions, the

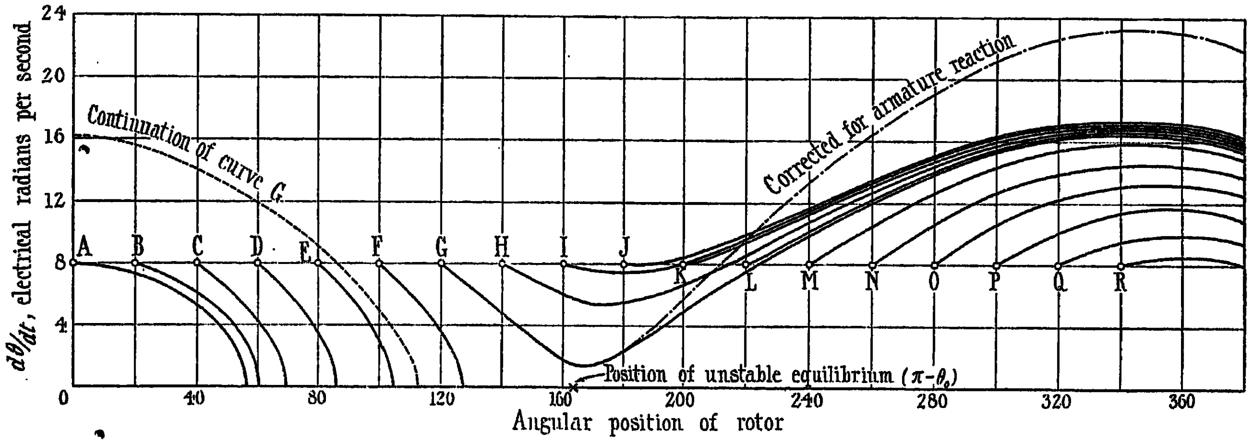

FIG. 13.

the excitation was switched on at the position $\theta = 0$. Using this value of ρ in the above expression for T_m we have

$$\omega_l = 3\cdot98 \times \frac{0\cdot7}{0\cdot286} = 9\cdot7$$

Therefore $\qquad \theta_0 = 2\cdot37$ radians.

Hence $\qquad T'_m = 8\cdot0$ lb.-ft.

This is as near to the actual value of 6·04 lb.-ft. as can reasonably be expected for such a small motor. Since the above method of determining T_m gives the least value for which it is possible for the motor to synchronize, even under the most favourable conditions of switching in, while the methods of other investigations give the maximum value of T_m required for the worst conditions, a good value of the necessary exciter capacity is obtained from these two extreme cases.

There is one other criticism of Mr. Carr's method of calculating the limiting value of T_m, i.e. in determining the value of ω used in his expression the angular velocity is assumed to be zero both at $\theta = -(2\pi - \theta_0)$ and at experimentally determined values of ρ and ω (the initial slip) were used. The curves obtained are shown in Fig. 13. It will be noticed that each curve has an initial ordinate of 7·96 electrical radians per second and that the commencing points A, B, C, D, etc., correspond to the angular positions of the rotor, 0°, 20°, 40°, 60°, etc., at which the d.c. excitation was switched on. The effect of the synchronizing torque immediately after switching on is very clearly indicated by the initial gradients of the various curves. With $\theta = 0$ the initial component $T'_m\sin\theta$ of the synchronizing torque is zero, the curve therefore being at first horizontal. As θ is increased up to 90°, $T_m\sin\theta$ increases and is in a direction opposed to the slip, the curves therefore having a gradually increasing initial negative gradient. From 90° to 180° this initial gradient gradually reduces to zero again. Similar changes in initial gradient occur for the various switching positions between 180° and 360°, except that in this case $T_m\sin\theta$ is negative, i.e. in the same direction as the slip, the initial gradients therefore being positive.

According to the curves the angular velocity for

switching positions of 0°, 20°, 40°, 60°, 80° and 100° becomes zero before the displacement attains that corresponding to unstable equilibrium, 163·5° in this case. Hence the motor should synchronize. When switching-in occurs at 120° the motor just fails to synchronize in the first swing, the rotor therefore passing the critical position of 163·5° with gradually increasing velocity. In order to cut down the tedious step-by-step method of calculation to a minimum, a value of the initial slip when passing the position $\theta = 0$ was found for which the motor would just synchronize, i.e. for which the angular velocity at $\theta = 163 \cdot 5°$ was zero. This was 19·97 electrical radians per second. Knowing this critical value at $\theta = 0°$ (or $n \times 360°$) it is only necessary to calculate the various curves as far as the position $\theta = 360°$. If the angular velocity at 360° is less than this critical value, the motor will synchronize; if greater it will not synchronize. It will be seen from the curves that in every case the angular velocity at 360° is less than 19·97 electrical radians, from which if follows that the motor should synchronize no matter where the excitation is switched on. This is, of course, contrary to the experimental evidence and shows very conclusively that the generally accepted equation of motion is not correct. In Fig. 13 the curve corresponding to the switching position $\theta = 120°$ is continued as a dotted line beyond the position $\theta = 360°$.

Comparing the theoretical with the actual behaviour of the motor, we see that the conditions for synchronizing in the actual case are much more severe than in the theoretical case. The difference is undoubtedly due to the effect of armature reaction on the form of the synchronizing torque. It will be seen from Fig. 13 that the most important curve in the family is that corresponding to the switching-on of the excitation when $\theta = 120°$, since this curve very nearly meets the θ axis at the position of unstable equilibrium. This curve has therefore been re-drawn, as shown by the chain-dotted curve, on the assumption that the synchronizing torque is modified by armature reaction so that it varies with θ as indicated by Fig. 7. Up to $\theta = 180°$ there is very little difference between this curve and the original curve G, but beyond 180° the new curve rises very rapidly, the angular velocity at $\theta = 360°$ being now 23 electrical radians per second. It was found by trial and error that the maximum possible velocity at $\theta = 0$ (or $n \times 360°$) for the motor just to synchronize was 19·97. This shows that the effect of armature reaction is sufficient to explain the difference between the actual behaviour and the theoretical behaviour on the assumption that the synchronizing torque is a sinusoidal function of θ. The same correction applied to the group of curves G, H, I, J, K and L, brings them also above the critical value of 19·97 at $\theta = 360°$, thus bringing the theoretically determined operation of the motor into reasonably close agreement with the actual performance on test.

Conclusion.

The comparison of the theoretical and experimental investigations indicates that the conditions of operation of a synchronized induction motor during the process of pulling into synchronism are much more severe than they are generally taken to be. Owing to the magnetic weakness of the rotor and the very small air-gap used, the effect of armature reaction is enormously greater than in the case of the salient-pole synchronous motor. It is probable that in a commercial motor the effect will not be so great as in the small motor used in the experimental work, because the excitation was purposely kept at a low value throughout. This naturally gave a very weak field, the result being an exaggerated distortion of the curve of synchronizing torque. In an actual case the distortion will undoubtedly be considerably less than that indicated by Fig. 7, but it is obvious that it will still be of sufficient importance to justify the use of the more accurate formula for the synchronizing torque when investigating slip motions extending into the generating region. This does not introduce any extra work in the step-by-step calculation, since, if the curve of synchronizing torque is drawn, the mean value corresponding to the steps used can be calculated by Simpson's rule from three ordinates read off directly.

The difficulties encountered in the experimental investigation of the slip motion illustrate very forcibly that for work of this nature the speed indicator used must be rigidly attached to the motor shaft, and that even a very stiff spring coupling is not permissible. The simple disc and magnet dynamo is absolutely accurate and the small voltage corresponding to the slip can be magnified to any desired extent by means of a thermionic valve of sufficient capacity. As pointed out previously, the use of a speed indicator of this kind does not necessitate the exciter being deprived of its proper function. The result of this is that the record of speed variations as obtained by experiment will be a true reproduction of the variations that take place under actual working conditions.

Case of the Salient-pole Synchronous Motor.

The behaviour of this motor during the process of synchronizing is somewhat different from that of the non-salient-pole type, owing to the fact that the synchronizing torque now possesses two components. The first component is that due to the flux produced by the d.c. excitation of the rotor, or, in the case of a rotary converter, of the stator. This can be represented as before by the expression $T_m \sin \theta$. If the excitation is zero during starting, this component will be set up by residual magnetism, and in such a case T_m will of necessity be very small. Secondly there is a torque set up by the flux induced in the salient poles by the synchronously rotating field will induce opposite polarity in each of the salient poles in turn, no matter what the ultimate polarity of those salient poles has to be. This torque is an alternating function of the angle θ and we see from the manner in which it is produced that its frequency must be twice that of the component $T_m \sin \theta$. Also it is zero when θ is zero. It can therefore be represented by an expression of the form $T_m \sin 2\theta$. The assumption of a sinusoidal function is only approximate for this component as it is for the other, but an experiment showed that the departure from the true sinusoidal form is not very great.

The results of this experiment are given in Fig. 14, and the sin 2θ curve is drawn for comparison. It will be seen that the curve does not differ greatly from a sine curve. The equation of slip motion of a salient-pole motor can be written thus :—

$$-\rho T_m + T_m \sin\theta + \xi T_m \sin 2\theta + \frac{\rho T_m}{p\omega}\cdot\frac{d\theta}{dt} + \frac{\mathrm{I}}{p}\cdot\frac{d^2\theta}{dt^2} = 0$$

where ξ is a constant depending upon the degree of excitation of the salient poles.

If the angular velocity of phase swing is required for the case of a salient-pole machine, this can be determined for the no-load case by transforming the equation of motion as follows. Put $\rho = 0$, multiply by $2d\theta/dt$ and integrate with respect to t. Let $\theta = \theta_0$ when $d\theta/dt = 0$. Then

$$2T_m(\cos\theta_0 - \cos\theta) + \xi T_m(\cos 2\theta_0 - \cos 2\theta) + \frac{\mathrm{I}}{p}\left(\frac{d\theta}{dt}\right)^2 = 0$$

$$\therefore\quad \frac{d\theta}{dt} = 2\sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]}$$

$$\times\{(\sin^2\tfrac{1}{2}\theta_0 - \sin^2\tfrac{1}{2}\theta)(1+2\xi-2\xi\sin^2\tfrac{1}{2}\theta_0 - 2\xi\sin^2\tfrac{1}{2}\theta)\}^{\frac{1}{2}}$$

This enables the calculation to be made for the maximum allowable value of the slip for which the motor will

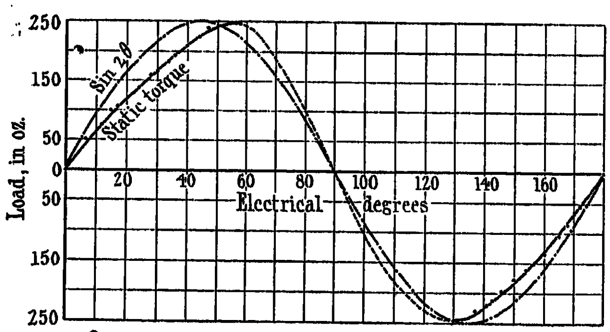

Fig. 14.

just synchronize. For values of $\xi \not> \frac{1}{2}$ the author has shown * that the conditions for a salient-pole motor are the same as for a non-salient-pole motor. Thus if the excitation is switched on at the instant $\theta = 0$, the above equation gives for the maximum allowable value of the slip

$$\left(\frac{d\theta}{dt}\right)_{\theta=0} = 2\sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]}\ \dagger$$

When $\xi > \frac{1}{2}$ the expression for the critical angular velocity is of the form

$$\left(\frac{d\theta}{dt}\right)_{\theta=0} = f(\xi) \times \sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]}$$

It is possible to determine the nature of $f(\xi)$ in the general case by making the assumption that the mean decrease of slip as θ varies from zero to θ_0 is equal to one-half of the total decrease. The error introduced by this assumption is not great, being less than the error introduced when it is assumed that the mean value of a sinusoidal function is one-half of the maximum value. The positions of equilibrium are given by the equation

$$\sin\theta + \xi\sin 2\theta = 0$$

$$\therefore\quad \sin\theta(1 + 2\xi\cos\theta) = 0$$

Putting $\sin\theta = 0$ we have $\theta = 0$, π, or 2π, and these values apply to the case in which $\xi < \frac{1}{2}$.

Putting $(1 + 2\xi\cos\theta) = 0$

we have

$$\theta = \text{arc cos}\left(-\frac{1}{2\xi}\right) \quad\text{or}\quad 2\pi - \text{arc cos}\left(-\frac{1}{2\xi}\right)$$

and these values apply to the case in which $\xi > \frac{1}{2}$. Let us consider that the slip at $\theta = 0$ is such that the system is just brought to rest at the first unstable position defined by

$$\theta = \text{arc cos}\left(-\frac{1}{2\xi}\right)$$

Putting $\omega = d\theta/dt$ we have for the equation of motion

$$\frac{\mathrm{I}}{p}\cdot\frac{d\omega}{dt} = -T_m\sin\omega t - \xi T_m \sin 2\omega t$$

Let $\delta\omega$ be the mean decrease in ω over the interval we are considering, then the mean value of the slip speed will be $(\omega - \delta\omega)$. Hence the time taken to travel from the position $\theta = 0$ to $\theta = \text{arc cos}\left(-\frac{1}{2\xi}\right)$ is

$$\frac{\text{arc cos}\left(-\frac{1}{2\xi}\right)}{\omega - \delta\omega}$$

We therefore have for the total decrease in slip during this interval

$$\frac{T_m p}{\mathrm{I}}\int_0^{\text{arc cos}\left(-\frac{1}{2\xi}\right)/(\omega-\delta\omega)} \sin(\omega-\delta\omega)t\,dt + \frac{\xi T_m p}{\mathrm{I}}\int_0^{\text{arc cos}\left(-\frac{1}{2\xi}\right)/(\omega-\delta\omega)} \sin 2(\omega-\delta\omega)t\,dt$$

$$= -\frac{T_m p}{\mathrm{I}}\times\frac{1}{\omega-\delta\omega}\Big[\cos(\omega-\delta\omega)t\Big]_0^{\text{arc cos}\left(-\frac{1}{2\xi}\right)/(\omega-\delta\omega)}$$

$$-\frac{\xi T_m p}{\mathrm{I}}\times\frac{1}{2(\omega-\delta\omega)}\Big[\cos 2(\omega-\delta)t\Big]_0^{\text{arc cos}\left(-\frac{1}{2\xi}\right)/(\omega-\delta\omega)}$$

$$= \frac{T_m p}{\mathrm{I}}\times\frac{1}{\omega-\delta\omega}\left(1+\frac{1}{2\xi}\right) + \frac{\xi T_m p}{\mathrm{I}}\times\frac{1}{2(\omega-\delta\omega)}\left(2-\frac{1}{2\xi^2}\right)$$

$$= \frac{T_m p}{\mathrm{I}}\times\frac{1}{\omega-\delta\omega}\left(1+\frac{1}{4\xi}+\xi\right)$$

$$= \frac{\xi T_m p}{\mathrm{I}}\times\frac{1}{\omega-\delta\omega}\left(1+\frac{1}{2\xi}\right)^2$$

But the total decrease in slip must be equal to ω, the angular velocity as the system is passing the lowest

* *Electrician*, 1924, vol. 92, p. 220.
† Also see L. H. A. Carr, *loc. cit.*, p. 696.

point, and therefore we have finally, making the above-mentioned assumption of $\omega = 2\delta\omega$:—

$$\omega_{\theta=0} = \left(\frac{d\theta}{dt}\right)_{\theta=0} = \sqrt{(2\xi)}\left(1 + \frac{1}{2\xi}\right)\sqrt{(T_m p/\mathrm{I})}$$

$$= \sqrt{\left(2 + 2\xi + \frac{1}{2\xi}\right)}\sqrt{(T_m p/\mathrm{I})}$$

Hence $$f(\xi) = \sqrt{\left(2 + 2\xi + \frac{1}{2\xi}\right)}$$

An expression for the time of one complete oscillation of phase swing can be determined as follows. First take the case of a non-salient-pole machine. We have :—

$$T_m \sin\theta + \frac{\mathrm{I}}{p}\cdot\frac{d^2\theta}{dt^2} = 0$$

$$\therefore \left(\frac{d\theta}{dt}\right)^2 = 2\frac{T_m p}{\mathrm{I}}\cos\theta + K$$

If $d\theta/dt = 0$ when $\theta = \alpha$, where α is an angle less than θ_0, the position of unstable equilibrium, then

$$\frac{d\theta}{dt} = 2\sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]}(\sin^2\tfrac{1}{2}\alpha - \sin^2\tfrac{1}{2}\theta)^{\frac{1}{2}}$$

$$\therefore \frac{dt}{d\theta} = \tfrac{1}{2}\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{(\sin^2\tfrac{1}{2}\alpha - \sin^2\tfrac{1}{2}\theta)^{\frac{1}{2}}}$$

Hence the period of phase swing

$$P = 2\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]}\int_0^{\alpha}\frac{d\theta}{(\sin^2\tfrac{1}{2}\alpha - \sin^2\tfrac{1}{2}\theta)^{\frac{1}{2}}}$$

Putting $$\sin\tfrac{1}{2}\theta = \sin\tfrac{1}{2}\alpha\sin\phi$$

this reduces to the standard form of elliptic integrals, namely

$$P = 2\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]}\int_0^{\frac{1}{2}\pi}\frac{d\phi}{\sqrt{(1 - \sin^2\tfrac{1}{2}\alpha\sin^2\phi)}}$$

$$= 2\pi\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{\pi}\int_0^{\frac{1}{2}\pi}\frac{d\phi}{\sqrt{(1 - \sin^2\tfrac{1}{2}\alpha\sin^2\phi)}}$$

Values of $$\frac{1}{\pi}\int_0^{\frac{1}{2}\pi}\frac{d\phi}{\sqrt{(1 - \sin^2\tfrac{1}{2}\alpha\sin^2\phi)}}$$

have been tabulated for different values of α. In the particular case in which α is equal to π the period is theoretically infinite.

In the case of the salient-pole motor we have :—

$$\sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]}\{(\sin^2\tfrac{1}{2}\alpha - \sin^2\tfrac{1}{2}\theta)(1 + 2\xi - 2\xi\sin^2\tfrac{1}{2}\theta - 2\xi\sin^2\alpha)\}^{\frac{1}{2}}$$

If the extent of the swing is such that $\alpha = \theta_0$, the position of unstable equilibrium, then

$$\frac{d\theta}{dt} = 2\sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]}\sqrt{(2\xi)}\,(\sin^2\tfrac{1}{2}\theta_0 - \sin^2\tfrac{1}{2}\theta)$$

$$dt = \tfrac{1}{2}\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{\sqrt{(2\xi)}} \times \frac{d\theta}{(\sin^2\tfrac{1}{2}\theta_0 - \sin^2\tfrac{1}{2}\theta)}$$

and for the period we have

$$P = \frac{2}{\sqrt{(2\xi)}}\cdot\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]}\int_0^{\theta_0}\frac{d\theta}{\sin^2\tfrac{1}{2}\theta_0 - \sin^2\tfrac{1}{2}\theta}$$

This is equal to ∞, as would be expected from the analogy of the non-salient-pole motor with an amplitude of phase-swing of 2π radians.*

If $\alpha < \theta_0$ then

$$\frac{dt}{d\theta} = \tfrac{1}{2}\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]}$$

$$\frac{1}{\{(\sin^2\tfrac{1}{2}\alpha - \sin^2\tfrac{1}{2}\theta)(1+2\xi-2\xi\sin^2\tfrac{1}{2}\theta-2\xi\sin^2\tfrac{1}{2}\alpha)\}^{\frac{1}{2}}}$$

and

$$P = 2\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]}$$

$$\int_0^{\alpha}\frac{d\theta}{\{(\sin^2\tfrac{1}{2}\alpha - \sin^2\tfrac{1}{2}\theta)(1+2\xi-2\xi\sin^2\tfrac{1}{2}\theta-2\xi\sin^2\tfrac{1}{2}\alpha)\}^{\frac{1}{2}}}$$

This integral does not appear to be amenable to solution, even by the use of elliptic integrals.† Some idea of the period of oscillation can be obtained from the following treatment of the problem. Let the line of centres of the two weighted discs whose motion is a reproduction of the slip motion ‡ be horizontal. Then the height of the centre of gravity of the system above the line of centres is

$$\frac{-\cos\theta - \xi \times \tfrac{1}{2}\cos 2\theta}{1 + \xi}$$

Hence if z is the height of the centre of gravity of the system above the lowest possible position (given by $\theta = 0$), we have :—

$$z = \frac{1 - \cos\theta + \tfrac{1}{2}\xi(1 - \cos 2\theta)}{1 + \xi}$$

$$= \frac{1}{1 + \xi}(1 + \xi - \cos\theta - \xi\cos^2\theta)$$

$$\frac{dz}{d\theta} = \frac{\sin\theta}{1 + \xi}(1 + 2\xi\cos\theta)$$

$$= \frac{2\xi}{1 + \xi}\sin\theta\left\{\cos\theta - \left(-\frac{1}{2\xi}\right)\right\}$$

Case (1). $\xi < \tfrac{1}{2}$ $\therefore$ $\dfrac{1}{2\xi} > 1$.—$dz/d\theta = 0$ only if

* The integration is given in Appendix 1.
† An integration in terms of a converging series is given in Appendix 2.
‡ H. Cotton, *loc. cit.*

$\sin\theta = 0$, i.e. if $\theta = 0$ or $n\pi$, where n is a positive or negative integer.

$\theta = 0$ gives a minimum,
$\theta = \pi$ gives a maximum,
$\theta = 2\pi$ gives a minimum, and so on.

If $\theta = 0$; $z = 0$, the minimum value.

If $\theta = \pi$; $z = \dfrac{2}{1+\xi}$, the maximum value.

The variation of z with θ is shown in Fig. 15.

Case (2). $\xi > \frac{1}{2}$ $\therefore$ $\dfrac{1}{2\xi} < 1$.—$dz/d\theta = 0$ for $\theta = 0$ or $n\pi$ as before, but also for

$$\theta = \text{arc}\cos\left(-\frac{1}{2\xi}\right), \text{ or } \theta = \pi - \text{arc}\cos\left(-\frac{1}{2\xi}\right),$$
$$\text{or } \theta = \pi + \text{arc}\cos\left(-\frac{1}{2\xi}\right),$$

taking only values of θ between 0 and 2π.

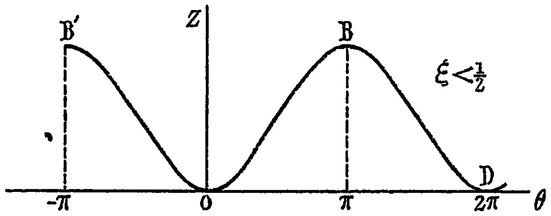

FIG. 15.

Now maxima and minima occur alternately, and $\theta = 0$ obviously gives a minimum.
Hence

$\theta = 0$ gives the minimum value $z = 0$

$\theta = \pi - \text{arc}\cos\left(-\dfrac{1}{2\xi}\right)$ gives a maximum value

$$z = \frac{1}{1+\xi}(1 + \xi - \cos\theta - \xi\cos^2\theta)$$
$$= \frac{1}{1+\xi}\left(1 + \xi + \frac{1}{2\xi} - \frac{\xi}{4\xi^2}\right)$$
$$= 1 + \frac{1}{4\xi(1+\xi)}$$

$\theta = \pi$ gives a minimum value $z = \dfrac{2}{1+\xi}$

$\theta = \pi + \text{arc}\cos\left(-\dfrac{1}{2\xi}\right)$ gives a maximum value

$$z = \frac{1}{1+\xi}(1 + \xi - \cos\theta - \xi\cos^2\theta)$$
$$= 1 + \frac{1}{4\xi(1+\xi)} \text{ as for } \theta = \pi - \text{arc}\cos\left(-\frac{1}{2\xi}\right)$$

$\theta = 2\pi$ gives the minimum value $z = 0$, as for $\theta = 0$.
The variation of z with θ is shown in Fig. 16.

Consider now the dynamical aspect of the problem. If the moments of inertia of the two discs A and B, including their added weights, are $\mathbf{I}_1$ and $\mathbf{I}_2$ respectively, then the rotational energy of the system is

$$\tfrac{1}{2}\mathbf{I}_1\left(\frac{d\theta}{dt}\right)^2 + \tfrac{1}{2}\mathbf{I}_2\left(2\frac{d\theta}{dt}\right)^2$$

$= \frac{1}{2}\dot{\theta}(\mathbf{I}_1 + 4\mathbf{I}_2)$ [using the notation $D'(\theta) = \dot{\theta}$]

Replace $(\mathbf{I}_1 + 4\mathbf{I}_2)$ by $\mathbf{I}/p$ and let the weights in absolute units (i.e. including g) be T_m and ξT_m.

Then by the principle of the conservation of energy, if $\dot{\theta} = \omega$ when $\theta = 0$ we have :—

$$\tfrac{1}{2}\cdot\frac{\mathbf{I}}{p}(\dot{\theta}^2 - \omega^2) + T_m(1 - \cos\theta) + \xi T_m\cdot\tfrac{1}{2}(1 - \cos 2\theta) = 0$$

This is the integrated form of the equation of motion for no-load conditions, namely :—

$$\frac{\mathbf{I}}{p}\ddot{\theta} + T_m\sin\theta + \xi T_m\sin 2\theta = 0$$

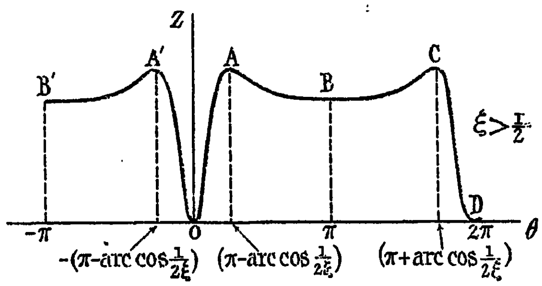

FIG. 16.

Substituting the previously obtained expression for z we have

$$\tfrac{1}{2}\cdot\frac{\mathbf{I}}{p}(\dot{\theta}^2 - \omega^2) + T_m(1 + \xi)z = 0$$
$$\therefore\quad \dot{\theta}^2 = \omega^2 - \frac{2pT_m}{\mathbf{I}}(1 + \xi)z$$

Hence

$$\dot{\theta} = 0 \text{ if } \omega = \sqrt{\left[\frac{2pT_m}{\mathbf{I}}(1 + \xi)z\right]}$$

Case (1) $\xi < \frac{1}{2}$.—For complete revolutions the system has to get past the point B (Fig. 15) for which $z_B = 2/(1 + \xi)$

$$\therefore\quad \omega > 2\sqrt{\left[\frac{T_m p}{\mathbf{I}}\right]}$$
$$> \omega_1, \text{ say.}$$

If $\omega < \omega_1$ the system will oscillate between $\pm\alpha$ where $\alpha < \pi$, and the period can be calculated exactly by means of elliptic functions.

Case (2) $\xi > \frac{1}{2}$.—For complete revolutions the system has to get past the angular positions A and C (Fig. 16) for which $z_A = z_C = 1 + 1/[4\xi(1 + \xi)]$

Hence

$$\omega > \sqrt{\frac{T_m p}{\mathbf{I}}\left(2 + 2\xi + \frac{1}{2\xi}\right)}$$
$$> \sqrt{2\xi}\left(1 + \frac{1}{2\xi}\right)\sqrt{\left[\frac{T_m p}{\mathbf{I}}\right]} > \omega_2, \text{ say.}$$

This gives the same form of $f(\xi)$ as the integration on page 225. If $\omega < \omega_2$ the system will oscillate between $\pm\beta$, where $\beta < \pi - \text{arc cos}\,[-1/(2\xi)]$.

If there is some friction, as of course there is in a practical case,* and ω is only a little greater than ω_2 initially, the system might oscillate somewhere between the positions corresponding to the points A and C, or to similar positions later on.

We can obtain some measure of the time of revolution (for complete revolutions) as follows.

$\dot{\theta}$ has a maximum value of ω, and a minimum value of ω_1 when $\xi < \frac{1}{2}$.

Hence

$$P < \frac{2\pi}{\omega} \quad \text{and} \quad > \frac{2\pi}{\sqrt{(\omega^2 - \omega_1^2)}}$$

$\dot{\theta}$ has a maximum value of ω and a minimum value of ω_2 when $\xi > \frac{1}{2}$.

Hence

$$P < \frac{2\pi}{\omega} \quad \text{and} \quad > \frac{2\pi}{\sqrt{(\omega^2 - \omega_2^2)}}$$

APPENDIX 1.

$$\int_0^{\theta_0} \frac{d\theta}{\sin^2 \frac{1}{2}\theta_0 - \sin^2 \frac{1}{2}\theta} = \int_0^{\theta_0} \frac{\sec^2 \frac{1}{2}\theta\, d\theta}{\sin^2 \frac{1}{2}\theta_0 \sec^2 \frac{1}{2}\theta - \tan^2 \frac{1}{2}\theta}$$

$$= \int_0^{t_0} \frac{2dt}{(1 + t^2)\sin^2 \frac{1}{2}\theta_0 - t^2}$$

where $t = \tan \frac{1}{2}\theta$, $t_0 = \tan \frac{1}{2}\theta_0$

$$= \int_0^{t_0} \frac{2dt}{\sin^2 \frac{1}{2}\theta_0 - t^2 \cos^2 \frac{1}{2}\theta_0}$$

$$= \frac{1}{\cos^2 \frac{1}{2}\theta_0} \int_0^{t_0} \frac{2dt}{t_0^2 - t^2}$$

$$= \frac{1 + t_0^2}{t_0} \int_0^{t_0} \left(\frac{1}{t_0 + t} + \frac{1}{t_0 - t}\right) dt$$

$$= \frac{1 + t_0^2}{t_0} \left(\log \frac{2t_0}{0} - \log \frac{t_0}{t_0}\right)$$

$$= \infty$$

APPENDIX 2.

We have :—

$$\frac{d\theta}{dt} = 2\sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]} \times \{(\sin^2 \tfrac{1}{2}\alpha - \sin^2 \tfrac{1}{2}\theta)(1 + 2\xi - 2\xi \sin^2 \tfrac{1}{2}\alpha - 2\xi \sin^2 \tfrac{1}{2}\theta)\}$$

where $0 = \alpha$ when $d\theta/dt = 0$ and $\xi > \frac{1}{2}$.

$$\therefore \frac{d\theta}{dt} = 2\sqrt{\left[\frac{T_m p}{\mathrm{I}}\right]} \times \sqrt{(2\xi)}\{(\sin^2 \tfrac{1}{2}\alpha - \sin^2 \tfrac{1}{2}\theta)(a - \sin^2 \tfrac{1}{2}\theta)\}^{\frac{1}{2}}$$

where $a = \dfrac{1}{2\xi} + 1 - \sin^2 \frac{1}{2}\alpha$

Hence the period in seconds

$$P = 2\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{\sqrt{(2\xi)}} \int_0^{\alpha} \frac{d\theta}{\sqrt{[(\sin^2 \frac{1}{2}\alpha - \sin^2 \frac{1}{2}\theta)(a - \sin^2 \frac{1}{2}\theta)]}}$$

In order that the integration may be possible it is obvious that we must have $a > \sin^2 \frac{1}{2}\alpha$, otherwise the function would become infinite and then imaginary before θ attained the value α. This condition is fulfilled because $\alpha > \theta_0$, where $\theta_0 = \text{arc cos}\,[-1/(2\xi)]$.

Substituting $\sin \frac{1}{2}\theta = \sin \frac{1}{2}\alpha \sin \phi$

we have $\phi = 0$ when $\theta = 0$
and $\phi = \frac{1}{2}\pi$ when $\theta = \alpha$

Hence

$$P = 2\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{\sqrt{(2\xi)}} \int_0^{\frac{1}{2}\pi} \frac{d\phi}{\sqrt{(1 - \sin^2 \frac{1}{2}\alpha \sin^2 \phi)}\sqrt{a}\sqrt{\left(1 - \frac{1}{a}\sin^2 \frac{1}{2}\alpha \sin^2 \phi\right)}}$$

$$= 2\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{\sqrt{(2a\xi)}} \int_0^{\frac{1}{2}\pi} (1 - m^2 \sin^2 \phi)^{-\frac{1}{2}} (1 - n^2 \sin^2 \phi)^{-\frac{1}{2}} d\phi$$

where $m^2 = \sin^2 \frac{1}{2}\alpha$, $n^2 = \dfrac{1}{a}\sin^2 \frac{1}{2}\alpha$

Either bracket expanded alone gives a converging series. Hence expanding and collecting similar terms we have :—

$$P = 2\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{\sqrt{(2a\xi)}} \int_0^{\frac{1}{2}\pi} [1 + (\tfrac{1}{2} + \tfrac{1}{2}k)m^2 \sin^2 \phi + (\tfrac{3}{8} + \tfrac{1}{4}k + \tfrac{3}{8}k^2)m^4 \sin^4 \phi + (\tfrac{5}{16} + \tfrac{3}{16}k + \tfrac{3}{16}k^2 + \tfrac{5}{16}k^3)m^6 \sin^6 \phi + \ldots] d\phi$$

where $k = 1/a$

$$\therefore P = \pi\sqrt{\left[\frac{\mathrm{I}}{T_m p}\right]} \times \frac{1}{\sqrt{(2a\xi)}} \left[1 + \tfrac{1}{2}(\tfrac{1}{2} + \tfrac{1}{2}k)\sin^2 \tfrac{1}{2}\alpha + \frac{3 \,.\, 1}{4 \,.\, 2}(\tfrac{3}{8} + \tfrac{1}{4}k + \tfrac{3}{8}k^2)\sin^4 \tfrac{1}{2}\alpha + \frac{5 \,.\, 3 \,.\, 1}{6 \,.\, 4 \,.\, 2}(\tfrac{5}{16} + \tfrac{3}{16}k + \tfrac{3}{16}k^2 + \tfrac{5}{16}k^3)\sin^6 \tfrac{1}{2}\alpha\right]$$

From this expression the period P can be calculated for any value of ξ and for any amplitude α. For the case in which $\xi = 1$ the function in the brackets is

remembered that the motion of the mechanical model is a he slip motion, not the actual motion of the motor. Thus an will cause an increase in the angular velocity of the model, use a decrease in the velocity of the motor.

plotted in Fig. 17. The range of a is from 0 to $\theta_0 (= \text{arc cos } \frac{1}{2})$, the function becoming infinite at this latter value.

When a is small the expression for the period reduces to

$$P = \pi\sqrt{\left[\frac{I}{T'_m p}\right]} \times \frac{1}{\sqrt{(2a\xi)}}\left\{1 + \frac{a^2}{8}\left(\tfrac{1}{2} + \tfrac{1}{2}k\right)\right\}$$

In the figure the elliptic integral $\frac{2}{\pi}F_1(K)$ is plotted for comparison, the scale of a being so modified that both functions become infinite at the same point.

For values of α which make $\sin^2 \frac{1}{2}\alpha < 1/(2\xi)$, $k < 1$. The series is therefore rapidly convergent and, as can be seen from the figure, the curve lies below that of the elliptic integral.

When $\sin^2 \frac{1}{2}\alpha = 1(2\xi)$, $k = 1$. The series is, in consequence, much more slowly convergent because, in addition to the greater importance of the $\sin^n \frac{1}{2}\alpha$

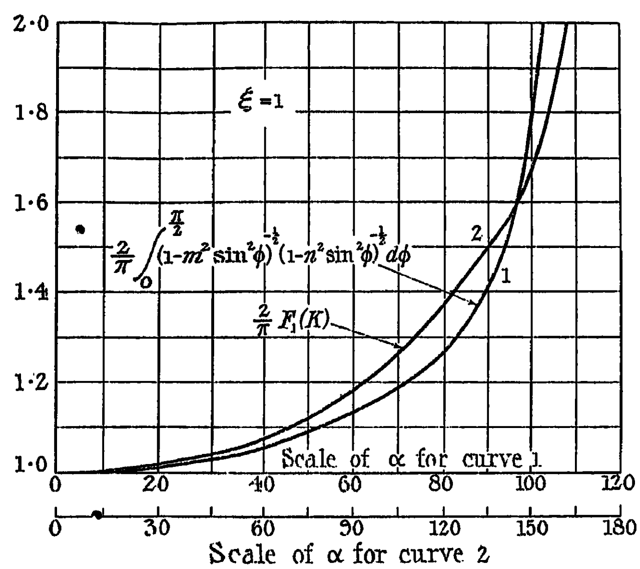

Fig. 17.

coefficients, k raised to increasing powers does not decrease. For $\xi = 1$ this angle is given by

$$\sin^2 \tfrac{1}{2}\alpha = \tfrac{1}{2} \quad \text{or} \quad \alpha = 90°.$$

When $\sin^2 \frac{1}{2}\alpha > \frac{1}{2\xi}$, $k > 1$. The series then converges very slowly and the curve rises very steeply as shown in Fig. 16.

DISCUSSION ON "AN ELECTRIC HARMONIC ANALYSER."*

SCOTTISH CENTRE, AT GLASGOW, 9 DECEMBER, 1924.

Professor G. W. O. Howe: In watching the experimental demonstration † I was very much impressed with the number of adjustments that have to be kept accurate, and the general complication of the measurement compared with many electrical measurements. In estimating these, however, one must take into account the complication of the problem being tackled and compare it with other methods of obtaining the same result. What other methods are there of obtaining this result? The classical method is simply to take an oscillogram, enlarge the curve and then laboriously analyse it. This method certainly gives results, but what these will be worth when one reaches the 13th, 15th and 19th harmonics is, I am afraid, a matter of very great doubt. With an oscillograph, an expert of many years' experience can get tolerably accurate results, but the results obtained by those who have not had such experience often leave very much to be desired with regard to accuracy, especially when the results are afterwards subjected to enlargement and mathematical analysis. In the bibliography at the end of the paper the authors mention a paper of mine on the "Amplitude and Phase of Higher Harmonics in Oscillograms," in which I went into the subject of the accuracy with which the oscillograph reproduces these higher harmonics. As the frequency increases and approaches the natural frequency of the oscillograph, the truthfulness of the representation of the harmonics gradually decreases and as those harmonics usually have a very small amplitude compared with the fundamental, a very little error in the oscillograph makes a very large percentage error in the amplitude of the harmonic obtained from it. That method, then, is a very roundabout one, and the authors have worked out a method which really gives what is required by a direct reading, however laborious and complicated the preliminary arrangements may be. The method demonstrated by the authors marks a very great advance on anything that has been done before, and I sincerely hope that they will develop this method to a stage at which it can be handed over to an electrical engineer who is not an expert and enable him to analyse a wave-form with tolerable certainty that the results which he is getting are correct. The wave shown on the screen and analysed by the authors is one in which the harmonics are very pronounced. The practical problem with which the electrical engineer is more often faced is the finding of the relative amplitudes of harmonics which are very small compared with the fundamental. The problem is not merely an academic one; although alternator builders have made great improvements in the wave-form of their alternators, the necessity of eliminating harmonics has also increased on account of the greater use of high-tension distributing overhead wires and the great spread of telephone and telegraph wires. As we all know, one of the principal reasons for eliminating harmonics from wave-forms is to prevent interference with telephone wires running parallel with power conductors, and high harmonics of relatively small amplitude compared with the fundamental are likely to be the chief offenders in this respect.

Mr. B. Hague: The use of a triode-valve generator to produce a standard wave-form rich in harmonics is finding applications in many branches of electrical measurement. It is of interest to note that the principle of the multi-vibrator wave-meter is very similar to that of the device used by the authors; in this instrument a valve generator is used to produce a wave-form containing strong harmonics, the prime frequency of the generator being controlled by a carefully standardized, electrically maintained tuning-fork. The desired harmonic can then be picked out by means of a suitable circuit tuned to resonance with it, in much the same way as that employed by the authors in their analyser. Although the paper is almost exclusively confined to the determination of the amplitudes of the harmonics, I can imagine problems in which a knowledge of the phases of the harmonics might also be required. I should be glad if the authors would say whether their method will easily give these quantities and enable the harmonics to be completely determined.

Dr. G. E. Allan: I think it fitting that this paper should have been read in Glasgow, since it was in Glasgow that the first practical application of harmonic analysis was made: I refer to the Kelvin tidal analyser, and it is a point of interest that a short time ago the Kelvin tidal gauge which recorded the tidal wave-forms was presented to the University by the Clyde Trust. I suppose that Descoudres' method was the first successful application of the dynamometer method. I should like some information in that respect, and for comparison I would point out that the Kelvin instrument was built to deal with four components; Descoudres was able to deal with nine, and we now see that with the new method it is possible to deal with 23 or more components. It seems to me that the authors have materialized Fourier's mathematical process of singling out the different components of a complex wave.

Dr. S. Parker Smith: Is it possible to measure harmonics which are so small as to be invisible in an oscillogram? I have in mind a case where a three-phase line, when the neutral was earthed, interfered seriously with a neighbouring communication circuit. The oscillogram showed strong 17th and 19th harmonics only, but no trouble was experienced when the star point was isolated. The trouble was traced to small 15th and 21st harmonics. Would the authors' device

* Paper by Messrs. J. D. Cockcroft, R. T. Coe, J. A. Tyacke and Miles Walker (see page 69).

† Before the discussion the authors gave a demonstration of the neon-lamp method of analysis by analysing a rectangular wave-form of current up to the 13th harmonic. This latter current, which was passed through the moving coil of the dynamometer, was obtained from the a.c. supply by a special arrangement of three-electrode valves. The analysing current was kept constant so that the audience could read off directly, from a 20-ft. scale, the percentage value of each harmonic present.

enable us to determine the magnitude of such harmonics ?

Dr. M. G. Say : I do not think it is generally realized that this paper is the result of three—possibly four—years of strenuous post-graduate research. That part dealing with the magnitude of the errors to be expected well deserves the attention of other authors in similar circumstances. To my mind, the form of the paper is the best that could be presented, and should certainly provide an example of what Institution papers should be. There appear to be some minor errors in Table I. Referring to the foot of page 74, it would appear that λ_{nx} is given in Equation (4*b*) as $(\omega L/r)[(x^2 - n^2)/n]$. Now $L/r = 1/15$ and $\omega = 314$, so that $\omega L/r = 21$ approximately. Inserting this value for $n = 1$ and $x = 3$ (in the first line of the table) the result is $8 \times 21 = 168$, whereas the table gives 128. The same appears to hold for the other lines of the table. However, if my figures are correct, matters are rather improved than otherwise. It is stated on page 78, with reference to the phase-swinging of the commutator-driving gear, that "it would no doubt be possible to reduce this source of trouble very considerably by using a properly designed motor." Suppose that the alternator under test had a cyclic speed variation represented, say, by a sine wave superimposed on its steady mean speed. Then the commutator and its driving motor would have a cyclic variation representable by a sine wave displaced in phase by a half-period of the frequency of the speed variation. The commutator would never be in true synchronism with the supply, and damping would only reduce the amplitude of the variation and not its phase. A steady reading could not therefore be obtained, and the oscillation might be serious when measuring high orders of harmonics. Perhaps, however, I have overestimated the severity of this trouble. If I read Fig. 16 correctly, it would appear that it is impossible, with the neon-lamp method, to measure the amplitude of the fundamental of the wave-form under test with an accuracy comparable with that to which, say, the 9th harmonic might be obtained. Surely the fundamental is the most important of the harmonics. With this method also the volt-ampere consumption of the saturated transformer circuit is somewhat high: it is given as 10 amperes at 200 volts, or 2 kVA. Does this have any distorting effect on the true wave-form of small apparatus under test ? A very interesting form of harmonic analyser has recently been constructed in America.* Here the supply to be analysed is fed into an input network, paralleled with which is an oscillatory circuit whose natural frequency may be altered continuously in a definite manner by pneumatic power. Thus the analysed wave-form has, as it were, withdrawn out of it, in succession, all its harmonics from the fundamental upwards. Probably by some form of reflecting dynamometer the deflections are indicated on a specially scaled photographic plate, which is moved across the field of the dynamometer beam, again by pneumatic means. In this way the developed negative shows a record composed of a series of troughs and sharp peaks traced on a graph marked directly in percentages and in cycles per second. Any harmonic (indicated by a peak) can be picked out by reference to the base line of frequency. The whole process is said to occupy about 5 minutes and is entirely automatic, and the calibration is approximately constant for all frequencies within a wide range. The accuracy of the instrument is not comparable with that of the present one, but its ease of manipulation offers some advantages. Have the authors something in view on these or other lines which would add to the already considerable value of their analyser ?

* *Journal of the American Institute of Electrical Engineers*, 1924, vol. 43, p. 798; also *Electrician*, 1924, vol. 93, p. 552.

Messrs. J. D. Cockcroft, R. T. Coe, J. A. Tyacke and **Miles Walker** (*in reply*) : In reply to Prof. Howe, it should be pointed out that the demonstration of the apparatus before the audiences in London and the Local Centres was greatly complicated by the fact that, in order to enable the audience to read off the value of the harmonics of a square wave without any calculation, all the harmonics had to be projected on the screen to the same scale. In addition, the fundamental had to be made 100 scale divisions so that the higher harmonics would appear in their proper percentage. The main difficulty arose from the variation of the voltage of the supply mains. This in the ordinary use of the instrument does not cause much trouble because, whatever the voltage happens to be at any instant, it is not difficult to take a snap reading of the wattmeter and the voltmeters and work out the value of the harmonic for the set of readings obtained. It is not necessary to bring back the voltage of supply to some fixed value for each set of readings, as is necessary when all harmonics are to be shown to the same scale. We are making up a portable form of the apparatus which will occupy a space of about 1 foot cube. The process of measuring a harmonic will be nothing more than the plugging in of a suitable capacity, the tuning of a circuit by means of a variometer, and the taking of three simultaneous readings if the conditions are rather unsteady. From these three readings the harmonic is worked out in the manner described in the paper.

Mr. Hague asks whether the phases of the harmonics can be determined. Using the synchronous motor and copper disc commutator as described above, the phase of a harmonic could easily be determined by measuring the shift of the brushes required to give a maximum reading.

Since harmonics of less than 1/1 000th of the amplitude of the fundamental can be detected, it should certainly be possible to determine the approximate amplitude of harmonics of the type referred to by Dr. Smith, which are not visible on the oscillograph but yet produce marked interference.

The authors are indebted to Dr. Say for pointing out the omission in the text preceding Table 1. Table 1 was calculated from Equation (4*a*), using values of R_1 and C actually employed in practice. These values were generally chosen to make $R_1 Cr/L$ of the order of 3. Provided the amplitude of phase swing of the synchronous motor is kept below $\frac{1}{2}°$ the dynamometer reading for the 23rd harmonic will not vary by more than 2 per cent. The power consumption of the saturated transformer can be very much reduced by special design. Dr. Say is quite correct in his contention that it would not be possible to measure the

fundamental of a wave very accurately with the neon-lamp method. It is not intended to do this. The E.M.F. wave induced in the oscillatory circuit is deliberately made to have a small fundamental in order to reduce to a minimum the dynamometer torque and consequent error due to fundamental currents in both coils. This is important owing to the large fundamental in most waves likely to be analysed. Since the harmonics in the pressure-coil voltage are found directly in volts, the best way of determining the value of the fundamental is to find the R.M.S. value of the wave with a good commercial instrument and to correct this if necessary for the effect of such harmonics as may have been found. The method recently developed in America and referred to by Dr. Say is in principle exactly the same as the resonance methods described in Section 2 (1), and is subject to the type of errors there described. Since the eddy-current and dielectric losses cannot be inappreciable at the frequency of the 23rd harmonic, it is difficult to see how the calibration can be constant over the whole range of frequencies required. In fact, no statement is made in the paper as to the possible accuracy of the method described.

ALTERNATORS FOR OPERATION ON A TRANSMISSION LINE.

By N. B. HILL, Student.

[ABSTRACT *of paper read before the* NORTH-WESTERN STUDENTS' SECTION, *6th November, and before the* MERSEY AND NORTH WALES (LIVERPOOL) STUDENTS' SECTION, *13th November*, 1923.]

SUMMARY.

When laying out the design of an alternator that will be used to transmit power over a long transmission line, it is necessary to consider several factors in addition to the specified full-load rating before one can decide on the relative electric and magnetic loadings of the machine, or even the frame size on which it should be built.

In attempting a survey of the problem, the paper was divided into six sections, which may be summarized as follows :—

(1) General discussion of the possible instability of an alternator connected to a transmission line.
(2). Varying-voltage and constant-voltage transmission lines.
(3) A more detailed consideration of the alternator, showing that it is possible to determine directly from its open-circuit and short-circuit characteristics the maximum leading kVA with which it can deal at normal voltage, for complete stability down to zero voltage.
(4) Effect of the exciter on the stability of the generating unit.
(5) Variations in station voltage to be expected when operating the high-tension line switches.
(6) Particulars of an alternator built for a 50-period line demanding a charging current equivalent to 8 100 kVA at 11 000 volts.

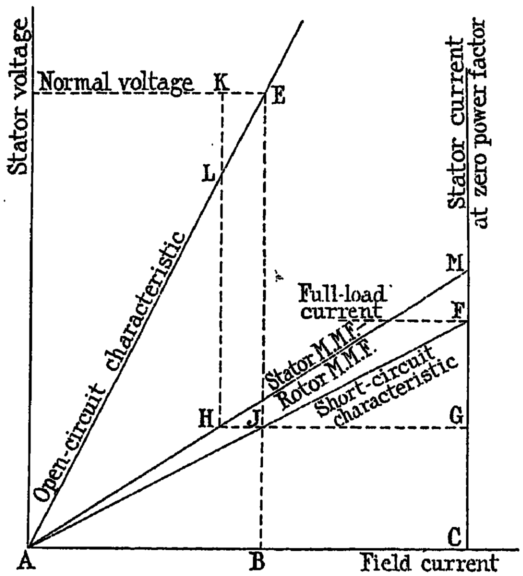
In Section 1 of the original paper, it was pointed out that an alternator connected to a transmission line through transformers becomes a self-exciting unit when the combined "line and transformer characteristic" lies to the right of the "generator characteristic." Without d.c. excitation the voltage of the machine will rise to the point where the characteristic curves intersect.

The "line and transformer characteristic" is the relation between the alternator terminal voltage, and the total leading current taken by the line and transformers. The "generator characteristic" is the relation between the alternator terminal voltage and the leading stator current necessary to maintain that voltage; in other words the saturation curve of the machine when magnetized from the a.c. side. With machines of the size with which we are dealing, it is an advantage if we can make use of the open-circuit and short-circuit characteristics to predict the generator characteristic, as the experimental determination of the former curves does not call for any elaborate tests on the completed machine.

When the machine is excited from the stator, the stator leakage flux provides a portion of the terminal voltage, and the flux crossing the air-gap will be correspondingly less than the flux required to produce the same terminal voltage on open circuit.

Let AE in the figure be the air line of the open-circuit characteristic of the machine, and AF the short-circuit characteristic, E being the point of normal voltage and F the point of full-load current. If we assume zero stator reactance for the moment, the short-circuit curve will represent the relation between stator and rotor M.M.F.'s, and the generator characteristic will be given by a straight line passing through the origin and a point the ordinate of which represents normal voltage and the abscissa a stator current equal to CG. If AB/AC = y, the alternator will evidently be capable of dealing with a maximum charging kVA at

normal voltage of y times its rated full-load kVA. Let us now consider the case where the stator reactance is X per cent, and the open-circuit and short-circuit characteristics are unaltered; we shall assume that the alternator can still deal at normal voltage with a leading current equal to CG. Neglecting the small amount of saturation which is usually present at normal voltage, the portion HJ of the short-circuit excitation maintaining the flux in the machine when the stator current



equals CG, is $XyAB$, and the connection between stator and rotor M.M.F.'s is given by AM. At normal terminal voltage the leading stator current CG now supplies a portion ($KL = XyAD$) of the voltage, and the flux crossing the gap is correspondingly reduced. Since $HJ = XyAB$, and $KL = XyAD$, L must lie on the line AE, and we see that the current CG provides just sufficient M.M.F. to maintain the reduced flux. This means that the generator characteristic is identical with the case of zero stator reactance, and justifies the assumption previously made.

The maximum charging current with which the alternator can deal at normal voltage, for complete stability down to zero voltage, can therefore be obtained directly from the short-circuit characteristic of the machine, by reading from that curve the stator current corresponding to the rotor current needed by the air-gap at normal voltage on open circuit. The maximum charging kVA at normal voltage is thus equal to the normal full-load kVA multiplied by

$$\frac{\text{Excitation required by the air-gap at normal voltage on open-circuit}}{\text{Excitation required to maintain full-load current on short-circuit.}}$$

If the stability is estimated in this way no correction is needed for stator reactance, but it will be realized that this is not equivalent to saying that the stability is independent of the reactance. For example, if by some means we could reduce the reactance of a machine without altering any other of its characteristics, a smaller proportion of the terminal voltage would be provided by a given leading current in the stator, and to maintain the correspondingly increased flux in the machine a larger leading current could be taken from the line—in other words the stability would be increased. This is also evident from the formula given above, since less excitation is needed to maintain full-load current on short-circuit when the stator reactance is reduced without altering any other feature of the machine.

It may be mentioned that the wave-form of the alternator has no effect on the stability. If harmonics are present in the voltage wave these will cause additional currents of a corresponding frequency to flow in the line, but it is only the currents of fundamental frequency that assist in magnetizing the machine. The M.M.F.'s produced by currents of other frequencies move at a high velocity with respect to the field system, and as far as the harmonics are concerned the machine may be considered to be an induction motor on short-circuit.

Since the line capacity is in series with the inductance of the alternator windings, the possibility of voltage resonance, either at fundamental frequency, or at one of the harmonic frequencies, must be considered. From this point of view it is desirable that the wave-form of the alternator voltage should be free from harmonics.

PROCEEDINGS OF THE INSTITUTION.

718th ORDINARY MEETING, 23 OCTOBER, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, F.R.S., Past-President, took the chair at 6 p.m.

The minutes of the Annual General Meeting of the 8th May, 1924, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see vol. 62, pages 558, 651, 728, 816 and 900) was taken as read and the thanks of the meeting were accorded to the donors.

The Chairman announced that the Council had decided to make a donation of 100 guineas to the Cavendish Laboratory, Cambridge, as a token of appreciation of the electrical researches carried out there by Sir Joseph Thomson, Sir Ernest Rutherford and other Cambridge physicists.

The Premiums and Scholarships (see vol. 62, pages 528, 529 and 727) awarded during the session 1923–24 were presented by the Chairman to such of the recipients as were present.

The chair was then vacated by Dr. Russell and taken by **Mr. W. B. Woodhouse** amid applause.

Mr. Ll. B. Atkinson : Once again we meet at the commencement of a new session and a new year's work. Once again we commence those series of meetings of our whole Institution and of our Committees which form so important a part of our work. Again a new and energetic leader takes his place before us, and we are fully confident that he will bring to us, as others before him have done, new ideas and new ideals to which we shall give our heartiest support. But once again also we part with a leader, our President of last session. We consign him delicately to the limbo of past-presidents, to that group of (as it has been stated to me) extinct volcanoes, of which there are fortunately a good many still in existence. Before we do so, however, we want to bid him a grateful farewell—not a farewell in the sense that we shall see him no more, but only in his official capacity. In doing so, we express the belief and the hope that we shall long have him with us to assist us in the work of the Institution and to guide and help those who follow him in the chair he has just vacated. A year ago, when Dr. Russell took over the office of President, we all felt that the Institution was once again fortunate in having the right man at the right hour. It has been a very important year for the electrical profession and industry. That great demonstration of British electrical engineering at Wembley, and the World Power Conference associated with it, have brought together many hundreds of engineers and leading electrical men from all the world over; and it was right and proper that at that moment we should have as our President a man who was internationally known and respected as a scientist. Dr. Russell was such a man. We know him and honour him; and we may well take pride in the fact that during the year he was in office others also showed that they endorsed our view of him. It was during his year of office as President that he was elected a Fellow of the Royal Society, and that his own University of Glasgow, which he visited on the occasion of the Kelvin Celebration, conferred upon him the degree of Doctor of Laws. In his year of office he served the Institution well, at the Council Meetings, at our Ordinary Meetings, on all those occasions when he has had to represent the Institution officially, and in the visits which he has paid to, I believe, every one of our Local Centres. I beg to propose: "That the best thanks of the Institution be accorded to Dr. Alexander Russell for the very able manner in which he has fulfilled the office of President during the past year."

Mr. J. S. Highfield : I have very great pleasure in seconding the resolution proposed by Mr. Atkinson. We all know how admirably Dr. Russell has filled the presidential chair; some of us know of the vast amount of work he has done for our Institution. It is not only what is done by our President that alone is important; the manner of the doing is equally important. By his courtesy and geniality Dr. Russell has done much to enhance the popularity of the Institution. In this particular year when so many foreign friends were here whom we had the honour to entertain, Dr. Russell was a host the embodiment of kindly geniality, carrying in his eyes the light of hospitality, that essentially English characteristic. Truly he concentrated for us our desire to entertain our friends to the full, and in so doing coped with, I believe, some 30 different languages. Mr. Atkinson referred to past-presidents as extinct volcanoes. Contrasted with the new President entering with new eagerness on a year's congenial work, this may be true. But if the work that Dr. Russell does in his ordinary vocation is considered, the skilful training of young engineers at Faraday House, an institution universally respected and held in high honour and in which I know he takes the greatest pride; when it is considered that that work started long before he became President, continued during his term of office and still goes vigorously forward, I am sure you will agree that he, for one, is by no means an extinct volcano. May he live long to enjoy the honour and esteem with which we all regard him. I have the greatest pleasure in seconding the resolution.

The resolution was put to the meeting by the President and carried with acclamation.

Dr. A. Russell: I have to thank you most warmly for the kind way in which you have received this resolution, and especially to thank Mr. Atkinson and Mr. Highfield for the many kind things they have said. What has impressed me most during my year of office is the able way in which our Local Centres co-operate with the parent Institution. The organization by which we keep in touch with our members in all parts of the world is most efficient, and for its smooth working we are largely indebted to Mr. Rowell, the Secretary. I shall never forget the kind welcome that I received, as President of the Institution, from the Local Centres, and also their great hospitality. These friendly relations between the Council and the Local Centres augur well for the future. As an Institution we are deeply indebted to many friends for the unstinted hospitality shown last summer to our overseas visitors. These benefactors include His Majesty the King, Cambridge University, Birmingham University, the London, Midland and Scottish Railway, the North-Eastern Railway, the London General Omnibus Company, Lord Ashfield, and many others too numerous to mention. I very much appreciated the invaluable work done in this connection by Sir James Devonshire, and also by our Secretary. In conclusion, I want to thank the Council and all the members for the great kindness and consideration which they have shown me during my year of office. I am looking forward with the greatest confidence to the continued growth of the Institution in knowledge, influence and popularity under the presidency of Mr. Woodhouse.

The President then delivered his Inaugural Address (see page 1).

Mr. C. P. Sparks: The Address to which we have just listened is one of more than ordinary interest. First, it is written by one who has devoted his entire business life to private enterprise, which, in the opinion of many of us, is the mainstay of this country's prosperity. Secondly, our new President is the first who can speak as a manager of a power company. While it has required many years of hard work for the power companies to establish their position, their importance is now recognized, and they have recently been brought to the fore by more than one political party. Thirdly, our new President is the first for many years who specially represents local interests. He has already served as Chairman of the North Midland Centre for two sessions. I have much pleasure in moving: "That the best thanks of the Institution be accorded to Mr. W. B. Woodhouse for his interesting and instructive Presidential Address, and that, with his permission, the Address be printed in the *Journal* of the Institution."

Mr. Roger T. Smith: Among those who listen to Presidential Addresses I think perhaps those who have already occupied the chair have a distinct advantage. Others can think how much better—or how much worse—they would have done it themselves. The past-president knows how much worse, or perhaps how much better, he did it. But I doubt if there is any past-president here to-night—not even myself—who would be sufficiently vain to think that he had produced an Address better than that to which we have just listened. Teachers, because they generally know nothing at first hand of what they teach, can generally make their lectures interesting, although students will bear me out that that is not always the case. It is, however, a much harder task for a man who has spent all his life in doing things to put the results of his experience into an address confined to one hour, and at the same time to make that account of his work as absorbingly interesting as our President has done; and for his doing that and giving us the pleasure of so instructive and important an Address, I have very great pleasure in seconding the resolution.

The resolution was then put to the meeting by Dr. Russell, Past-President, and was carried with acclamation. After the President had briefly replied, the meeting terminated at 7.30 p.m.

40TH MEETING OF THE WIRELESS SECTION, 5 NOVEMBER, 1924.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 7th May, 1924, were taken as read and were confirmed and signed.

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Wireless Section, then delivered his second Inaugural Address (see page 60).

A vote of thanks to Mr. Shaughnessy for his Address, proposed by the President and seconded by Professor G. W. O. Howe, D.Sc., was carried with acclamation, and the meeting terminated at 7 p.m.

INSTITUTION NOTES.

Faraday Medal.

At the Ordinary Meeting of the Institution held on the 22nd January, the President announced that the Council had made the fourth award of the Faraday Medal to Sir Joseph Thomson, O.M., M.A., F.R.S., an Honorary Member of the Institution and Master of Trinity College, Cambridge.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 25 December, 1924–25 January, 1925.

	£	s.	d.
"C. A." (London)		10	0
Abraham, F. H. (Bradford)		5	0

SPEEDING UP THE TELEGRAPHS: A FORECAST OF THE NEW TELEGRAPHY.

By DONALD MURRAY, M.A., Member.

(*Paper first received* 15*th September, and in final form* 29*th October; read before* THE INSTITUTION 18*th December*, 1924.)

SUMMARY.

This paper, which is mainly a forecast of the probable form that the telegraph service will take in the course of the next 25 years—a form that is described as the "new telegraphy"—refers to the world-wide complaints about the unsatisfactory condition of the telegraph service and the need for improving it and speeding it up until it takes its proper place alongside the telephone.

It is agreed that these complaints are well founded, and the telegraph service is described as being dear, slow and inaccessible. Speeding up the telegraphs and bringing them into closer touch with the industrial and financial life of the world is put forward as a necessity of the future. We must type as well as talk. We must "teletype" as well as "teletalk."

It is pointed out that the telegraph has many important advantages over the telephone, especially for communicating over distances of more than 50 miles, and the present ailment of the telegraph is diagnosed as excessive circuit facilities and defective terminal facilities. That is to say, there are more circuits than are required for the traffic at present available, and not sufficient telegraph machinery, and the telegraph equipment is not arranged, like the telephone, so as to be linked up closely with the business life of the community. The telegraph is not, but should be, at every business-man's elbow, like the telephone.

The remedy is the creation of printing telegraph or, more briefly, teletype exchanges, giving telegraph facilities similar to the telephone facilities we now enjoy. This will evidently be the result of certain developments now taking place in America, where both the Western Union and the Bell Telephone Companies are about to offer telegraph typewriter service to business men, that is to say to subscribers. If this proves commercially profitable, it will inevitably lead to the establishment of teletype exchanges in all the American cities, and they will be linked up by trunk or long-distance telegraph lines. This will put business men all over the United States directly in touch with each other by printing telegraphy. In this way the new telegraphy will be born.

The paper foretells that, in the course of years, this new development will have a revolutionary effect on telegraph offices, which will become automatic switching exchanges, very like an automatic telephone exchange; and the telegraph operators, like the telephone girls, are doomed to disappear, and their places will be taken by a few telegraph engineers and mechanics wandering about in the deserted telegraph operating-rooms, looking after the telegraph switching apparatus.

Examples are given of the advantages that this new telegraphy will confer on the business community.

The machine that has made this new telegraphy possible is the start-stop telegraph printer—provided with a typewriter keyboard and requiring only momentary synchronism. It can therefore be readily switched from one circuit to another. It can work at from 40 to 80 words a minute over any distance from 100 feet to 5 000 miles, and any girl typist can use it. This is the business-man's printing telegraph—the Ford car of telegraphy.

TABLE OF CONTENTS.

Part 1.

THE WORLD'S UNSATISFACTORY TELEGRAPH SERVICE.

(1) *The modern demand for speed, and why.*—A paragraph in the newspapers, entitled "Speeding up the Telegraphs," has supplied the title and inspiration for this paper. The paragraph, which has already been widely quoted and commented upon, appeared in the following form in the London *Daily News* of the 26th February, 1924:—

"SPEEDING UP THE TELEGRAPHS.—RIVALRY OF WIRELESS AND AIR MAILS.

"PARIS, Monday.

"It is announced here that the International Telegraph Union at Berne is proposing a world inquiry into the growing neglect of the telegraph in internal and international communications.

"In some countries, such as the United States and Scandinavia, the telegraph now contributes hardly more than 1 per cent of the total number of electric communications, and in France, where lack of enterprise still leaves over 40 per cent of the 36 000 communes unserved by the telephone, the proportion is only about 10 per cent.

"The air-mail is mentioned as becoming a powerful rival to the telegraph wire. A letter posted in Paris at 7.50 p.m. is now delivered at Casablanca, in Morocco, on the following morning but one, which is not always, but is sometimes, as rapid as the telegraph, and has other advantages.

"In a single month last year 200 000 communications were sent by this air route. The use of wireless telegraphy is growing very rapidly. The great station near Bordeaux sends messages as far as Saigon. Saint Assise serves America, and Lyons, Moscow and Central Europe.

"It is suggested here that if the plant and cables of the old system representing hundreds of millions are not gradually to be scrapped, tariffs will have to be reduced, and the service everywhere speeded up. In France it still often takes five hours to telegraph between Paris and Nice, and this is only an instance of the wide margin left for reform."

The same paper published another significant paragraph on the 18th June, 1924, as follows:—

"TELEPHONING EXPRESS.—QUICKER METHOD OF TRANSMITTING PHONOGRAMS.

"The telephoning of express messages is to be expedited.

"Hitherto a telephone subscriber has telephoned his message to the nearest exchange, whence it has been sent to the next exchange, and so on, necessitating its being re-written perhaps three or four times.

"Under the new system a subscriber is to be plugged through to the nearest central transmitting office. He will be charged only the local fee. A subscriber, for example, who wishes to dictate an express message from Stockport will be put through to Manchester, and one who speaks from (say) Norwood will be put straight through to the Central Telegraph Office, St. Martin's-le-Grand.

"The new scheme is criticized by the Union of Post Office Workers. Mr. Fred Riley, the assistant secretary, said yesterday:

"'The union claims that phonogram work is strictly telegraph work, requiring a full knowledge of telegraphic rules and regulations.

"'In the transfer of work from telegraphists to telephonists the Post Office is guilty of down grading of work contrary to the trade union practice. The union agrees to such transfer only on the condition that telegraph rates are paid.'

"Mr. Riley added that errors in telegraphy were negligible compared with those in telephony. He said the scheme appeared to be a great menace to the staff, and had no advantages for the public."

As these two paragraphs deal with a subject of the greatest importance to the industrial and business world, namely, quick and cheap intercommunication, it seems to be desirable that a clear, hill-top view of the facts and probable and possible developments of telegraphy, as they appear to one who has devoted many years to the subject, should be put on record in circumstances which may lead to wide public discussion. By such discussion the business world will become conscious of the possibilities, and a very desirable stimulus will be given to the growth of the great telegraphic facilities that will be available to us in the course of the next 25 years. I have therefore avoided technicalities, and comcmuniation engineers will find nothing new in this paper, except the unusually extensive landscape.

If we had no telephones, the world would be very proud of its marvellous telegraph service; but the colossal growth of the telephones, and the wonderfully quick and cheap service that they render, have made people dissatisfied with the results at present obtained from the telegraphs.

There have been articles innumerable in the technical and lay Press about the unsatisfactory condition of the telegraph service and the need for cheapening and speeding up the telegraphs to save them from extinction, and all sorts of weird remedies have been proposed. We have been told that the world's telegraphs are in the melting-pot, and that they are liable to be swept away by the telephone and wireless and by the air-mails, and nobody seems to know what to do to remedy this state of affairs. The ideologues and word-merchants suggest that the telegraphs need to be "reorganized," and practical telegraph men recommend "advertising the telegraphs" and "cultivating the telegraph habit." Advertising is good as far as it goes, and the Western Union Telegraph Company finds that this policy pays, and a really remarkable telegraph advertising campaign is carried on in America.

The company has been good enough to send me a collection of its advertising leaflets. These are amazingly clever, and cover all phases of life from the use of telegrams to collect overdue accounts, to sample telegrams to radio artists with the advice "Applaud by Telegraph." Amongst scores of others, there is a card giving the average cost of letters at 52 cents and telegrams at 60 cents. In Great Britain the corresponding cost of an average letter is probably about 1s. and a telegram about 1s. 3d. The argument is that the saving of time at the cost of a few extra cents is extremely profitable. Through all the advertisements runs the refrain: "Don't write—Telegraph!"

Note these last words attacking the mail-bags.

Practical telegraph men realize that telegraph traffic is not likely to grow faster than the slow annual increment due to increase of population, if the present lines of development are adhered to, and they know that there are only two other directions from which increased traffic can be expected. The telegraphs have suffered from the pressure of the telephones on one side and the Post Office on the other, and the obvious remedy is for the telegraph men to attack the telephones and make war on the mail-bags. Hence the advice in the advertisement, "Don't write—Telegraph." There are also night-letter telegrams and various other devices to divert correspondence to the telegraph wires, especially during the ebb-tide when the volume of telegraphic traffic is low.

Clearly this advertising shows that the Western Union telegraph plant is not being used up to its capacity; and that is the position with all telegraph administrations. There is a shortage of telegrams and there is no shortage of telephone messages. Unfortunately it is not much use to advertise the telegraph service while it is dear, slow and inaccessible. When the telegraphs become as cheap, quick and accessible as

the telephones, the telegraphs will not have so much need to advertise.

The chief complaint is about the slowness of the telegraph service, and the complaint is world-wide. For instance, a paragraph in the *Telegraph and Telephone Journal* for June 1924 says:—

"The annual report of the P.M.G. of Australia shows a loss on the telegraph branch of some £78 000 on the year 1922–23. Out there, as here, the speedier delivery of telegrams is a problem not yet solved. It is, however, noted that a distinct promise of an acceleration in that direction has been made."

This demand for greater speed has a deep economic significance, and it may be pointed out, in passing, that the idea of doing things quickly is modern, and it exists only in highly industrialized communities. Some years before the war when I was in Moscow, I was told that "Time is not money in Russia." I was also told that "The Lord God has plenty of time." However, the Russians are adopting modern habits, and all over the world "mañana" is giving way to "pronto."

The explanation of this modern haste lies in the fact that a profit of a shilling an hour is better than a profit of a shilling a day. In other words, the faster one does business the more business one will be able to do and the greater will be one's annual dividend. Every business man knows that, and every business man knows how profitable it is to use the telegraph and telephone. The telephone saves a colossal amount of time, and is one of the main factors in the vast production of modern wealth. The telegraph, the senior service, helps, but not to anything like the extent that it ought to do.

Examples of this speeding up of business may be found throughout every community, and an amusing instance is the speeding up of moving pictures so as to get more programmes through and to get more audiences squeezed into one day. This gives a bigger turn-over in audiences and a bigger profit on the day.

In the language of political economy an essential part of the process of division of labour is exchange of the goods produced, and anything that increases the velocity of that exchange facilitates the division of labour which is one of the two great factors in the production of our modern wealth.

In this speeding up of the turn-over, the telephone and telegraph play a very large part, but the telegraph, for various reasons, has lagged behind. Recent developments, however, with which this paper deals, indicate a great extension of the telegraph service. The business man wants to speed up business, and for that purpose he needs a vastly improved telegraph service, and he is going to get it. He will have to pay for it; but the profit is so great that he will pay gladly when he gets accustomed to the price. By business men I mean not only individuals but organizations, merchants, banks, stockbrokers, factories, railways, farmers—in fact the whole financial and industrial community.

(2) *Telephone versus telegraph.*—In order to get an idea of the possibilities of telegraphy, it has to be remembered that there are only two practicable methods of communication—by the ear, and by the eye. We can talk and we can write; we can telephone and we can telegraph. At present the telephone has no effective rival, it has interwoven itself into the industrial life of the world to an extraordinary degree, and to a substantial extent it is doing work that the telegraph could do better, especially over considerable distances; but for a variety of reasons the telegraph has not been able to stand up against the competition of the telephone, and the result is that the telegraph has been cramped and stunted between the competition of the telephone service and the postal service.

This stunted growth of the telegraph is economically unsound. It is not good for the community, and it is also certainly not permanent. It has been due essentially to the imperfect development of the telegraph plant. It is true that the telephone also is only now reaching the machine stage; but the telephone has always had the great advantage that the transmitting and receiving mechanisms, the human tongue and the human ear, cost nothing, are ready made, and are highly perfected and capable of any speed up to about 150 words a minute. All the telephone engineer had to do was to provide wires and suitable switching arrangements and extremely simple transformation devices to catch and reproduce the human voice. The telegraph engineers, on the other hand, were heavily handicapped by the burden of having to make satisfactory machinery that would typewrite at a distance. This proved to be a very difficult task, and although printing telegraphs have been in existence for 50 years, the business-man's printing-telegraph has only been perfected during the last few years. The reasons will be given later. This is the one and only important reason for the backward condition of the telegraph compared with the telephone. We realize this fact at once when we consider that if we could all speak the Morse Code language the telegraph would not be the Cinderella of communication. It is only now that this handicap is beginning to be removed, and speeding up the telegraphs, or, more strictly, speeding up the transit of telegrams, has begun. This perfecting of the telegraph machinery will be dealt with presently.

It is, of course, hopelessly idealistic to suppose that, for moderate distances, the telegraph can ever be as quick and as intimately connected with the life of the community as the telephone; but we are safe in assuming that in 15 or 20 years business men will have at their disposal a telegraph service, by wire and wireless, far quicker and more accessible than at present, and progressively cheaper than the telephone for distances exceeding, say, 50 miles. If business men could telegraph over distances exceeding 50 miles more easily and quickly and cheaply than they can telephone (and that will be the case by and by) what would be the result? Clearly the new facilities would create much new traffic; but, in addition, many messages now going by telephone would go by telegraph, and also a great many letters that now go by mail would go by wire. The telephone has great advantages over the telegraph, but a perfected telegraph network would have other great compensating advantages over the telephone. We must type as well as talk; we must teletype as well as teletalk. A telephone message is a voice, and nothing more—a sound leaving no record. Nothing is more evanescent. There are sound-recording machines, but the sounds are still

sounds, and there is no conceivable mechanism, outside of the human brain, that will translate a sound-message into a sight-message. It is sight-records and not sound-records that we need for business purposes, because they occupy so little space compared with any sound-record and are so much cheaper. They can also be glanced over so quickly and read at the rate of 300 words a minute. Business demands speed, and we must type and teletype when records are needed. Civilization began when we started to write, and modern civilization began when we started to type. Now we are starting to type by telegraph on a large scale by modern mechanisms.

(3) *Weaknesses of the telephone.*—Not only is a telephone message merely a passing sound, but also in order to gain its undoubted advantages it has to be exceedingly wasteful of signalling material. This is readily seen when we examine the vibrations or signals that have to be transmitted over *two* telephone wires for a single word, say "Paris," compared with the vibrations or signals required to transmit over *one* telegraph wire the same word in the five-unit alphabet.

In Fig. 1, A is an oscillograph record of the electric oscillations in a telephone circuit when the word "Paris" is spoken rapidly into a telephone receiver. I am indebted to the Post Office Research Station at Dollis Hill for this extremely instructive oscillograph.

B (Fig. 1) is a timing record with a frequency of 1 000 cycles or vibrations per second. On B therefore 100 waves mark off $\frac{1}{10}$ second, and it will be seen that the word "Paris" spoken rapidly into the telephone occupied about $\frac{1}{3}$ second, or 1/18th of a second per letter. (Five letters and the space after the word, or, in all, six letters, are taken as the standard word.) Dividing 60 seconds by 1/18 we get 1 080 letters or 180 words a minute. The number of waves or cycles required to transmit the word "Paris" telephonically was 365.

Immediately below, in C (Fig. 1), there has been marked off the number of cycles in B required to transmit the word "Paris" in a telegraph wire by the five-unit alphabet. As start-stop printers use what is really a seven-unit alphabet, we multiply the six letters of the standard word by seven, thus getting 42 units, or 21 waves required to transmit the word "Paris" telegraphically by a start-stop printer, compared with 365 waves required for the telephonic transmission of the same word. It is to be noted that 365 is an average figure, including the low as well as the high frequencies. For a real comparison with the telegraph we have to take the highest frequency that must be used to transmit clear speech, and not the average. If we take this average of 365 cycles for the five letters of the word "Paris," we get 75 cycles per letter, compared with $3\frac{1}{2}$ cycles for the telegraph, a ratio of 21 to 1 in favour of the telegraph.

In D (Fig. 1), I have given the word "Paris" in the seven-unit alphabet transmitted in the same time as the telephone word. This again illustrates the advantage of the telegraph in the fewness and slowness of its signals compared with the telephone. Obviously this handicap in signalling places the telephone at an extreme disadvantage compared with the telegraph so far as the line is concerned, and the longer the line

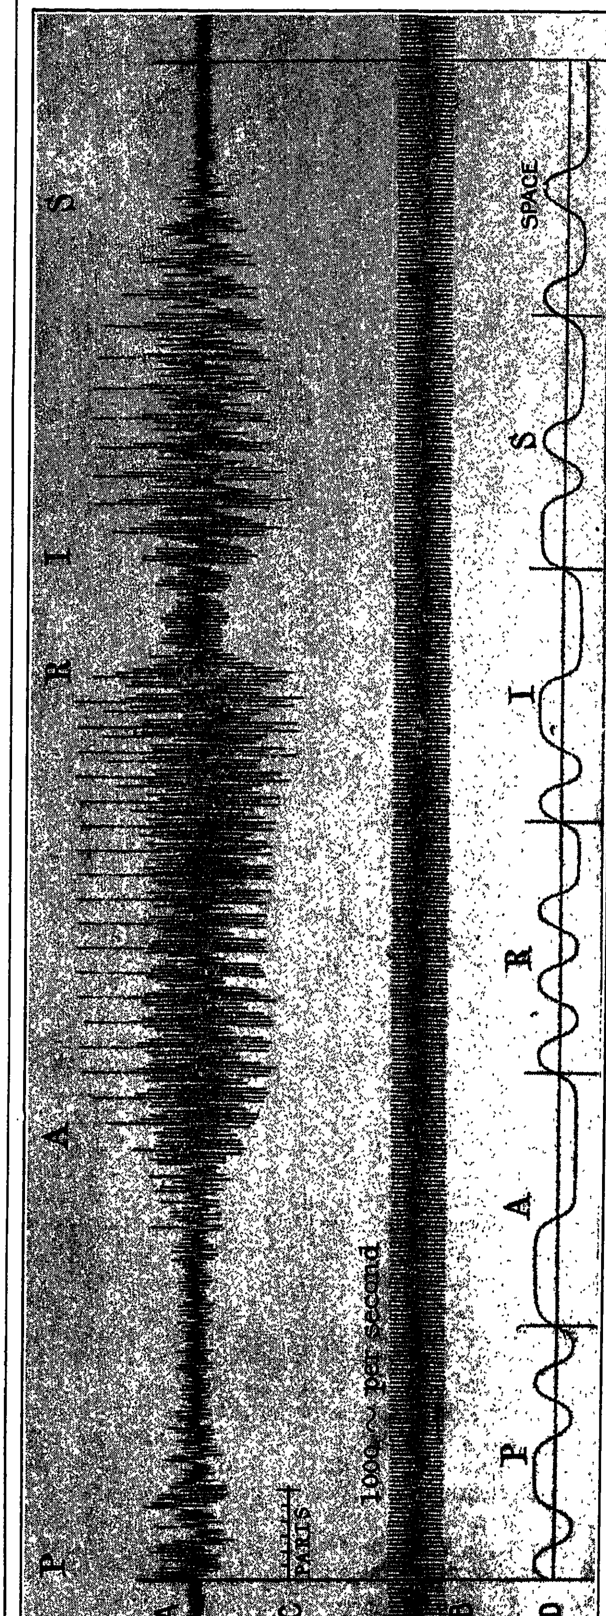

FIG. 1.—Comparative diagram of telephone word and telegraph word "Paris."

Line A.—Oscillograph record of word "Paris" spoken rapidly. Line B.—Time record (1 000 waves per second). Line C.—Telegraph record of word "Paris" in 7-unit start-stop alphabet on same time scale as line A. Line D.—Telegraph record of word "Paris" in 7-unit start-stop alphabet expanded to occupy same time as telephone word "Paris" in line A. This shows the remarkable difference in the number and amplitude of the oscillations in the two cases.

the greater the handicap. Wonderful devices are used by telephone engineers to overcome this drawback; but the same devices can be used in telegraphy, and nothing can remove the handicap.

Another way of comparing the telephone and telegraph, so far as line signals are concerned, is to use the following information, for which I am also indebted to Dollis Hill:—

"The question of the lowest and highest frequency necessary for good speech is very largely dependent upon the quality of speech required. The following figures show the order of values :—

(1) Complete unintelligibility occurs with the elimination of all frequencies above 500 cycles or below 2 000 cycles per second.

(2) Experts can carry on a conversation with all frequencies either above or below 1 000 cycles eliminated, but the quality is poor.

(3) The most important range is from about 600 to 1 200 cycles.

(4) For good quality commercial speech it would probably be advisable to cater for all frequencies between 200 cycles and 2 000 or 2 500 cycles per second, while for perfect reproduction and for music 100 to 5 000 cycles at least are necessary. For the generality of cases 800 is an accepted frequency which can be used to represent speech frequency."

As the weakest link in the chain is the determining factor, we have to take the lowest limit of the highest frequency required for clear speech; that is 2 000 to 2 500 cycles, or, say, 2 400 cycles per second. Multiplying this by 60 gives us 144 000 waves per minute. Dividing this by the $3\frac{1}{2}$ waves per letter used by start-stop printers, we get 41 140 letters, or 6 850 words per minute if we used the same frequency for telegraph work.

The telephone will not give more than 180 words a minute; and actually the average rate is probably not in excess of 120 words a minute. A skilful public speaker does not exceed about 120 words a minute if he is wise, and the rate of the average speaker is about 150 words a minute. It is possible to read silently at the rate of about 300 words a minute. Normal conversation is extremely rapid, and runs up to about 200 words a minute; but such a high speed is impossible on the telephone, because a little more effort is required to speak into the telephone and there is also more effort to hear what is said. Taking the telephone speed, however, at the very favourable figure of 150 words per minute, we find, on dividing 6 850 words per minute by 150, that the telegraph is 45 times more efficient than the telephone so far as the utilization of the line signals is concerned. Even if we come down to what Dollis Hill calls poor-quality speech, namely the 1 000-cycle limit, the telegraph is still 19 times more efficient than the telephone so far as the line is concerned.

This calculation can be put in another form as follows: Taking the standard word as composed of six letters (including the space), 150 words a minute is 15 letters per second. Taking our upper limit of frequency for clear speech over the telephone, namely, 2 400 cycles per second, and dividing by 15, we get 160 cycles per letter for the telephonic transmission of intelligence. In telegraphy the rate per letter, using the five-unit alphabet, is $2\frac{1}{2}$ cycles, or $3\frac{1}{2}$ for start-stop printers. Dividing 160 by $2\frac{1}{2}$ we get a ratio of efficiency of 64 to 1, or with $3\frac{1}{2}$ cycles, 45 to 1, as before.

This takes into account only the handicap of frequency. The telephone, however, also depends largely on varying amplitude of vibration. There are hundreds of different amplitudes with the telephone and only one amplitude with the telegraph. Hence, if we take amplitude as well as frequency into consideration, we shall probably be within the mark in saying that there is a handicap of 100 to 1 on the telephone compared with the telegraph, so far as the line is concerned.

I have gone at length into this comparison, because the whole future of the new telegraphy depends upon it. The figures quoted make it clear why the telegraph can be so much cheaper than the telephone when distance becomes an important factor.

For the information of many non-technical people who, I hope, will read this paper, I may mention that there is a practical limit to the rate of electrical vibration and also to the variation of amplitude that can be transmitted over any given size and length of wire, and the longer the wire the lower the limit. It is this fact that imposes a handicap of 40 or 50 to 1, and even 100 to 1 on the telephone compared with the telegraph.

With the telephone the risk of error is great, because the electric currents representing the voice not only have a very high periodicity but also are extremely feeble. They are likewise very delicate, because varying amplitude is an important factor. To shut out disturbances which would ruin these extremely delicate telephone vibrations, it is necessary to use a loop made up of two costly telephone wires for one message. Also it is only possible to speak on the telephone simplex; that is to say, a man cannot talk and listen to the telephone at the same time. The telegraph can do so. It can work duplex, and the "single-operator duplex" is going to be important by and by. Consequently, the limit of speed on the two costly telephone wires is 150 words a minute, that is to say, 75 words a minute on one wire.

It is true that by various ingenious devices several telephone circuits can be so linked up as to give additional telephone circuits, and there is also the "carrier current" system. But we can apply to telegraphy all these expedients of telephony, including Pupin coils and valves and tone frequencies, the result being many times greater carrying capacity with telegraphy than is now obtained. The position, therefore, is that for working at 150 words a minute by telephone we need two costly telephone wires, that is to say, a telephone loop, or 75 words a minute on one good wire. The telegraph, on the other hand, only requires one wire at about half the cost of the telephone wire, and will give 240 words a minute each way simultaneously, or 480 words a minute in all, on the one cheap wire. This is from 12 to 16 times more than the telephone can do, and the consequence is either a correspondingly greater carrying capacity for the wire, or a correspondingly greater distance covered. It means that for any considerable distance, and particularly for long distances, the telegraph is far cheaper than the telephone. It is for this reason chiefly that the stunted growth of

the telegraph is economically unsound. There is also the great advantage with the telegraph process of being able to store up telegrams in order to send them at opportune times.

There are other serious handicaps to the telephone. For instance, it is impossible to talk in the absence of one of the parties to the conversation, and it is often a waste of time to have to receive a telephone message personally. In this respect telegraph printers offer the notable advantage of recording messages in the absence of the addressee, thus avoiding interruption of work and delay, the messages being stored automatically until an opportune moment arrives. Writing or typing a message saves much time. A business man in the morning finds a pile of letters opened by his secretary ready for him to read and reply to by the aid of his stenographer. In an hour he can dispose of matters by letter that would take him all day, even if possible at all, by telephone.

A letter is a great time-saver. We can dictate a letter when we please and when we have time, and the dictation can be interrupted by more urgent work and no harm is done. We have time to think when dictating a letter. Also the recipient is saved a great deal of time. He can glance through a dozen letters in the time that he would receive one corresponding message by telephone, and he can deal with letters at any time and in any way he pleases. He also has time to think about them and hunt up information. Under suitable conditions many of such letters could be sent by telegraph with great saving of time and without diminishing the foregoing advantages. It would not be practicable to send such letters by telephone. It would be too costly, except over short distances for which the post is better, there would be no typed record, and the possibilities of mistake by telephone are too great for commercial security.

The telephone, in its own way, is also a great time-saver, especially in getting an answer back forthwith; but let me repeat: We must type as well as talk; we must teletype as well as teletalk, and the reasonably perfect telegraph service, as good as the telephone, such as we expect to see in 15 or 20 years, will certainly do a lot of work well, now done by the telephone badly.

(4) *Other competitors of the telegraph.*—In the first paragraph quoted at the beginning of this paper reference was made to the competition that the telegraphs have to suffer from wireless and the air mail. This is a mistake. It is true that wireless offers great possibilities for rapid communication. Wireless, however, considered from the point of view of this paper, has only indirect connection with telephone and telegraph work. It is really a remarkable substitute for telegraph and telephone wires and submarine cables, and it multiplies the facilities for the use of the telegraph and telephone. A telegram is a telegram whether it is sent by wire or wireless, and wireless need not, therefore, be further considered in this paper.

So far as the air-mail service is concerned, it cannot compete with the telegraph except for handling documents. In this particular respect, aeroplanes may help to empty the ordinary mail-bags, but the risk of loss of valuable documents is too great in the case of aeroplanes; and for urgent communications such as are suitable for telegraphy the aeroplane has no chance in competition with the telegraph. Take London and Paris; under the most favourable conditions it takes about 4 hours for a letter posted in London to reach Paris by air mail.

The actual time of transit at the present day is as follows:—

Charing Cross to Croydon Aerodrome, about 40 minutes; Croydon Aerodrome to Paris Aerodrome, about 2½ hours; Paris Aerodrome to Paris, about 30 minutes; Total time of transit, about 3 hours 40 minutes.

This takes no account of the time required to make up the mail in London and to deliver the letter in Paris. Taking the total time at 4 hours, only 20 minutes would be allowed for posting and delivery. The speed of commercial aeroplanes is only about 80 to 90 miles an hour, and even this speed is greatly affected by the wind. If we reckon 100 miles an hour for the aeroplane, it would take more than an hour to post, transport and deliver a letter between London and Birmingham. With the new telegraphy between London and Birmingham, a message would go through from typist to reader in about 2 minutes, and a reply would go back within another 2 minutes if the subject-matter permitted an immediate answer. A properly developed system of telegraphy would deliver a long telegram from a correspondent in London to a correspondent in Paris within 10 minutes. The new telegraphy has nothing to fear from the air mail.

So far as the postal service is concerned, the fundamental advantage is the extremely cheap rate of postage, 1½d. per letter, and the letter may contain several thousand words if closely typed on thin paper. One reason for this cheapness is that the paper and envelope of an ordinary letter are not supplied by the Post Office, and the labour of writing or typing the letter is not done by the Post Office. There is distinct material- and labour-saving in this, or, more strictly, a transfer of labour and cost of material from the Post Office to the individual or firm, just as automatic telephones transfer the labour of making a connection from the telephone girl to the subscriber. It will be seen that the new development of the telegraphs foreshadowed in this paper will effect the same transfer of labour from the telegraph administration to the individual or firm. Another advantage of the postal service is that cheques and other documents that cannot be telegraphed or telephoned can be sent easily and cheaply by post. The great handicap of the mail, and one main reason for its cheapness, is its extreme slowness, at the outside 60 miles an hour on land, and by sea not more than about 25 miles an hour, and even by aeroplane not more than 120 miles an hour. For short distances within city limits this drawback is trifling and, on account of the extreme cheapness of the service, all communications that can stand a few hours' delay will always go by post within city limits. The greater the distance, however, the greater the advantage of the telegraph for messages requiring speedy delivery.

There is appropriate work for each of the three services of communication, the post, the telegraph and the telephone. There are certain things that each

can do better than the other two, and during the next quarter of a century the telegraph will recover ground which, through transient causes, has been lost to the telephone and postal service.

(5) *The defects of the telegraph service.*—The defects of the telegraph service are not appreciable to the average man, and it is not until we begin to consider how the telegraph service might be improved and how inferior it is compared with the telephone, that we realize that it is slow, costly and inaccessible. For moderate distances the telephone is as cheap as the letter post, and we can get through to anyone we want in a minute or two. The telephone is quick, cheap and very accessible. At my desk I am in close, quick and cheap touch with London, thanks to the telephone, and I ought to be in similar touch with the world by telegraph, but I am not. The telegraph does not possess the close linkage enjoyed by the telephone with the business world. It is true that I can telephone a telegram to the Central Telegraph Office, and so speed up the telegram to some extent; but at the Central Telegraph Office my telegram or cablegram has to do a lot of "circulating" before it reaches the point of departure over the telegraph line or the ocean cable, and at the other end it has to do more "circulating" before reaching its destination. The telephone-telegram, or, as the British Post Office calls it, the "phonogram" service is a valuable facility for an occasional telegram or cablegram; but it is a nuisance if one has to send many telegrams, and it is far from accurate, unless the message is repeated and the words spelled out analogically, "T" for Tommy, "H" for Harry, and "E" for Edward. That makes it irritatingly slow when sending many telegrams. The telegraph, with proper machinery, could beat the phonogram with ease when numbers of messages are concerned. Obviously, compared with the telephone, the telegraph is at present very inaccessible, and it is nothing like so quick. It is cheaper for long distances, but dearer for short.

The defects of the telegraph are clearly not due to lack of circuit facilities. There are enough telegraph circuits to carry more than double the present available traffic. There are, indeed, excessive circuit facilities, as will be explained presently. It will be found upon investigation that the shortcomings of the telegraph service are due almost entirely to defective terminal facilities. The patient's condition may be diagnosed as "excessive circuit facilities and defective terminal facilities." Fortunately the prognosis is favourable. The terminal facilities are going to be greatly improved in the course of the next 25 years, and the resulting increase of telegraph traffic will absorb the excess of circuit facilities.

Looking at the telegraph situation to-day, we see good organization and capable management; but we also see excessive development of circuit facilities, due to competition and to international jealousies and to unforeseen technical improvements. Side by side with the complaints about the unsatisfactory condition of the telegraph service, there are many reports in the Press about more telegraph cables to be laid. New and wonderful "permalloy" cables are being made to give 300 words a minute instead of 30 across the Atlantic; the nations are insisting upon having their own cable and wireless services; and investors are beginning to wonder where the traffic is to come from to pay interest on the heavy capital expenditure. Another important element in the creation of excessive circuit facilities is the widespread provision of telephone trunk lines, each composed of two wires; and the ease and cheapness with which telegraph circuits can be created by superposition on these telephone trunk lines adds to the present superfluity of telegraph circuits. Telegraph-circuit facilities are also increasing to an extraordinary extent in consequence of technical developments in radio-telegraphy, which have shed new light on the solution of old telegraph problems, and have shown how to split up one wire into 10 or more channels. There are phantom circuits, superposed circuits, carrier-current circuits or wired-wireless telegraphy giving wonderfully increased carrying capacity; and quite distinct from this are tone-selective methods or harmonic telegraphs, which appear at last to be getting on to a practical basis. Then, in addition, we have wireless telegraphy constantly improving its methods and range and practical carrying capacity. Some time ago that wise old institution, the British Post Office, seeing how matters were developing, altered the wording of its contracts for leasing wires by inserting the words "channel of communication" instead of "wire," so as to reap the benefit of the rental of, say, 10 or more channels into which one wire may now be split up. It is probably not an exaggeration to say that the present telegraph plant of the world, wire and wireless, can handle twice the present volume of traffic; and technical developments, now past the experimental stage, can multiply the present telegram-carrying capacity by 10. In other words, the telegraph circuit facilities of the world are, on the average, at least twice as great as the available traffic, and these facilities, by the expenditure of 15 to 20 millions sterling, can be increased sufficiently to handle from 15 to 20 times the present traffic.

But these wonderful facilities suffer from a grave defect. They do not link up closely with the business man. The telephone does, and the telegraph does not. The telegraph has to get the assistance of the telephone to complete the linkage. That is quite satisfactory for the occasional telegram and for the private and domestic message; but big users of the telegraph require something better. They need a telegraph linkage that will put them directly in touch with their correspondents, just as the telephone does. The really important part of the telegraph traffic is that devoted to business, and this paper is concerned chiefly with business telegraphy.

There is another important point to be borne in mind when considering future telegraph developments, and that is the underground cable. The world cannot afford to have communication between its great cities interrupted by the weather. Within comparatively few years all big cities will be connected by underground cables both for telegraphs and telephones, and this will alter the aspect of circuit facilities. Underground cables give conditions which are so stable and so free

from disturbance when loop circuits are used, that circuit facilities depending on the use of feeble high-frequency vibrations will become much more usable than they are at present. Aerial lines have to be employed as loop circuits like telephone lines to get satisfactory results by these new high-frequency methods, and it is a very interesting question whether such high-frequency aerial-loop circuits can show any commercial advantage over the ordinary multiplex. On underground cables, however, the conditions are very favourable, and attention is being directed to the question of using carrier-current methods, or, more strictly speaking, voice-frequency or tone-selective telegraphy for underground wires. American engineers—including particularly those of the Western Electric Co. and the American Telegraph and Telephone Co.—who have achieved such remarkable results with the carrier-current principle, have also employed these voice-frequency methods; and Siemens and Halske in Germany have worked along similar lines. The latter have issued an interesting pamphlet describing their system of "Tonfrequenzwechselstromtelegraphie." Using only telephone frequencies, fair distances can be spanned without repeaters by such systems, and, by employing the multiplex on each tone-selective circuit, two wires could provide 40 traffic channels. In the case of the Siemens and Halske system, the pressure used on the line is only 1 volt (underground circuits being free from weather and other disturbances), and therefore no trouble is caused in neighbouring telephone loops in the same cable.

Of course the plain multiplex, working duplex, can give 12 channels on a single wire without difficulty, and there is nothing inherently impossible in working the ordinary multiplex up to 12 channels each way simultaneously on one stable circuit such as an underground cable can give, should the improvement of terminal facilities create a demand for increased circuit facilities. Indeed there are grounds for contending that for the wire-splitting required by the new telegraphy, the unaided multiplex is superior to any other method on lines of considerable length.

(6) *They arise from lack of terminal facilities.*—Although telegraph circuit facilities greatly exceed present requirements, there is one respect in which the telegraphs are very deficient, and that is in terminal facilities, or, in other words, in machinery, which in most countries is still old, inefficient, clumsy and stupid. No doubt this will provoke a smile, and people will say that I, as a telegraph machinery merchant, am using the shoemaker's argument that there is nothing like leather. It is true, nevertheless. The terminal facilities are bad and incomplete, and it is because of the defective terminal facilities that the telegraph lags so far behind the telephone. Also, a large portion of telegraph traffic is still handled by the morse key. That is the same thing as using a pen. We have to use a pen to sign letters, and the morse key will always be with us; but letters are typed nowadays, and the typewriter keyboard should be as supreme in telegraphy as it is in business. That condition is coming rapidly. It is in full flood in the United States, and it is to significant developments in the United States that I want to call special attention this evening. The era is beginning when typewriter keyboards in the offices of business men will not merely type letters, but will type and transmit telegrams direct to correspondents in any part of the world. At last the missing link will have been supplied, and the telegraph service will secure the direct connection with business that has been so long the monopoly of the telephone.

In certain cases this is not a new development. For the past 10 years at least, the distribution of news, for instance, has been linked up directly from the news centres to the newspapers, and the news distributing network in English-speaking countries is cheap and quick and highly efficient. Also stock and exchange brokers in big centres like London and New York have not much to complain about, though the telegraph service will be improved, even in their case, by the increasing use of the typewriter keyboard. It is in connection with the banks, the big financial houses, large hotels, big stores, the railways, great industries and manufacturing plants, and, above all, the great farming industry, that a quicker, cheaper and more accessible telegraph service is badly wanted.

It is true that the telegraph has already been brought into offices and factories, but only to a relatively small extent. There are many firms using rented telegraph wires with morse key and sounder and morse operators, especially in the United States. In this country, stockbrokers and other firms use the telegraph to some extent; but they are hampered by the necessity of employing a skilled morse operator at each end of the line, and they cannot ring up anybody by telegraph, as they can by telephone. In other words their telegraph service is poor. It is cribbed, cabined and confined to one correspondent. Even now, stockbrokers, for instance in Glasgow, are each glad to pay nearly £4 000 a year for a private telephone line to London, though the telephone is notoriously bad for transmitting figures. A telegraph wire with the morse key would be cheaper, but it would be too slow. Competition is keen and a delay of 2 or 3 seconds in getting prices from London will result in business going to a competitor. There is also the considerable cost in wages of a morse operator at each end of the line.

Part 2.

The Twin Remedies.

(1) *Start-stop printers.*—The defective terminal facilities are due to a variety of causes; amongst others, to lack of faith and foresight on the part of telegraph administrations, and to a determination to buy cheaply by encouraging competition to such an extent that telegraph manufacturing does not pay. There is a natural tendency on the part of big consumers to encourage competition amongst manufacturers who supply them. The officials in the Reichspostamt in Berlin, long before the war, told me they liked to encourage competition, as they did not want the Reichspostamt to be at the mercy of one firm. This is the old Roman policy of "Divide and Conquer," and certainly printing telegraph inventors and manufacturers are a conquered race of helots who have made no particular profit up to the present out of printing telegraphy, or at least no

profit in proportion to their efforts and to the service they have rendered. This has resulted in telegraph development work being starved and stunted. Also the inventive and development work has been very intricate and deceptive. Arrangements generally recognized as excellent have proved to be hopeless in practice; and other solutions, that looked unpromising, have proved to be good. Lack of capital, lack of experience, lack of knowledge of the best ways, have all put the brake on progress until comparatively recently. Printing telegraphy has been a tropical jungle, with the axe in use all the time, and no compass and no map. It is only within the last 10 years that the multiplex in its modern form, with typewriter keyboards and speeds to correspond, has won acceptance as the best machinery for trunk-line telegraphy; and it is only within the last 2 or 3 years that the second great step, probably the greatest step of all, has been taken in the successful development of start-stop printers. It is only just dawning on the telegraph world what an immensely important thing the start-stop printer really is, and that it is the long-sought missing-link which will complete the telegraph network and give the world a really efficient telegraph service corresponding to the highly satisfactory telephone service to which we have been accustomed for years. It is true that in some countries the telephone service is not efficient; but that is not the fault of the inventors and manufacturers. The equipment is available. In the case of the telegraphs the equipment has not been available until now.

Before dealing more in detail with the start-stop printer special attention must be devoted to the question of using start-stop printers like the teletype, through telephone exchanges or through special teletype exchanges. Telephone experts inform me that there are grave engineering objections to the employment of telegraph machines through a telephone exchange; but these difficulties are not insuperable. During a recent visit to Paris, I was informed that a telephone engineer in the French Administration had devised a very simple instrument which would enable the teletype to be worked through any telephone exchange. I was also informed that a second device for the same purpose had been invented in Paris. I have no details, but I suppose it is done by that modern lamp of Aladdin, the valve, which enables very feeble currents to be used. In France considerable importance appears to be attached by technical men to this possible development of using the teletype in conjunction with the telephone for working through telephone exchanges; but it would appear to be better in all respects to have separate teletype exchanges. (I may explain here that in this paper I am using the word "teletype" more or less as a generic term. What is said, of course, applies equally well to any other printer designed for the conditions of the service.)

Apart from the engineering difficulties, one argument that has been advanced against the use of the teletype or other start-stop printers on telephone lines, is that such an arrangement would load up the telephone wires in a very undesirable manner. Subscribers to the telephone service buy the right to communicate with other subscribers, and if the other subscribers block up their wires with teletype as well as telephone communication, the result will be either that there will have to be special teletype as well as telephone wires, or the engaged signal will be heard much oftener than now and subscribers will not get what they pay for, namely, quick telephone service.

There are two answers to this argument. In the first place, if a subscriber loads his telephone line to such an extent that other subscribers have difficulty in getting through to him, the proper remedy is for him to get another telephone line, and in fairness to other subscribers the telephone authorities quite rightly insist on his doing so. The other answer is that the use of the teletype will not in this generation exceed, say, 5 or 10 per cent of the telephone calls, and the effect of this on the telephone traffic load would be trifling—and it would be much less if the subscribers making much use of the teletype had separate wires.

(2) *The teletype exchange.*—Evidently, however, the separate teletype exchange is the best arrangement; but this does not mean that there will be separate teletype exchange buildings. The telegraph traffic would not warrant such expense, except in a few special cases. By a separate teletype exchange I mean a small separate section in a telephone exchange devoted exclusively to start-stop telegraph circuits. It will be seen that such provision for teletype work will be sufficient if we realize that a total of 50 000 teletype exchange subscribers in London would probably not be reached for many years, though much will depend on the price of the teletypes. If they ever come down to the price of typewriters (and this is a possibility within the next 25 years) the number of teletypes in use would grow immensely, and no business man could afford to be without a telephone, a teletype, a typewriter, and a typist. The problem of the next year or two, however, will be to provide for perhaps 1 000 or 2 000 teletype subscribers. To this number would be added the local post offices and telegraph substations, telegraph offices in big hotels and stores, and also a big central teletype exchange at the Central Telegraph Office in London, for handling all the telegraph traffic reaching that office. Clearly 1 000 or 2 000 teletype subscribers divided over 100 telephone exchanges in London would not cause much inconvenience by the requirement of a special teletype section, and even 50 000 teletype subscribers would only average 500 for each exchange. On the other hand, probably most of the teletype subscribers would be concentrated in the City, and it would be cheaper and quicker to take them direct to the central teletype exchange at the Central Telegraph Office.

The teletype exchange equipment would be substantially the same as for telephones, and, as the maintenance and supervision would be the same and by the same staffs, the cost of a teletype section in a telephone exchange would therefore not be great.

Although there are engineering difficulties in working telegraph apparatus through telephone exchanges, it ought to be practicable for a subscriber having one telephone line and a teletype to ring up the telephone exchange and say "teletypes." He would then be plugged through to the teletype section, and it would

appear to be a simple matter for the teletype section to cut off his telephone loop completely from the telephone exchange and connect it to the teletype section. Wiring alterations would have to be made, but the alteration for each subscriber ought not to be great or costly. The subscriber having got through to the teletype section, a switch in his office would enable him to cut out the telephone and cut in the teletype. He would then teletype to the teletype exchange stating his requirements, and he would be put through in the same way by the aid of the telephone in the case of a local call, or direct to the central teletype exchange for a trunk or long-distance call, and he would then have his message typed direct at its destination. The *sine qua non* for improvement of the telegraph service is close co-operation between the telegraphs and the telephones, and the foregoing teletype call is an illustration.

(3) *Resulting in the new telegraphy.*—The teletype exchange plan, if it succeeds, will in time effect a complete revolution in telegraph methods and organization in head telegraph offices, especially in large cities, which will be provided with automatic telephone exchange equipment for the teletype exchange. The telegraph operator belongs to a doomed profession and he will disappear, for the same reason that the telephone girl is being driven out by the automatic telephone switches. On the other hand, there will be an increase in the number of engineers, and gangs of mechanics will wander about in the otherwise silent and deserted galleries at St. Martin's-le-Grand, and the screwdriver and the soldering iron will take the place of the morse key and sounder. The general public will continue to write out their occasional telegrams and hand them in at the nearest telegraph office. There, calls will be put through to Glasgow or Manchester or elsewhere, and the telegrams will be teletyped direct to their destinations. Every hotel and public place will have a teletype for delivery and reception of telegrams. There will be teletype call-offices or pay-stations at hotels, big stores, underground stations, post offices and other convenient centres, where it will be possible to use the teletype on similar terms to the telephone in similar circumstances, namely, payment of a sum according to time and distance.

The teletype can be left ready for receiving messages all night. Unlike the telephone, the teletype records messages without human assistance, and when the business man comes to his office in the morning he will find telegrams and cablegrams that have arrived during the night or early morning. For example, if we are in a country village in Kent and late at night we receive by telephone an important telegram from McDonald and Co. in Glasgow, we shall telephone our reply as a phonogram to the nearest telegraph office. There a teletype call will be put through to McDonald and Co. in Glasgow and the message will be printed direct on a teletype in their silent and deserted office ready for action when the office opens in the morning. There will be only one transmission and only one typing of our message, and there will be no "circulating" and no telegraph operator and no message-boy in Glasgow. The message will go direct and be recorded without human labour. Kleinschmidt makes a feature of this point in his advertisements of his start-stop printer. It records messages all night in empty offices at railway stations ready for the staff in the morning.

As another example of the new telegraphy, let us consider a large manufacturing plant, say in Newcastle, equipped with start-stop printers, such as teletypes. There would be a private-branch teletype exchange, as well as the usual private-branch telephone exchange. Orders and other departmental communications that have to be typed would go through the private teletype exchange, and any department could at once send a telegram through the private teletype exchange on to the Post Office telegraph wires, let us say, to a firm in Glasgow, the Post Office plugging the department direct through to the Glasgow firm, and the department would get a reply probably at once, or at any rate with only a few minutes' delay. That would be far more convenient and cheaper and quicker and more accurate than the telephone. Similarly, any department of the big manufacturing plant could receive outside telegrams direct, with substantial saving of time. In future days when there will be a dozen of the new permalloy Atlantic cables in use, each working at 300 words a minute in each direction simultaneously, and all fitted with sextuple duplex multiplex, there will be no difficulty in sending a message from any department of the manufacturing plant in Newcastle to San Francisco or other American city, and getting a reply within 10 minutes, subject always to the conditions of daylight between Europe and America. The circuit facilities will be still greater when half a dozen wireless beams work across the Atlantic, each at 300 words a minute.

Another important feature of the new telegraphy will be the assistance it will give to small newspapers which cannot afford to have a private wire of their own. Small country, local suburban and weekly journals would be glad if they could get news on 3-minute teletype calls. It would be cheaper than the telephone, more reliable and much more convenient, as the teletype would print the messages ready for use. In most cases these teletype circuits would be superposed on telephone lines. The teletype exchange is undoubtedly going to have a large effect on the distribution of news.

(4) *Printing telegraphs for farmers.*—Still another example of the new telegraphy must be given because of its great importance, and because it will open up an entirely new field for telegraphy. It may sound ridiculous to people in Great Britain, where the farming industry is so backward and unprofitable, but it is a fact that it is to the farming industry—the greatest and oldest of all industries in all countries—that the start-stop printer will render the most important service. In other lands, and especially in new countries, there is a very large and prosperous farming and plantation, and station- and ranch-owning class, especially in North America; and market prices are just as vital to such farmers as to any stockbroker; and another thing vital to the man who ploughs the land, as well as to the man who ploughs the sea, is the weather. The sailor must rely for his weather reports on his barometer and wireless, but not so the farmer, who can also have his teletype.

In Australia the inch of rain is divided into 100 points, and weather reports are distributed and put up by the

Government on the bulletin board at every country post office or railway station; and the keen interest that the settlers and station-owners take in these weather reports is astonishing. The fact that 3 points of rain have fallen at a township 30 miles away is a matter of intense interest. Rainfall or no rainfall spells wealth or ruin to the farmer and station-owner. In other lands warnings about storms and blizzards are not less important. Prices of sheep and cattle, pigs, wool, hides, wheat, butter, coffee, tea, rubber, and other farm, station, plantation and ranch produce, not only at the nearest local market, but in the big markets of the country, and also the world prices, bring wealth or poverty to the man on the land. Next to the stock market and produce brokers, there is no other man in the world so interested in prices as the farmer, and the farmer's concern about the weather is proverbial. The latest market and weather reports are so valuable to him that he will pay gladly for them, just as the stock-broker pays willingly for his ticker service. Hitherto the farmer has never had an opportunity to pay for it. He will also appreciate getting a prompt service giving all the important news of the world.

The start-stop printer, for the first time, fills the requirements of the farmer for a stock-ticker service and it is far and away superior to any stock-ticker. The speed is greater, 40 to 80 words a minute; it will work over any distance, 5 000 miles if necessary; it can be superposed on the farmer's telephone circuit; it can be used on a farmer's party line jointly with other farmers; and it has a keyboard on which the farmer can send out messages as well as receive them. After reading the market prices he can give immediate orders on the teletype to buy or sell. By means of the teletype keyboard, he can communicate with his neighbours along the top wire of his fences. (In Australia, on the great sheep stations, the head station is always in communication with the outstations by telephone along the fencing wire.) Of course, start-stop printers are not suitable for the remote districts; they need an occasional inspection and a drop of oil, and also electric power to drive them. That is a fairly simple matter in the settled districts of the world, where also the distances are not so great as to render the cost of the telegraph or telephone line prohibitive; but even in newly opened-up country with a sparse population there is always the local post and telegraph office (often the general store and centre of gossip for the whole countryside), and a teletype at such a centre would pour out invaluable news of the world, including prices and weather reports, printed on tape ready for the bulletin board, giving a flood of news that could not be received in any other way. In such a case the electric power problem would be difficult, but not insoluble.

Taking more particularly the United States, because of the enormous number of very prosperous farmers in that country it is obvious that farm news-distributing organizations will spring up all over the country for the supply of market and weather reports and other news of interest to farmers, and the farmers will have the opportunity of talking back on the keyboard of the teletype. It may be said that it will be cheaper for the farmers to listen to market and weather reports broadcast by wireless; but a little consideration will show how hopeless that is. To get wireless reports the farmer or some member of his household would have to be in attendance at fixed hours to write down the wireless news. The idea of a farmer or his wife or family trying to note down market prices rattled off quickly by wireless is absurd. Even if this were possible, there are the inaccuracy of wireless, interference troubles and atmospherics, and there is no way of answering back. The only practical plan is a tape-printing teletype recording any news accurately in plain type without human labour, and on duty at all hours. The farmer and his household can read the news and market reports at any time at leisure and he can also get a service of general news. The market reports can be far fuller, as well as far more accurate, than would be possible by any wireless distribution, and far quicker than through any newspaper. The teletype will bring the farmer right into the Chicago Wheat Pit and other market centres. He will know and compare the latest prices straight from the sales of his local market town and also from the big centres of the world.

The prosperous farmer in America and many other countries has his telephone and his motor-car as a matter of course, and it is certain that as soon as the opportunity presents itself and he gets accustomed to the idea, he will add the teletype to his telephone and his wireless set, and in time he will value his teletype above all his earthly treasures. When the farmers of the world adopt the teletype superposed on their telephone circuits, we shall have real telegraphy—a vast printing-telegraph network of wire nerves linking up all industries and all countries.

(5) *Starting the new telegraphy.*—That this idea of teletype exchanges on the lines of telephone exchanges is not a mere speculation is shown by very interesting developments in the United States. Realizing the importance of the machines, the Western Union Telegraph Co. has been giving careful attention to the development of start-stop printers for some years, and this class of machine appears at last to have reached a sufficiently reliable and permanent form to justify the Western Union in offering to furnish its patrons with printing-telegraph service. That will, of course, include circuits and printers connecting patrons to the head telegraph office of the Western Union in each city. The Western Union will also no doubt supply what is known as point-to-point service—that is to say, will connect any two points desired by telegraph lines and start-stop printers. In other words the Western Union is arranging to sell telegraph typewriter service to business men and firms—that is to say, to subscribers. Assuming that the scheme proves popular and commercially profitable, then the Western Union will have hundreds of subscribers in New York alone, to say nothing of other cities. Inevitably the company will have to supply intercommunication between these subscribers. The object of the subscribers or business men buying printing-telegraph service in New York will be to send and receive telegrams quickly, and they will want to do that between each other and also over long-distance telegraph wires with subscribers in other cities. It is clear that if the Western Union can secure a considerable number

of telegraph typewriter subscribers in the leading cities of the United States, then the printing-telegraph exchange and the new telegraphy will have been successfully inaugurated. The Western Union being a very big, old telegraph company with great resources and 50 years of accumulated experience of printing-telegraphy in all its forms, and operating in a great and highly industrialized community, is specially qualified for making a success of the new telegraphy, if that is commercially possible under present conditions.

Another element that makes for progress is competition, and the Bell Telephone Co. is starting to sell telegraph typewriter service to business men in Chicago on similar lines to the Western Union. Chicago, being a great business centre in the heart of the United States, is very favourably situated for the growth of the new telegraphy. I have a copy of a handsome booklet, artistically illustrated and persuasively written, which the Bell Telephone Co. is issuing in Chicago, with the idea of inducing business men to buy printing-telegraph service. It does not propose to establish a printing-telegraph exchange, but simply to supply wires and printing-telegraph apparatus to enable firms to link up their various branches and offices by a private printing-telegraph wire system. Although there is no mention in the pamphlet of a printing-telegraph exchange, a moment's reflection will show that, just as in the case of the Western Union, the existence of a number of private printing-telegraph networks each linking up the various branches of one firm's activities in Chicago would soon lead to a demand for intercommunication facilities, and that would result in a printing-telegraph exchange. If the Bell Telephone Co. finds that selling printing-telegraph service to business men and firms in Chicago is profitable, then it will lead inevitably to the teletype exchange and so on step by step to the new telegraphy. The pamphlet is called: "The Doorway of Opportunity"—"Telephone Typewriter Service"—"It Typewrites by Wire."

(6) *"The Doorway of Opportunity."*—The booklet describes some of the attractive features of the telephone typewriter service, and as the subject is of such great importance I quote some of the paragraphs as follows:—

"Modern business of to-day is very largely conducted by means of the telephone and the typewriter. It has long been felt that if these two giants of industry could be combined and efficiently operated as one unit, we would have made long strides in furnishing the business world with the last words in telephony. After years of study and research work, we feel that we are now able to furnish to our patrons a machine that will efficiently combine these two. This machine is known as the Telephone-Typewriter.

. . . . .

"This is not a new and untried service. For a number of years it has been in daily use by modern business organizations for the rapid and constant transmission of typewritten communications between the executive office—branch offices—warehouses—mills—factories located in distant cities, by the Long Lines Department of the American Telephone and Telegraph Co. in transmitting official communications to all of their offices located in principal cities, and by the Associated Press in accurately and expeditiously distributing current news simultaneously to its newspaper clients.

"Messages can be typewritten in your office and come out at one or more of your local or distant offices with a home record. No operator or attendant is necessary at the receiving end.

"It will do practically anything a typewriter can do and can be operated by anyone who can operate a typewriter.

"This service is now being used by a number of modern business organizations, Press Associations and newspapers with very satisfactory results in the handling of messages, letters, routine matters, such as operations, administration, sales, purchasing, statements of stocks on hand, shipments, orders, quotations, accounting and for the dissemination of news.

"This service may also be used for conference purposes between groups at different offices, locally or in distant cities, thus effecting the saving of a great amount of time and expense incurred by travelling.

"Your branch office is no farther away from you than the telephone typewriter."

. . . . .

"Telephone Typewriter Service will be found dependable and economical as an adjunct to the telephone for the transmission of communications in factories, banks, hotels, and mail-order houses; between the sales, order, credit, accounting, and shipping departments and the executive offices of an establishment; accurately and privately without loss of time or error in giving or taking instructions.

"We have established a Telephone Typewriter Service department and will, without charge, make a study of your communication requirements to ascertain if the Telephone Typewriter Service will be advantageous to you in the conduct of your business."

A skeleton map is given showing combination circuits for the telephone typewriter service within the city of Chicago and nearby territory. Five circuits are shown, each connecting in series from seven to nine city and suburban centres. One line, for instance, connects the General Office in Chicago with branch offices, Factory, Maywood, Melrose-park, Wheaton, West Chicago, Aurora and Elgin. The illustrations show the Morkrum typewheel teletype, which prints on a tape at 40 words a minute, and the Morkrum typebar page teletype which prints on sheets of paper at 60 words a minute. The pamphlet concludes with the statement: "Our telephone typewriter department will appreciate the opportunity of calling on you and explaining the service more in detail."

The publication of such a booklet by a great concern like the Bell Telephone Co., and the corresponding movement by the Western Union, show that this paper cannot be dismissed as idealistic dreaming.

Assuming that teletype exchanges are successfully established by the Western Union and the Bell Telephone Co. in the leading cities of the United States, then it will be a comparatively short step to link up these teletype

exchanges by trunk telegraph wires all over America. Of course, in the case of the Bell Telephone Co., telegraph circuits superposed on its telephone lines will be used, and various systems of multiplexing the trunk wires will also be put into operation more extensively than now.

(7) *Some results.*—The result of this development will be that a business man in New York, wishing to communicate with a business man in San Francisco, will get through to his teletype exchange and be connected to his San Francisco correspondent, with a certain amount of delay similar to, but less than, that which takes place in putting through a telephone trunk call. Once connected, a typist in his office will teletype the business communication, and in many cases an immediate answer will come back on the teletype. In this way business will be linked up directly to the telegraph network, just as it is now linked up to the telephone service, and the present telegraph delays will be eliminated. There will be much greater accuracy than with the telephone and there will also be the advantage of much cheaper rates of communication than are possible with the telephone service; multiplexed telegraph wires being far cheaper than telephone wires. In fact, in the case of an immense concern like the Bell Telephone Co. the use of its telegraph circuits in this way will really be the utilization of a by-product of its telephone business. The same remarks apply in the case of the British Post Office and other administrations supplying telegraph and telephone service. The economies that will be effected by cutting out all telegraph labour, and by transmitting and printing direct, have already been explained.

One remarkable idea in connection with the proposed teletype exchange scheme hinted at in the Bell Telephone pamphlet is its use for conferences, because the teletypes at each point could be linked up so that all would record the messages transmitted at each station. Half a dozen business men, 10 or 20 or 1 000 miles apart, could get together by teletype for a conference at very short notice. The teletypes in each office would record the minutes of the conference, including the discussion and the full text of the resolutions passed or decisions arrived at, and each member of the conference would have a complete typed record of the proceedings in his office. Also, the conference would be secret. There would be no overhearing or eavesdropping. The teletype language is spoken and understood only by teletypes, and the code-bars can be mixed at will to scramble the messages and make them doubly secure against overhearing by outsiders. There is something deeply impressive about this idea of a conference taking place between men hundreds or even thousands of miles apart, with no sound but the slight tapping of the typebars, and the men in silence, each alone, watching the words being recorded, or transmitting on his keyboard. Not even a secretary need know about it. The saving of the precious time of business or political magnates would be great, and the acceleration of the business, which could not otherwise be transacted until the members of the conference had actually met after much delay and railway travelling, would be important. Vital decisions might be made in this way, possibly a week sooner than would otherwise be possible. Take, for instance, the British Government; an urgent meeting of the Cabinet could be held and decisions arrived at with the members of the Cabinet scattered all over the country. Members of Parliament could confer with their constituents, and even international conferences could be held in this way with every advantage of "secret diplomacy." The only parallel to such a teletype conference would be a wireless telephone conference between heads of Governments, to which all the world would listen in, and we should have "open covenants openly arrived at."

Returning again to realities, the new telegraphy with its cheap and quick long-distance communication will be an immense boon to the industrial and financial world, and many interesting practical results of political and social importance will flow from it. Two may be briefly referred to as illustrations. One will be the upsetting of the present balance of telegraph and telephone interests in the United States, the probable result being consolidation under the control of the Interstate Commerce Commission. The new telegraphy will lead inevitably to competing teletype exchanges in each city. This development will be as great a nuisance as competing telephone exchanges, and the public convenience will be best served by consolidation, the result being a telegraph and telephone organization in the United States by far the largest and most remarkable in the world. Another result will be increased impetus to the extension of the Garden City movement and decentralization. Obviously the great book-keeping industry can be carried on in low-rented premises in pleasant surroundings in the country just as well as in London city offices, dirty, smoky and dark, and costing exorbitant sums for rent. The teletype and the telephone bring the Garden City book-keeping factory alongside the London city office, which will contract into a showroom and calling-place for visitors. This process of decentralization in connection with factory work has been going on for years and the teletype and telephone will extend and accelerate the process.

As these great changes will be brought about by the start-stop telegraph printer, it will be realized that this is a machine of outstanding commercial and political importance.

(8) *How the teletype exchanges will work.*—Just as in the case of the telephone service, there will be private-branch teletype exchanges, and these will of course connect up to the main telegraph network of the country through the city teletype exchange. In Chicago, for instance, the Morrison Hotel is equipped with 32 of the little tape teletypes, forming an internal intercommunicating system in all respects like a private-branch telephone exchange, and other American hotels are being fitted in the same way. Naturally, these private-branch exchanges will be linked up with their respective city teletype exchanges and in this way put in telegraphic communication with the whole of America and, in the course of time, via the new 300-words-a-minute Atlantic cables, also with Europe.

It is possible that the number of teletype subscribers in one city may not, for many years, be more than one exchange could handle, and in that case the teletype

exchange would be situated in the chief telegraph office of each city. This, however, would depend on the size of the city and the length of the local lines to connect subscribers to the teletype exchange. It is a detail that will be settled by local circumstances. In London, for instance, there will probably be teletype sections in most of the telephone exchanges, with a big central teletype exchange at the Central Telegraph Office.

This telegraph service will be paid for just as the telephone service is paid for. There will be a local message rate, and time and distance rates for trunk or long-distance messages. Fortunately for this new development of the telegraphs, most of the problems have already been worked out in connection with the telephones, and telephone technique will be used in the teletype exchanges and wherever else it can be employed with advantage. The mechanism of telephone exchanges, with some modifications, will do equally well for teletype exchanges. A subscriber will be able to ring up any other subscriber, with all the usual "engaged" and other signals; but the teletype subscriber will have an advantage that he cannot have now on the telephone trunk service. Suppose he is a London merchant. He will be able to ask the Central Telegraph Office in London to put him through to Glasgow, and he will be put through exactly as now in the case of a trunk telephone call—with this important difference, that the delay in getting through will probably be small in the case of the telegraph service, perhaps not more than a minute or two, or even with no delay at all, because there will be far more "channels of communication" available to Glasgow and other cities than would be financially possible in the case of the telephone. A single telegraph wire will give at least six separate channels, compared with one channel of communication on two telephone wires. Take, for instance, some results obtained by the Western Electric Co. on four aerial wires between Chicago and Omaha, 450 miles. These four wires gave three telephone circuits, four earthed telegraph circuits and no less than 20 two-way carrier telegraph circuits, or more than six "channels of communication" on each wire.

In London alone about 18 minutes' delay would be cut out by getting direct in this way to Glasgow, and even if the message were sent by the customer by telephone as a "phonogram" it would still go to the phonogram room, where it would be written down and sent "circulating" until it reached the Glasgow circuit. On the average in a provincial telegraph office in Great Britain the "transit time," that is to say, the time elapsing from the handing over of a telegram by the public until it reaches the circuit over which it is to be transmitted, is about 5 minutes, and in London about 8 minutes. The average "circuit delay," that is to say, the time that a telegram has to wait its turn at the circuit before being transmitted, is about 10 minutes. This circuit delay corresponds to the delay in getting through on a trunk or long-distance telephone line. Hence, in provincial offices there is an average delay of 15 minutes from the time a message is handed in to a telegraph office until transmission begins over the telegraph line. In London this combined delay of transit time and circuit delay averages 18 minutes. There is also telegraph messenger time, which may run into anything from 5 minutes to half an hour or more, depending on the size of the staff of messengers available and the distance to be traversed. The aim of the new telegraphy is to cut out all these delays.

With teletype exchanges in operation, manual "circulation" of telegrams will give place to manual switching and, finally, to automatic switching. That is to say, the handling of telegrams will be greatly reduced, and instead of many telegrams being rewritten several times in the course of their wanderings, they will go straight through to their destinations, like the modern loaf of bread, without being touched by human hand. At present some telegrams have actually to be rewritten four or five times. A message handed in at a suburban office in London is rewritten at the Central Telegraph Office and then telegraphed, say, to Glasgow, where it is once more rewritten and sent to another suburban telegraph office, and once more rewritten before being delivered by a message-boy.

Obviously, cutting out the circulation of telegrams will eliminate great waste of time and labour, especially in big cities like London. Telegrams received at the Central Telegraph Office in London have to go through an elaborate journey before reaching the London end of the telegraph lines over which they are to be transmitted. They are taken in and dealt with by counter-clerks, blown through pneumatic tubes, shuffled at distribution tables, pigeon-holed, and then taken to their respective circuits for transmission. Delay also takes place at the receiving office. There are similar delays in large offices where telegrams have to be retransmitted. They have to be circulated until they reach the right point for retransmission. The start-stop printer and the teletype exchange will short-cut all this delay and waste of labour. Also the ridiculous time- and labour-wasting process of checking and counting the number of words in telegrams at every stage, unavoidable by present methods, will disappear. One count will be sufficient, and when transmission is direct from the sender to the receiver of the message, there will be no counting at all, but a charge by time and distance.

With a start-stop printer and the teletype exchange, the subscriber in London would communicate, clear of all obstructions, direct from his office in London to the office of his correspondent in Glasgow, who could, if the message permitted, reply at once. Obviously this should be considerably cheaper than sending a telegram in the ordinary way, because no telegraph operators would be required. The work of sending the telegram would be done by a typist in the merchant's office, and all the handling of the message in "circulating" it to the Glasgow circuit would be cut out. The cost and delay of the telegraph messenger would also disappear. In addition, as the cost of the telegraph line used in sending the message from London to Glasgow would only be about one-twelfth of the cost of a telephone circuit, the message ought to cost much less than a telephone message to Glasgow. Also the duration of a teletype call could be reduced, compared with a telephone call, from, say, 3 minutes to 2 minutes. The latest start-stop printers work well up to about

80 words a minute, and a good typist can do 60 words a minute easily. Hence 120 words could go through in 2 minutes, or 10 times as many words as the usual 12-word telegram for which the Post Office charges a shilling. Clearly there would be great economy to the Post Office through the adoption of this form of telegraphy, and time- and distance-rates could be arranged that would be profitable to the Post Office and yet attractive to business men.

Of course, speaking in a general way, there is nothing new in all this, and therein lies good hope for success. There is nothing idealistic about it, and it is only a slight extension of what is already done. The telephone does it already, and substituting a telegraph transmitter and receiver for a telephone transmitter and receiver ought not to disturb the most conservative mind. Further, there is nothing particularly new in this, even from a telegraphic point of view. There are telegraph concentrator systems in all important telegraph offices, now used to concentrate and save labour, but which may be regarded as germs of telegraph exchanges. There is also the London intercommunication switch designed by the present Engineer-in-Chief of the British Post Office, Colonel T. F. Purves, and installed in 1902.* This may be described as an official and not a public telegraph exchange. It is a real telegraph exchange interconnecting London local telegraph offices; but it does not attempt the final linkage to business firms, because it uses the morse key, an instrument not commercially practicable in such cases. Colonel Purves's book contains some very interesting information on the subject of "through-switching" of telegraph exchanges. It was carried out in England as early as 1854, but it was used to connect telegraph office to telegraph office and not subscriber to subscriber. The telegraph exchange plan was used and abandoned by other administrations many years ago, but Belgium persevered with the arrangement and it is still in use in that country for morse telegraph working. Briefly the scheme is approximately as follows:—Station A, connected by direct wire to station B, has a telegram for, say, station F, whom he calls on his line to B. There may be more than one route from B to F, via, say, C, D, E, or G, H, J; the more appropriate route is selected by B and the call is passed on until F replies to A.

As a matter of fact the London intercommunication switch, after having been in use for 20 years, has gradually been killed by the competition of the telephone, and it is understood that the British Post Office proposes to abandon it. The intercommunication switch was primarily designed to link up about 200 local London telegraph offices so that telegrams could be transmitted direct between any of these local offices by way of the central switching exchange. Obviously this is not a subscriber system like a telephone exchange, and it does not possess the great advantage of the telegraph over the telephone of cheap long-distance facilities. It is a telegraph exchange attempting to compete with the telephone on ground most favourable to the telephone. Naturally the telephone has gradually drained away the traffic until there is very little left for the intercommunication switch to handle. People will not spend a shilling for a 12-word telegram in London with about an hour's delay, when they can send and receive 1 000 words with no delay and for less than twopence by telephone. A local London service of threepenny telegrams might revive the intercommunication switch, especially if combined with start-stop printers. Also to extend the area of service, so as to bring in the advantage to the telegraph of longer lines, might help; but it is on the subscriber, or what might be called the "direct user," that the success of the new telegraphy will depend.

It is necessary to point out the weaknesses of the London intercommunication switch, because its want of success will probably be used as an argument against the new telegraphy. A little space must therefore be devoted to it. Apart from the deadly competition of cheap short-line telephones at about one penny per message and answer, a telegraph exchange relying on the morse key and sounder cannot hope to be a success; first, because average private users cannot afford the expense of keeping a morse operator, although they can and do habitually keep girl typists; and secondly, because a morse operator sending needs a morse operator receiving. The start-stop printer solves these two difficulties. It supplies the private subscriber with a telegraph machine which his typists can use after a few minutes' practice and without additional expense for labour, and it substitutes an automatic and reliable machine in place of the receiving morse operator. In fact the morse operator will not be required. One typist can attend to half a dozen teletypes if the traffic is not heavy, and the receiving typist will be able to send at any moment when the line is free. There is also a possibility of some kind of duplex working, giving simultaneous communication each way on the one wire.

At present, in the case of these local London telegraph offices linked up by the intercommunication switch, the Post Office, and not subscribers, has to pay the wages of the morse operators at both ends of the lines. The teletype exchange with private subscribers will relieve the Post Office of payment of wages for a gradually increasing portion of the telegraph traffic. Another point not to be forgotten is that the start-stop printers will enable the typists to do about double as much work as with morse key and sounder, and a receiving typist will not be required for each printer. The engaged signal has seriously reduced the economic efficiency of the intercommunication switch, because paid Government operators are kept waiting. With private subscribers any loss due to engaged signals will not fall on the Government any more than in the case of telephones. In the case of a typist attending to several teletypes in a local telegraph office, acknowledgment of receipt of messages presents some difficulties, but a bell or a lamp signal at the end of messages would warn and guide the attendant in giving acknowledgments of receipt of messages without unreasonable delay even if half a dozen printers required attention.

Another plan would be to use the reservoir effect obtainable by means of receiving-tape perforators and retransmitters. This, however, introduces complexities,

* See "Telegraph Switching Systems," by T. F. Purves.

to say nothing of perplexities, and probably the best plan is the "engaged" signal if a message cannot be accepted at once.

It is to be noted that even the connecting-up of outside customers to telegraph offices is not new. The use of the Steljes step-by-step printer in this way is very old in England, and a similar arrangement has been in use in Germany for years, the little Ferndrucker of Siemens and Halske being very largely employed for the purpose. This, however, like the Steljes, is merely a step-by-step printer like a stock-ticker, provided with a typewriter keyboard, and the speed is low, about 25 words a minute; and, being on the step-by-step principle, neither the Steljes nor the Siemens Ferndrucker is satisfactory for working much beyond city limits. In "Telegraph Switching Systems," Colonel Purves mentions that ABC telegraph exchanges between ABC subscribers for direct telegraphy were in actual use in England in the late seventies, but the telephone swept them away. This is of real historical interest, because it shows that the telegraph would long ago have developed on the lines indicated in this paper if modern printing-telegraph machinery had been available. As it was, the telephone, when it arrived, swept all before it. Whether the telegraph can recover lost ground now that the machinery is available, is purely a commercial question.

The really new feature of the service about to be put into operation in America is the use of start-stop printing-telegraph machines capable of high speed, 40 to 80 words a minute, tape-printing or page-printing, and able to work with ease over thousands of miles, and capable also of linking up with the multiplex telegraph network of the country, and with the potentiality of sending messages automatically all over the world. That is quite new and of the greatest importance, and it is the start-stop printer that has made this development possible.

(9) *Linking up the telegraph network.* I have referred to the possibility of linking up the start-stop printers with multiplex trunk circuits. A good deal of work has been done in this direction by the Western Electric Co., and several years ago it exhibited in London an installation of its multiplex system with start-stop printer extensions from various channels. In a description issued in the course of its demonstration, the company mentioned that the start-stop printer had been in duplex operation on a circuit 1 000 miles long between New York and Chicago with one girl operator at each end. This circuit was obtained by superposing on a telephone line, and the daily average load for 9 hours was 22 000 words, or about 1 000 messages. The company also mentioned that it is possible to provide intercommunication between a number of offices by means of the start-stop printer when working simplex, and also to use selectors by means of which any one of a number of stations may be called, the printers at the other stations remaining idle while a message is being printed at the selected station. These facilities can of course be supplied by any other modern start-stop printers such as the Morkrum teletype, the Kleinschmidt, the Creed direct printer, or the Siemens and Halske.

The Western Electric Co. has some interesting patents on methods of linking up start-stop printers with channels of multiplex installations. There is, for example, British patent 165783, showing various branching arrangements for connecting up several cities with both forked multiplex and start-stop printers. Fig. 1 in the above patent, for instance, shows a Y-forking arrangement comprising three terminal multiplex distributing stations arranged for four channels from each terminal multiplex station, through a repeating station, to each of the other terminal multiplex stations, and also illustrates how one arm or channel of the multiplex distributor at, for example, St. Louis, may be extended by means of start-stop equipment to two outlying cities or stations. It is also pointed out that any or all of the channels of each terminal multiplex station may be extended, if desired, to an equal number of distant or outlying stations by means of start-stop equipment.

In France, forked and series working with the Baudot multiplex has been in use for many years, and the French have wonderful methods of linking up various cities on one wire by the multiplex. The Western Union has likewise been doing a good deal of work in this direction, and those who are interested will find it fully dealt with and illustrated by clear diagrams in Mr. H. H. Harrison's book on "Printing Telegraph Systems and Mechanisms"; but, to refresh the memory of those who are familiar with the subject and to enlighten those who are not, in Fig. 2 two diagrams from the Western Electric patent above referred to, with the addition of start-stop printers to each channel and teletype exchanges in the cities, are given.

Fig. 2 will help us to realize the enormous extension of telegraph facilities rendered possible by the start-stop printer. It represents two wires from New York via Pittsburg to Chicago, one of the two wires having a branch from Pittsburg to St. Louis. These wires are equipped with multiplex printing-telegraphs working quadruple-duplex, giving four channels of communication simultaneously each way, solid lines representing channels working in one direction and dotted lines channels working in the other direction. The small rectangles marked M indicate sending and receiving sets on the multiplex. The rectangles marked S are start-stop printer extensions linking up to the multiplex channels. The rectangles SS are a number of start-stop printers in series on one wire, selective callers enabling any one or more of the SS sets to be called up and communicated with. The teletype exchanges explain themselves. To complete the picture, subscribers are needed. They are scarce at present and hard to convince, but their numbers will grow geometrically as the facilities extend, just as they did in the case of the telephone.

A great advantage that the telegraph possesses over the telephone is that a telegraph message can be stored up at any point where there may be a "bottle-neck," until its turn comes for transmission. A telegraph operator usually has several telegrams in hand, which he transmits one after the other. They wait their turn. A telephone message cannot wait. In a vast telegraph network such as that contemplated in this paper, the bottle-neck is a factor for which provision must be made. The excess in the supply of telegraph circuits will not

last for ever, and in any case there will be certain points where delay will be liable to occur at times, especially during rush hours. The flow of telegraph traffic is very irregular, and there will be advantage in having reservoir mechanism at bottle-neck points, such as ocean cable terminals. Hitherto the receiving tape-perforator has been neglected by telegraph traffic managers; but it is possible that the receiving perforator will come into its own in the new telegraphy. A business man in New York will dictate a telegram, a typist will transmit it to the nearest teletype exchange, and it may succeed in going direct as far as Chicago, and all channels west of Chicago may be engaged for a time. In that case the message might be stored up as perforated tape ready for transmission to San Francisco as soon as a channel is available. Otherwise the messages, in such cases, could be received on printers and retransmitted in their turn on typewriter keyboards. suddenly called upon to send a message on the teletype for her employer. Quite obviously your teletype exchange would only be for big business firms and companies, banks, railways and the like. For the thousands and thousands of small men it would be useless. It would not pay them to use a teletype for one or two telegrams a week."

The best reply to this supposed criticism will be to quote a few figures. The financial advantage possessed by the telegraph when distance becomes an important factor is a powerful argument in favour of the long-distance telegraph and against the long-distance telephone, and the telegraph administrations will be glad to increase their profits by reducing their expenditure on wages by throwing the burden of transmitting and receiving telegrams on to the business community, and the business community will be glad to shoulder that burden in return for the boon of quick telegraph service.

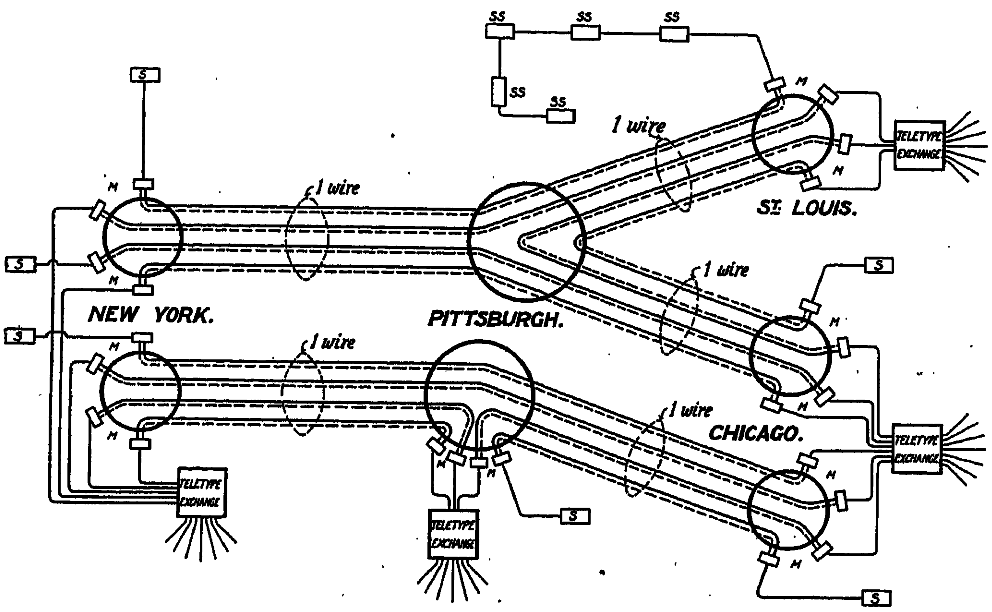

FIG. 2.—Diagram of multiplex printing-telegraph combined and extended by start-stop printers, single and in series, and with teletype exchanges.

Naturally there are many difficulties in the way, including human nature and established routines, and there are also serious arguments which have to be met. For instance, I can imagine the British Post Office saying to me: "Three-minute calls on your teletype exchange would be only 20 telegraph messages an hour per channel, and there is the loss of time in calling, answering calls, getting through, giving the line to the subscriber and disconnecting, which would diminish the output to perhaps 15 messages an hour, or even less. We can quite easily send 60 messages an hour by our present methods, as long as there is enough traffic, and at times we send 80 and 90 and even 100 messages an hour per channel. If your teletype exchange cuts down the average to 15 messages an hour, we shall have to charge more. Also our professional operators steadily employed on telegraph circuits will send far more messages than a girl typist There is every indication that there is money in the new telegraphy, and if that is the case the matter is settled.

It must not be forgotten that the telegraph administrations and companies lease telegraph wires or "channels of communication" for long terms, 6 months or a year, and they will be glad to lease telegraph wires for 3 minutes, just as they lease telephone wires, if they can make money by doing so. The financial case for the new telegraphy will be realized after a little study of the table on page 262 giving the British Post Office annual charges for telegraph and telephone wires.

Taking, first, London to Birmingham, roughly about 100 miles, the Post Office will lease a complete telegraph wire during the day for a rental of £685 a year. There is no difficulty in getting six channels each way on one telegraph wire from London to Birmingham. Hence dividing £685 by six we get a rental of £114

a year per channel. Dividing this by 300 days in the working year, we get 7s. 7d. per day. Taking the business day at 8 hours, we get a rental per hour of a trifle under 1s., or only 0·2d. per minute. Assuming that the active time of communication is 3 minutes and that the time spent in connecting and disconnecting is 3 minutes, or, in all, 6 minutes per call, the rental would be only a trifle over 1d. for 6 minutes. Even if the Post Office tripled this rate and charged 3d. for a 3-minute teletype talk between London and Birmingham with a "no delay" service, it would be regarded by the business community as a godsend. The minimum for a London—Birmingham telephone call of 3 minutes is 2s. There is a big difference between 3d. and 2s., and the difference is still greater if we deduct the cost of postage, 1½d., which is saved in each case by using the telegraph or telephone instead of the mail. It becomes 1½d. extra for the teletype call of 3 minutes transmitting at least 100 words, and 22½d. extra for the telephone call, an advantage of 15 to 1 in favour of the telegraph, even over only 100 miles.

Now working backwards, the Post Office is to get 3d. for 6 minutes (a 3-minute call and 3 minutes con-

Approximate Annual Rentals for Lines.

	London to Birmingham	London to Manchester	London to Glasgow
A telegraph wire, but not including apparatus ..	£ 685	£ 1 120	£ 2 415
A telephone circuit with apparatus	905	1 520	3 350

necting) on one channel between London and Birmingham. This is 2s. 6d. per hour, or £1 a day of 8 hours, or £6 a day for the six channels on one wire, or £1 800 rental for the year of 300 days. This is, of course, on the assumption that the wire is kept busy with calls every 6 minutes. Actually it is possible to divide up a wire between London and Birmingham into at least 12 channels each way, so that there would be a future possibility of penny teletype calls between London and Birmingham, exchanging about 50 words each way. In other words the business community will get an extremely cheap and quick telegraph service and the Post Office will get a greatly increased rental for its telegraph wires and will save the wages of operating staff at present employed handling telegrams. £1 800 a year should leave ample margin for the wages of the exchange attendants and for maintenance and other charges.

Now take London–Manchester, about 200 miles. The Post Office annual rental for a telegraph wire is £1 120. Five channels can be provided easily each way on the one wire, making the annual rental £224 per channel. Dividing this up as before we get 0·375d. per minute. Allowing 6 minutes per call as before, we 2¼d. per call, and, tripling this as before, the call d cost a trifle under 7d. This charge would give 'ost Office an annual rental of £3 500 for a London–hester telegraph wire. This again is on the assumption that there is a call every 6 minutes. A 3-minute telephone call to Manchester from London would be about 4s., compared with 7d. Taking London–Glasgow, the rental is £2 415, and five channels each way can be easily secured. Hence, dividing by five, we get £483 a year rental per channel, or 0·8d. per minute, or 4·8d. for a 6-minute call (3 minutes communicating and 3 minutes getting through). If we increase this to 1s. as the rental for the 6 minutes, the total rental would be £6 000 a year for the five channels on one wire. A 3-minute telephone call to Glasgow would be about 8s. At present a shilling telegram from London to Glasgow would contain only 12 words, and it would take about an hour on the journey from sender to recipient and another hour for a reply. For the same shilling the new telegraphy would handle at least 100 and possibly 180 words, or a message and reply with little or no delay. At present the Post Office is working at a loss when charging 1d. a word, and at present the 180-word message would cost 15s.

Apart from the direct saving due to the new telegraphy, the wealth of the community would be increased by the speeding up of business resulting from the improved telegraph service. It is all a question of whether the scheme of public teletype exchanges is economically sound. It appears to be sound, but time and experience will tell in due course. There is no millennium for telegraphy; but as long as we do not expect too much from telegraph machinery and human nature, we have good reason to be hopeful about the great improvement in the telegraph service that will take place within the next 25 years, thanks to the multiplex printing-telegraph, the start-stop printer and the teletype exchange.

(10) "*Emptying the mail-bags.*"—An important aspect of the new telegraphy is where the increase of traffic is to come from, that will be necessary to pay for the new developments. Of course the new facilities will create a large volume of new traffic beyond the small annual increment due to growth of population and civilization; but, in addition, the increase of telegraph traffic will come by diversion of a certain amount of traffic from the telephones, and by what Delany used to call "Emptying the Mail-Bags." This is what American publicity men call a slogan; but it is a very poor one, because it is an impossible ideal, and the maximum that the telegraphs can hope to effect is a slight lightening of the mail-bags. Even 1 per cent of letters diverted from the Post Office would result in a great accretion of telegraph traffic.

The mails consist very largely of circulars, newspapers, printed matter, invoices, receipts, postal and money orders, cheques, drafts, securities, advice and receipt notes, waybills, bills of lading, drawings, blueprints, maps, plans, photographs—in short all the vast variety of business documents which cannot be telegraphed. There is also an enormous volume of private and domestic letters, of which only a minute proportion would ever be telegraphed, unless telegraphy became so excessively cheap that it could compete with the penny stamp and the postcard. There remains, however, a large volume of ordinary business correspondence which could be profitably sent by telegraph if the rates were low,

though not so low as the penny post. We should have to educate the business man up to paying more and the telegraph administrations to charging less, so as to bridge the gap and enable a portion of the mails to be poured through the telegraph wires.

It is impossible to say even to what very limited extent the mail-bags can be depleted by the telegraph; but anything in letters and figures can be transmitted, and even complicated formal printed documents can be filled in by telegraph if a tape-printing telegraph is used. An illustration of this is given in Fig. 3, and be telegraphed. The proportion of business letters, otherwise telegraphable, which must go by post on account of enclosures is not known, but the matter was looked into by a London firm in connection with their departmental correspondence. This firm, with offices in London and works 30 miles away, have a private telephone circuit connecting their London offices with their works. This telephone circuit is overloaded with traffic, and a proposal to superpose a teletype circuit on the telephone circuit proved attractive to them. Not only would the carrying capacity of their private

FIG. 3.—Printed-form tape telegram.

the bits of teletype tape pasted all over the printed form will be noticed. A page-printer could not do this.

Signatures, on the other hand, are hopeless in spite of telautographs and copying telegraphs, and telegraphic transmission of pictures and drawings will seldom pay.

There is, in addition, one interesting obstacle in the path of transmission of letters by telegraph, about which more may be heard in the future, and that is "enclosures." Many business letters which could be telegraphed with advantage contain cheques, bills of lading and various other business documents, which cannot wire be increased, but orders and other correspondence that now reach the factory on the following day would arrive by telegraph by the aid of the teletype in a few minutes, thus saving a day in the case of a factory 30 miles away; and time is money.

Upon investigation, they found that 40 per cent of their correspondence with their factory contained enclosures which could not be telegraphed, leaving 60 per cent that could be handled by the teletype. This is instructive, but not sufficiently generalized to be any guide to the average contents of the mail-bags. The

proportion of letters that could be telegraphed is well worth investigation by inducing a number of business firms of various kinds to look into the matter and prepare statistics. Also it is obvious that the proportion of letters that it would pay to telegraph would be still smaller. Many firms could no doubt be induced to prepare statistics on this point also. In this way a fair estimate could be made of the extent to which the new telegraphy may benefit at the expense of the mail-bags.

(11) *The first steps.*—The problem of making a beginning with the new telegraphy deserves a little consideration. It will have to start on a small scale, because administrations cannot be expected to spend hundreds of thousands of pounds to install teletype exchanges in all leading cities, and then spend more money in canvassing for subscribers to the new service. There must be healthy growth from small beginnings. It will probably start very much as the telephone service began. A start has already been made in connecting business firms and banks to the Central Telegraph Office. The Dutch Government has installed a considerable number of teletypes for this purpose, and the British Post Office is beginning to do the same. If this service grows it will lead to a concentrator system, because subscribers' lines will not always be busy, and by means of a concentrator switch the traffic can be handled by a considerably smaller number of teletypes at the Central Telegraph Office than the number of subscribers. It seems reasonable to suppose that this arrangement will gradually extend to switching subscribers direct to the particular circuits over which their telegrams would have to be transmitted. The British Post Office already has teletypes in use on long lines, and "through switching" would appear to be inevitable in the course of time.

Another line of growth has already been indicated in connection with the offer of the Western Union and the Bell Telephone Co. of telegraph typewriter service on the private wires of private firms. These private lines will naturally be linked up in due course, with resulting growth of the new telegraphy.

Part 3.

The Start-Stop Printer.

(1) *Various machines and what they must do.*—It remains now to give a general idea of what is meant by the title "Start-Stop Printer." As far as possible details will be avoided, because this paper is being written not for telegraph engineering specialists but for the vast number of people who are mainly concerned about better telegraph service. Before beginning this last section of the paper, however, I may also explain that I have refrained from expressing any opinion about the relative merits of the various machines now on the market or being developed. They are the product of a vast amount of ingenuity and research and practical experience, and time will in due course settle which is the best, or what particular combinations of the ideas materialized in these machines will prove to be the most suitable for various classes of work.

The conditions to be fulfilled by a successful start-stop printing-telegraph may be set out as follows:—

(*a*) It must be a start-stop printer; that is to say, it must start operating as soon as a key is depressed on the keyboard, and it must stop as soon as a letter has been printed.

(*b*) Most of the successful machines have a mechanical distributor and a single recording magnet.

(*c*) It must have the standard typewriter keyboard, with easy touch.

(*d*) It must have a speed of from 40 up to 80 words per minute.

(*e*) It must use the five-unit alphabet.

(*f*) It must be able to work over any distance, from 50 feet to 5 000 miles.

(*g*) The option of tape- or page-printing is desirable.

(*h*) For speeds above 50 words per minute, Western Union experience indicates that typebar machines are best; but good results are being obtained by some of the typewheel printers.

(*i*) It must be simple, compact, strong and durable, and able to print at least 5 million words without an error.

(*j*) It must be able to run for at least one month without attention, apart from the supply of fresh paper and ink.

(*k*) Maintenance must be possible without highly skilled labour.

(*l*) The manufacture must be strictly on the interchangeable mass-production basis, to ensure cheap maintenance, quick repair and moderate prices.

(*m*) It should be possible to stop the printer completely and shut off all power at out-station B from head-station A, and start it again from station A.

(*n*) It would be desirable to have a universal printer which, with comparatively slight modifications, could be used on multiplex circuits, or as a start-stop printer with typewriter keyboard, or with perforated-tape transmission, or as a rapid stock-ticker; but there are grave difficulties in the way of making such a machine.

With the exception of the first-mentioned in the following list (which, after being widely used in America for 15 years, is now being superseded by a more recently developed machine of the same company), the only machines at present on the market which attempt, more or less successfully, to fulfil these conditions are the following:—

Start-Stop Printers.

	Approximate speeds *
(i) Morkrum typewheel page-printer (Blick typewheel), the first of the commercially successful start-stop machines. Page-printer only ..	70 w.p.m.
(ii) Morkrum typewheel teletype; the first start-stop machine to achieve wide success outside the United States. Tape-printer only ..	40 w.p.m.

* w.p.m. = words per minute.

(iii) Western Electric start-stop printer. Page-printer only .. .. 60 w.p.m.
(iv) Kleinschmidt direct printer. Tape or page-printer .. .. .. 80 w.p.m.
(v) Siemens and Halske "Pendeltelegraph." Tape-printer only .. 40 w.p.m.
(vi) An improved machine by Siemens and Halske based on Siemens automatic system.. .. .. 80 w.p.m.
(vii) Creed direct printer. Tape- or page-printer .. .. 80 w.p.m.
(viii) Morkrum page teletype. Typebar page-printer .. .. .. 65 w.p.m.
(ix) Morkrum model-15 typebar teletype. This is the latest start-stop machine. Tape- or page-printer 80 w.p.m.

(2) *Historical.*—Speaking in a general way, what the Western Union calls the simplex printer is a very old idea, going back to the beginning of telegraphy, and it is an astonishing fact that it is only during the last year or two that real success has been achieved. There have been many pioneers, and scores of simplex printing-telegraph inventions fill the shelves of the patent libraries. They were pioneers, and they all failed for themselves; but not for us, because "by their bones about the wayside we have come to our own." They have guided us on the road, and within the last 2 or 3 years we have arrived.

It might be thought that the complicated automatic and multiplex high-speed printing-telegraphs with their enormous carrying capacities of 100 to 300 words a minute in each direction on one wire, and, in the case of the multiplex, with two to six separate channels each way on one wire, would have developed after the much simpler business-man's printing-telegraph; but the requirements of the business-man's teletype are very severe, as will be realized from the list just given of conditions to be filled by a successful machine of this class. Many beautiful machines have been designed; but for 50 years the Hughes printing-telegraph has been practically the sole one-man machine that would work successfully even in a large telegraph office with skilled attention immediately available, and it is not a start-stop printer. The Hughes would be quite unsuitable as the business-man's teletype for several reasons, the chief objection being that it is a synchronous printing-telegraph. It is also big and clumsy, with a piano instead of a typewriter keyboard, and it requires skilled operation to reach even 30 words a minute, whilst 60 words a minute is far beyond its powers. A girl typist cannot sit down and work it forthwith. The fact that it prints on a tape is not a serious objection, though it is believed that page-printing will be demanded in many cases by the business community. They will want at least the choice of tape- or page-printing to meet their particular needs. What business men require is typewriting at a distance. The need has been known for years, but not the way. Twenty years ago Mr. W. A. Hatfield, one of the engineers formerly employed in the Engineer-in-Chief's Office, G.P.O., repeatedly urged me to make a start-stop printing-telegraph with a direct keyboard; but I was too busy with the Murray automatic and the Murray multiplex printing-telegraphs to attempt any other development work. In any case the conditions of success were not known at that time, and the labours of many men and much capital and years of time were necessary to discover the conditions.

The first really successful machine of this kind was the Morkrum start-stop printer, which was put into commercial service in 1910. It was a typewriter keyboard machine with a typewheel page-printer very similar to the Blickensderfer typewheel typewriter. It came into extensive use in America; but it depended for its operation on a considerable number of magnets and electrical contacts, and it required much maintenance attention. It is therefore being superseded by later Morkrum machines. American as well as French experience appears to indicate that a successful telegraph printer should be, as far as possible, mechanical in its action, and further development in America has gone along these lines.

This resulted in the production of the little typewheel "Teletype," which was put on the market in 1920 by the Morkrum Company and proved highly successful. The teletype is the first machine of the kind that has had a wide sale outside of the United States, and from the date of the established success of this new machine the era of the new telegraphy may be said to have begun.

Kleinschmidt came close on the heels of the successful Morkrum machines, with an extremely clever, direct, keyboard page-printer, very neat and compact in design, which is meeting with considerable success. About the same time the telegraph development engineers of the Western Electric Co. were doing valuable work on the start-stop problem. Their start-stop printer worked well, and amongst other things they designed a most ingenious centrifugal governor for their start-stop printer motor, which is easily the best yet made. The work done in developing arrangements for linking up start-stop printers to channels of multiplex installations has already been referred to. Dr. Louis M. Potts also did extremely ingenious start-stop printer work, especially on the idea of the mechanical distributor and single receiving magnet or relay.

The Western Union and the British Post Office, being telegraph-operating and not manufacturing and development concerns, the Western Union engineers, like the British Post Office engineers, and the engineers of other administrations and operating companies, have had to discharge the important duty of testing and criticizing the machines designed by the various manufacturers and inventors, and it is largely from the conclusions arrived at and the requirements and conditions laid down by the telegraph-operating organizations that the manufacturers and inventors have been guided to commercial success.

I mention this because there is often uninformed criticism of the British Post Office on account of the Post Office engineers not having produced any of these printing-telegraph machines. They have not had time, and it would have been quite outside of their duties to have done so. The modern world is highly specialized, and the production and the operation of machinery are two entirely separate functions. Criticism and

valuable practical advice can come very properly from the operating administrations, but the work of development of machinery has to be left to the manufacturing concerns that specialize in that class of work.

German engineers, instead of accepting the conclusions of England, France and America in favour of mechanical operation, have employed automatic and electrical principles with success, and Messrs. Siemens and Halske of Berlin have produced a very interesting machine which they call the "Pendeltelegraph," printing on a tape at a speed of 40 words a minute. They have also developed another start-stop printer based on the Siemens automatic system, with a speed for manual operation of 60 to 70 words a minute, and, for automatic tape transmission, of 80 words a minute. It depends on many electrical contacts, brushes and condensers, devices that are not regarded favourably in the light of English and American experience, but it is stated to work well. Those who are interested will find an illustrated account of it in the *Elektrotechnische Zeitschrift* for 24th July, 1924, by F. Lüschen, entitled "Die Technik der Telegraphie und Telephonie im Weitverkehr." It is very instructive to compare the illustrations of this German machine with those of the Morkrum Company, Kleinschmidt, and Creed, all of which are mechanical. The same article gives an interesting diagram showing the remarkable network of Siemens' automatic printing-telegraph circuits linking up all the leading cities of Germany and Central Europe, and extending to London, Rome, Budapest, Vienna, Warsaw, Riga, Moscow and Kristiania and other Norwegian cities. This extension is due to German influence, and not to any superiority of automatic systems compared with multiplex; and if the forecast in this paper of the future of telegraphy is correct, then the whole of this automatic network will in due course find its way to the scrap-heap, because the multiplex is necessary for splitting up wires into a number of separate channels. Tone-selective methods are a practical alternative under certain conditions; but automatic systems are hopeless for the new telegraphy. Although multiplex are undoubtedly superior to automatic systems, yet even multiplex systems will be much modified by the requirements of the new telegraphy.

More recently others have entered the market, including F. G. Creed. The Creed machine, like all these printers, is most ingenious. It is based on the well-known Creed automatic printer, and it is unique in being a typewheel-typebar machine. The typebars are only $\frac{3}{4}$ inch long, and very high speed is secured in this way. The five-unit alphabet is used, and Mr. Creed is to be congratulated on his conversion from the morse to the five-unit system.

The essentials for success are now known, and from what has just been said it will be seen that healthy competition is springing up, and it is all for the good of civilization that every possible way of carrying out the start-stop idea should be investigated and tried, in order that the best may survive. That is specially desirable because of the very great importance of the start-stop printer.

(3) *Technical features of start-stop printers.*—The first essential of a start-stop printer is that it must start and stop for each letter transmitted and printed. Prefixed to each letter signal is a starting signal, which upon arrival at the receiving station starts the printing mechanism, which makes one revolution, in the course of which the letter is printed, and the machine then stops ready for the next letter. This cycle is repeated for every letter transmitted. (For simplicity, I have disregarded the overlap, as this does not affect the argument.)

A little consideration will show that there must also be a stopping interval to give the machine time to come to rest and return to zero. Hence the start-stop printers, although they employ the five-unit alphabet, are really seven-unit systems. The morse uses eight units per letter. The start-stop printers have therefore a slight advantage over the morse key of $12\frac{1}{2}$ per cent so far as the telegraph line is concerned.

The only alternative to starting and stopping for each letter is for the sending mechanism at station A and the receiving mechanism at station B to run continuously. For simplicity let us consider the Hughes printing-telegraph, which runs in this way. At each end of the telegraph line there is a typewheel, and these two typewheels have to run synchronously, that is to say, the same letters on each typewheel must point to the 12 o'clock position at the same instant, and mechanism has to be provided for correcting any lapse from synchronism. It is only while signals are being transmitted over the line that the synchronism of the Hughes is maintained. When transmission stops the Hughes falls out of synchronism, and synchronism would have to be re-established for each new connection before messages could be transmitted. In any case, to keep a number of Hughes circuits all tuned to the same speed would not be easy with the present governing mechanism. Also, in the event of no one being present at the receiving station there would be no certainty that synchronism had been established. Hence a printing-telegraph depending on continuous rotation, and therefore on synchronism, could not be used in a printing-telegraph exchange. The start-stop principle is essential. In any case, for reasons already mentioned, the Hughes would be out of the question for such a purpose.

The start-stop printer comes to rest between each letter or during intervals between messages, and it can then be switched easily from one circuit to another. The only condition is that there shall be approximately a standard speed for all the teletypes or other start-stop printers. About the subject of speed more will be said presently. It is true that even the "start-stop" machines depend on synchronism, but only during the one revolution that prints a letter, and it is very easy to preserve synchronism for such a short period as $\frac{1}{8}$ second or even less, and in this fact lies one of the great advantages of the "start-stop" machines for exchange work.

The next point about which some explanation is desirable is the mechanical distributor and single recording magnet of the successful start-stop printers. The Hughes is a single-magnet printer, but it does not have a mechanical distributor. In the Hughes the chariot is an electrical transmitting distributor only, and sends

out at station A an electrical impulse at the right moment for printing correctly at station B, the typewheel at station B revolving in synchronism with the typewheel at station A. The typewheels are the distributors, and in the Hughes there is no mechanical distributor in any sense corresponding to the mechanical receiving distributor of the modern start-stop printers.

(4) *Electrical and mechanical distributors.*—The value of the mechanical receiving distributor will be best understood by considering an electrical distributor and a printer in schematic form as shown in Fig. 4.

The receiving line-relay is shown at 1; 2 is the electrical start-stop distributor, the brush arm 3 being kept from revolving by the pawl 4. When a starting signal arrives in relay 1, it closes the contact at 5, and local current then passes from the battery 6, through ring 7, position, and the pawl 4, catching the brush arm 3, stops the machine until another starting signal, followed by a letter-signal group, arrives.

In electric distributors the chief difficulty is the contact brushes, which wear badly and require frequent attention. In the case of multiplex distributors the traffic and the carrying capacity are very great and the cost of daily attention to the brushes is trifling compared with the results achieved; but in the case of the start-stop printers the position is far less favourable. Such machines are necessarily scattered over a considerable area, often miles apart, and it would consume too much time and wages to send a man daily to attend to the brushes. The maintenance attention should not exceed once a week and preferably once a fortnight, or even once a month. Compared with an electric distributor using brushes, the mechanical

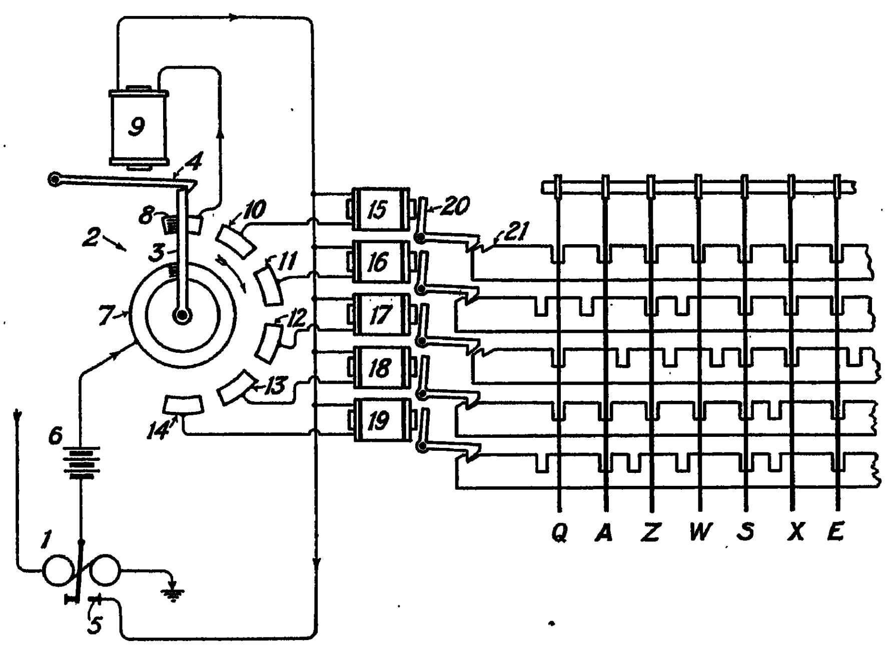

FIG. 4.—Diagram of principle of five-magnet printer and an electric distributor.

brush arm 3, starting contact 8, starting magnet 9, and back through contact 5 to the battery. The magnet 9 attracts the armature pawl 4, releasing the brush arm 3, which starts revolving to the right, the brushes making successive contact with the segments 10 to 14, which are connected to the five selecting magnets 15 to 19. Depending on whether the contact at 5 is open or closed by a line signal when the brush makes successive contact with the segments 10 to 14, impulses or no impulses will pass through one or more of the magnets 15 to 19, and one or more of the five armature pawls 20 will be attracted, and will release their corresponding selector plates 21. In this way a special permutation group of slots in the selector plates, corresponding to the letter signal transmitted, will be aligned and a latch, in this case corresponding to the letter S, will be selected and, by suitable mechanism, will print the letter S. The printing action also restores the selector plates to zero distributor is a great step forward. It does not require attention for months at a time and even then it only needs a drop of oil, which can be given by anybody. With the exception of one magnet to record the signals coming over the telegraph line, the receiving and printing mechanism of the modern start-stop printer becomes in this way entirely mechanical. Another important advantage of the mechanical distributor is the fact that, on lines not sufficiently long or difficult to require a relay, a start-stop printer equipped with a mechanical distributor can be worked by alternating current and without any direct current. An alternating-current motor to drive the machine is all that is necessary, in addition to the signal magnet to record the line signals. No local direct current is needed.

The principle of the mechanical receiving distributor is the same in all the successful start-stop printers so far produced, and it will be readily understood from

the schematic illustration of one form of mechanical distributor, in Fig. 5, and the following description :—

The signals arrive in the single magnet 1, which corresponds to a morse sounder. The first signal is the starting impulse and causes the magnet to attract its armature 2. This trips the pawl 3, and also by the link 4 it trips pawl 5. This throws in a clutch 6, which couples the constantly rotating power shaft 7 with the start-stop shaft 8. This carries the cam 9, and by means of five-to-one gearing it also operates cam 10. Cam 9 oscillates the lever 11 pivoted at 12. Lever 11 carries a rod 13, which is pushed by the rod 14 along in front of the five selector plates 21 (ends only shown, but they are the same as in Fig. 4), the rod 14 being moved by the cam 10. The rod 13 reciprocates regularly as shown by the arrow 15, under the control of the rod 11, which is kept oscillating by the cam 9. If, however, there is no operating or marking signal in the line, the magnet 1 will cease to attract its armature 2 and

contacts. These have proved wonderfully goo electric distributors, and run for months at a without attention. As a matter of fact, tun; contacts opened and closed by spirally arranged on a transmitting spindle are employed in the Morl teletype for the transmission of signals, and exper. shows that they run almost indefinitely without a tion. It will be seen, therefore, that there is a deal of variety possible in the design and manufac of start-stop printers. The mechanical distrib however, appears to be cheaper and simpler and i compact than electric contacts with five selec magnets, and the Morkrum teletypes, the Kleinsch: and the Creed start-stop machines all use the mecha: distributor.

The demand for high speed, at least 60 wor minute, has been a stumbling block. Typew machines like the Hughes and Baudot appear to r their commercial working limit at about 40 wor

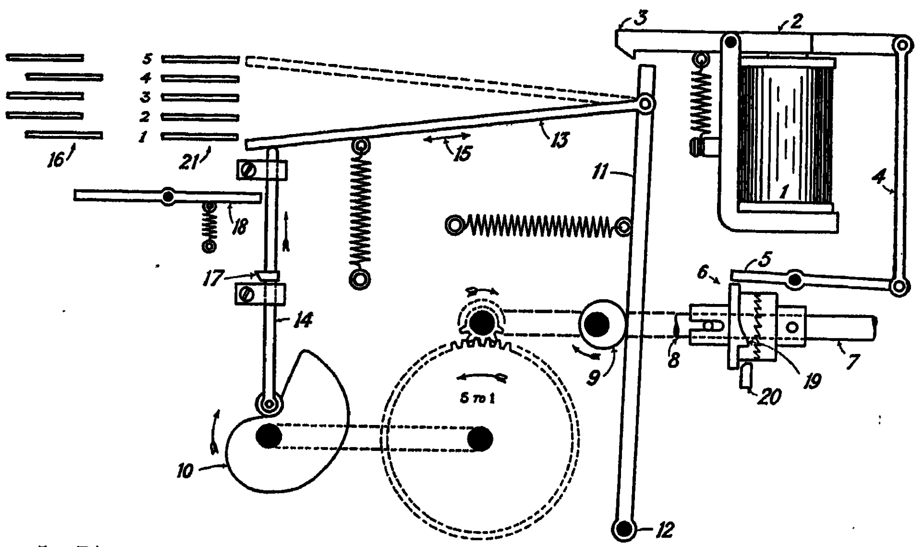

Fig. 5.—Diagram of principle of single-magnet start-stop printer with mechanical distributor.

the pawl 3 will catch and retain the rod 11, thus preventing the rod 13 from striking the selector plate opposite which it is passing at the time of no signal. Assuming that there is no signal operating the magnet 1 when the rod 13 is opposite selector plate 1, and that there is a signal when the rod is opposite selector plates 2 and 3, no signal when the rod is opposite plate 4 and a signal when opposite 5; then the selector plates will be pushed into the particular permutation shown at 16. Immediately afterwards, a tooth 17 on the rod 14 strikes the end of the lever 18, causing it to trip the printing mechanism into action, and a letter corresponding to the permutation set up in the selector plates will be printed. The clutch 6 is disengaged automatically by the cam surface 19 striking the plate 20, and the released half of the clutch is then caught once more by the pawl 5, ready for the starting impulse of the next letter signal.

On the other hand there has been a sort of rivalry between the mechanical distributor and tungsten

minute. Beyond that speed the cost of maintena rises rapidly, and American experience indicates t for speeds much beyond 40 words a minute the type principle is the best. The typewheel machine, howev has the advantage of great simplicity of print mechanism, and in one or two cases good results being obtained at higher speeds. There is a sin typewheel instead of 26 typebars and parts, and th is a simple little ink-roller instead of the necessar complicated ink-ribbon feed with automatic rever The demand for speed, however, is insistent, and t Western Union, as the result of great experience, l decided definitely in favour of the typebar machi: The Morkrum model-15 teletype is one reply to t: demand. This machine has an extremely ingenic mechanical distributor and, having typebars, it wo well at 75 words a minute and has been tested up to 1 words a minute. These high speeds are quite pra ticable for tape-printing, but, in the case of page-printir time has to be allowed for the carriage to run back, a

at 75 or 80 words a minute the time of at least three letter signals must be allowed for the return of the carriage. This is not a serious drawback, but it is a deduction from the high speed in the case of a page-printer. The Kleinschmidt direct keyboard printer is another answer to this demand for a rapid typebar typewriter-keyboard start-stop printer.

(5) *Curved code-bars.*—In the Morkrum model-15 teletype there are two, amongst other, interesting features demanding notice, namely, the curved code-bars and the combined striker-bar and lifting-bar. These two devices effect a surprising simplification in a typebar printer. I devised these two features and patented them in Great Britain in September 1922 (British patent 206975), only to find, on writing to the Morkrum Company, that they had hit upon the same ideas independently. We afterwards found that a French inventor named Eglin had patented a printer employing the curved code-bar idea in December 1912. He did not use the combined striker-bar and lifting-bar, and his selecting mechanism is rather complicated and apparently not very practical, and his printer is not provided with a distributor. It is for multiplex working with five selecting magnets, and it is not a start-stop printer like the machines referred to in this paper.

At B five magnets of the electrical distributor plan are shown controlling the code-bars, but the principle of the mechanical receiving distributor with a single magnet is readily applicable in the case of the curved code-bars, and it has been applied by the Morkrum Company in their model-15 teletype in a highly ingenious manner.

I have described this curved code-bar machine at some length because of the remarkable simplification obtained by the arrangement shown at A together with the semicircular code-bars shown at B. The importance of this simplification lies in the necessity for high speed, at least 60 words a minute, for start-stop printers. For such speeds typebar printers appear to be best; but typebar printers, owing to their complexity, have hitherto been very costly. The simplification resulting from the devices described above is therefore a distinct step forward, and in this respect there does not seem to be room for further improvement. The ink-ribbon mechanism of typebar printers is their one remaining drawback. It is more complicated than is desirable, and compares unfavourably in this respect with the simple ink-roller of the typewheel machines.

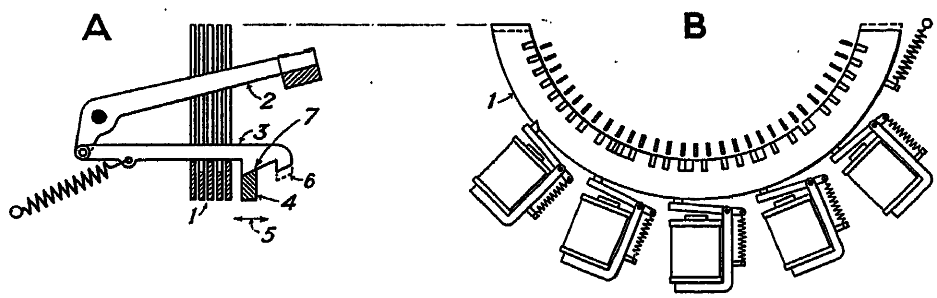

FIG. 6.—Diagram of curved code-bar printer.

In Fig. 6, A and B are the second and third diagrams in my British patent 206975. The Morkrum Company's solution of the problem is substantially the same. In A the curved code-bars are shown in section at 1; 2 is a typebar; 3 combines in one piece the selector latch, printing hook and connecting piece to the typebar, and 4 is the combined striker-bar and lifting-bar. At the right moment this bar moves forward and back as shown by the double arrow 5. When moving to the right it no longer supports the latches 3, which then rest on the curved code-bars. It is understood that there are 27 of these latches, corresponding to the 27 typebars. For any given permutation of the curved selector plates shown at B only one latch 3 will be selected and will be free to fall into the aligned group of slots, and the hook 6 will then engage with the striker-bar 4, and further motion of the striker-bar to the right will cause the typebar to rise and print. When the bar 4 moves to the left, the wedge portion at 7 lifts all the latches off the code-bars, which are then free to be set into a new permutation by the next signal transmitted over the line.

On the other hand, I am informed by the Western Union that as the result of 15 years' experience they found ink-rolls a source of great trouble and worry. They have found ink-ribbons far less troublesome and also cheaper than ink-rolls. This appears to be another case in which the complexity of the "Rolls-Royce" is preferable to the simplicity of the wheelbarrow.

(6) *Standard speed and tape- or page-printing.*—I have now completed the story of the new telegraphy and its machinery, and there remain only a few final words about one or two points that will cause difficulties if agreement is not reached in regard to them. They correspond in a curious way to the old problem of the standard railway gauge, which still gives the world some trouble.

The first and most important point is the question of a standard speed. Clearly the start-stop printers must run at approximately the same speed everywhere if there is going to be free intercommunication as on the telephone. In the case of the telephone this question of speed does not arise, because the speed is determined by the human voice, and we all talk at about the same speed (100 to 200 words a minute). In the case of printing-telegraphs the allowable speed variation

is small. Fortunately, so far as the machinery is concerned, this requirement is easily fulfilled by suitable governing mechanism, and tuning forks and the stroboscopic effect enable speeds everywhere to be regulated with great accuracy in less than a minute. The difficulty arises from other considerations.

The lower the speed the greater is the margin of security on the telegraph line; but the higher the speed the more words can be telegraphed within the time limit. The lower the speed the greater is the durability of the apparatus and the lower the maintenance cost, and the higher the speed the lower are the capital cost and the maintenance cost of the wire plant in proportion to the work done. The lower the speed the greater is the accuracy on the part of the human transmitter of messages; but the higher the speed the more business can be done and the more information and instructions can be transmitted within a given time. For circuits superposed on telephone lines, low speeds, say 40 words a minute, are desirable, while on ordinary telegraph lines higher speeds, say 60 words a minute, have advantages.

As start-stop printers or teletypes will have to be linked up with channels of the multiplex, the speed of the teletypes will be controlled by the speed of the multiplex, a matter quite easily arranged. Certainly it would not be practicable to alter the speed of big multiplex installations and networks, and quite impossible to give different speeds on different channels of the multiplex. Also the speeds of various multiplex installations differ in accordance with the line conditions. Certain fixed speeds for the multiplex are necessary, and a convenient solution of the intercommunication problem seems to be speed-change gears on the teletypes. The question does not arise in the case of carrier-current or tone-selective channels, except that the start-stop printer speeds between two correspondents must be the same.

There is still another question. What is the best working speed for a typist? There is complete disagreement everywhere on that point, and the rate advocated ranges from 40 to 80 words a minute. Apparently 60 words a minute may be accepted as the happy mean; but on long and difficult telegraph lines the speed of 40 words a minute gives a wider and safer margin for working. Evidently start-stop printers will have to be provided with three-speed or even four-speed gears like a motor-car, say 40, 60 and 80 words a minute. Two subscribers, on being connected at 40 words a minute, could agree on increased speed and gear up accordingly by moving a lever on each teletype. Even speed gears would necessitate agreement about the three or four speeds to be provided. These would have to be standard; but it would be much easier to agree on three or four speeds than on one. The question will have to be decided largely by experience, and fortunately in America there is a splendid field for experimental settlement of the problem. Later on, so far as Europe is concerned, there will have to be international agreement about start-stop printer speeds, and such agreement will have to include all leading nations because, in the course of time, teletype exchange and multiplex working will certainly extend through ocean cables and possibly by wireless across the great oceans.

The second and only other serious controversial point in connection with the new telegraphy is the question of tape- or page-printing. Tape-printing is considerably simpler than page-printing. It is therefore cheaper and the maintenance cost is lower. Also, for the distribution of market prices, weather reports and news to farmers and other private subscribers, tape-printing would appear to be the best arrangement. Using pre-gummed tape like postage stamps, the printed tape can be readily attached to sheets of paper. In the case of the Western Union Telegraph Co., after having about 2 000 page-printers in use all over the United States for the past 8 or 9 years, the company has decided to change over to tape-printing, and has already ordered over 800 tape-printers to replace page-printers. In this case, however, there are special reasons in favour of tape-printing, which do not apply in the case of Government administrations. There is sharp competition between the Western Union and the Postal Telegraph companies, and the Western Union prefers not to send out messages with visible corrections. Consequently, messages containing errors have to be retransmitted. This occasions loss of time and labour, which is avoided with tape-printing, as errors in tape can be cut out so as not to show in the finished message. There is also a considerable percentage loss of time in transmitting the signals to run the typewriter carriage back and turn up to a new line, and at the end of messages time must be given to the printer attendant to turn up to a new message form for printing the next telegram. In the case of news messages, on the other hand, page-printing has great advantages, because it saves time and labour, and it is doubtful if large firms with much telegraph traffic would accept tape-printing on their teletypes. They are accustomed to typewriters and they will demand typewriter service. That is to say, they will probably demand page-printing.

It is clear that there will be trouble if one subscriber has a tape-teletype and another a page-teletype. As it happens, a message containing page-printing signals will print all right on a tape-printer, but a message transmitted for a tape-printer without page signals will not print on a page-printer. A tape-printer typist could send the page-printing signals even on a tape-printer keyboard, but the situation is not as clear as could be desired. Of course as long as the Western Union and the Bell Telephone Co. confine themselves to their present plan of selling telegraph typewriter service only to business firms for use on their own private wires within their own organizations, the problem of tape- or page-printing will not arise. Each firm can choose tape- or page-printing; but when the inevitable linking up of such private-wire systems through a teletype exchange takes place, the tape- or page-printing problem will require consideration. One point to be borne in mind is that when start-stop printers are being used in great numbers, prices will come down, and it will then be practicable for firms to have several tape-printers and several page-printers, thus giving the option of either tape- or page-printing. For certain

classes of work page-printing is impossible. Fig. 3 is an illustration of what tape-printing can do and what page-printing cannot do. There is certainly much to be said for tape-printing in connection with the new telegraphy, but, on the other hand, page-printing saves time and labour when there is much traffic and it gives nicer-looking results.

(7) *A universal printer*.—Another point for consideration is whether it is not possible to have a universal printer available for all telegraph service. This, I understand, is the idea at the back of the mind of the Western Union, and there is much to be said in its favour. It certainly would be desirable to have a universal printer that would do for multiplex circuits, for start-stop circuits and also for stock-ticker service; and I, and no doubt others, have had our thoughts directed to this ideal for a long time past. Such a printer would be the real Ford car of printing telegraphy. A printer absolutely identical for all services is evidently impossible, but the modifications required for each class of work are not serious. The five-unit alphabet being used, all the essential parts of the machine would be the same for each service. This would allow of production in quantity, with corresponding reduction in cost and corresponding extension of the field of telegraph service. The answer of the Morkrum Company to this requirement is the new Morkrum model-15 teletype which will work up to 80 words a minute. It is tape-printing or page-printing as desired. It is a start-stop printer with a direct-transmitting typewriter keyboard, or it can be used with a keyboard perforator and automatic tape transmission. By substituting five selecting magnets it can be used on multiplex circuits. Apparently there is nothing to prevent any of the start-stop machines being so constructed as to be available with suitable modifications for these various services, and it will be a question for time and the telegraph administrations to determine which is the best.

Hitherto stock and news service has been confined to city limits on account of the step-by-step principle of signalling employed. The use of a modern start-stop printer for the distribution of news and market prices will sweep away the city limitations of stock-ticker service, and distribution will become nation-wide. The five-unit alphabet being used, there will be no bar to universal ticker service, including distribution to distant centres over channels of the multiplex. Prices are already being broadcast by wireless; but the arrangement is unsatisfactory. Only a few leading prices can be given, because to listen to a whole stock-list for the day by wireless would be unendurable. Also, broadcasting suffers from all the disadvantages of the telephone. It is a voice and nothing more. There is no record and there must be fixed times for listening, and there is the risk of error of the telephone plus the risk of error from atmospherics or static. The printing-telegraph for news is the only way.

In America, for instance, there is already a very fine ticker service (and so there is also in this country); but with the new machinery it will certainly develop to a marvellous extent, covering the whole of the United States and Canada, and serving not only stockbrokers and produce dealers but also farmers and private homes. Every well-to-do family will have its ticker service superposed on its telephone line for news and its radio set for amusement. The family will turn on the music and read the news.

(8) *Prices*.—At the back of all the wonderful possibilities outlined in this paper is the question of cost. Will it pay? That depends on the value of the service rendered. Printing-telegraphs have already proved extremely valuable to telegraph administrations, and there is acknowledgment of that fact in the annual report of the Western Union Telegraph Co. for the year 1920. In that report it was stated that, since 1915, multiplex printing-telegraph apparatus had been installed costing approximately $2\frac{1}{2}$ million dollars, saving the expenditure of $16 585 000 on wire plant, which otherwise would have been required. Nothing was said in the report about the labour-saving, which is known to be substantial; and during the four years that have passed since that report was issued there must have been still further expenditure and resulting economies both on lines and labour, bringing the total saving to the Western Union up to somewhere about 4 million pounds sterling. There is no doubt that printing-telegraphy is very profitable to the telegraph administrations. It is also very profitable to newspapers and news-distributing organizations, and the stock-ticker service manages to pay its way in most countries. This paper also will have been written in vain if the start-stop printers do not render profitable service on a large scale; but there is a law of diminishing returns in such cases, and the margin of cultivation may be taken as the employment of the start-stop ticker in the home. For stock and produce brokers, merchants and farmers, the teletype will undoubtedly render commercially valuable service for which it will be worth paying a substantial price; but in the home the ticker, like radio apparatus, must be regarded as a luxury, and the extent of this particular market will depend on low prices and cheap maintenance. These are also important considerations in the more profitable markets already referred to. In short, everything depends on the price.

Reference has already been made to the unprofitable years of development work and the heavy expenditure incurred in producing these simple-looking little machines, the start-stop printers. Naturally the manufacturers have to get their money back with a profit or go out of business, and the present selling price of these machines is therefore about £90 to £180, depending on the amount of apparatus and kind of service required. Not only has the production been expensive, but the cost of selling is high. The "education of the market" takes much time and money. However, with the increase in the numbers sold, the cost of selling as well as the cost of making will fall, and when the stage of mass production by tens of thousands is reached and orders run into thousands at a time, the prices will fall probably to about twice the cost of a typewriter of the better class. If the total sales ultimately go into the millions like typewriters, it is possible that the prices will come down to the typewriter level, and they will then find their

way into the more prosperous homes, just as the portable typewriters are doing. Mr. G. M. Yorke, Vice-President in Charge of Engineering, Western Union Telegraph Company, New York, writing to me on the 1st May, 1924, said:—

"We agree with you that one difficulty about the printing-telegraph business is the cost of the machines. We hope to get American manufacturers on a Ford-car basis within the next 5 or 6 years. However, on the whole, our regrets in connection with our printing-telegraph developments are small."

In conclusion, it may be of interest to add that official steps are already being taken to investigate the new telegraphy thoroughly under experimental conditions, and, if the results are promising, it is probable that some form of practical trial will be made. Fortunately, the new telegraphy lends itself readily to experimental laboratory trials with a couple of small 10-line switchboards and a dozen start-stop printers, and I anticipate that, as the result of this paper, experiments of this kind will before long be instituted by all the leading telegraph administrations.

Discussion before The Institution, 18 December, 1924.

Colonel T. F. Purves: Although I am not at liberty to speak very freely on this subject, I should not like it to be thought that the Post Office does not feel the keenest interest in the proposals put forward by the author. I might say, indeed, that any suggestion from him on a subject of this sort would always be treated with the greatest respect, and, as he knows, steps are already being taken in a practical way with a view to giving his proposed method of communication a practical trial under the most favourable conditions that we are likely to find in this country. In that way I hope that before very long we shall have a certain amount of actual evidence to show to what extent the British public is prepared to support the proposal to provide a printing-telegraph switching system for personal use by subscribers. I rather emphasize the words "British public" from a point of view that will appeal to those who have had occasion to study the viewpoints of different nations, or to compare their various degrees of responsiveness to publicity and advertisement, either private or governmental. I quite agree with the author that the great weakness of the telegraphs is lack of what he calls terminal facilities. On the engineering side his proposals involve many problems that will require much study in their economic realization, but in themselves they present no serious difficulties. The author describes enthusiastically and quite legitimately the large numbers of channels of communication that can now be obtained from a single telegraph or telephone line by modern methods of multiplexing or superposition. These methods have gone very far and will no doubt go further still in practice, but I should like to mention that another factor is also at work inasmuch as the scientific study of line conditions and construction, and the application of repeaters, is reducing the cost of providing lines in great numbers between important traffic centres. The annual costs associated with multiplex telegraph and telephone apparatus are fairly high, and the point at which it is economical to provide additional lines and use simple self-contained apparatus is a shifting one. There may be some reaction in favour of not demanding from the line all the effective signalling speed of which it is capable, especially in connection with switching systems which are apt to become so complex in themselves that the additional complexities of multiplexed channels are formidable. The author is quite entitled to claim, as he does, that the telegraph can transmit intelligence with a far smaller number of line impulses than the telephone, but I think that his arguments on pages 248 and 249—based on his Fig. 1—go rather too far. The telephone has to transmit over its line a frequency as high as 2 500 per second in order to be properly intelligible, and the equivalent telegraph speed of that line, at 7 impulses per letter, is 6 850 words per minute. It seems too good to be true! I think that the author is overlooking one thing which entirely alters the practical aspect of the comparison, and that is the respective efficiencies of the receiving apparatus—in one case a telegraph receiving apparatus, and in the other case the human ear. The power of the human ear to correct distortion and to transmit intelligible signals to the brain is nothing short of marvellous, whereas only a slight amount of distortion will completely upset a printing-telegraph receiver and convert its record into a mass of meaningless symbols. It is generally admitted that the telephone is not well adapted for the transmission of written messages and figures, but that disadvantage applies rather to its use by the public than to its use by practised experts who are accustomed to work together. It is generally a slow and painful business to dictate a phonogram, but I have listened to the transmission of news at a very rapid conversational speed between London and Paris on frequent occasions, practically without any hitches or any requests for repetition, and being taken down, of course, in shorthand at the other end. I have been, too, in the offices of busy stockbrokers who have been transacting important business over the telephone, and receiving figures and fractions at high speed, and the work has been going on with perfect facility and no sign of any strain. I feel that one must be fair to the telephone in this respect. I think also that the author is a little less than fair to the possibilities of broadcasting market news by wireless; and I would suggest that it is not very safe policy for a printing-telegraph engineer to make light of such possibilities. I welcome the paper as a notable contribution towards the very desirable end of revivifying the telegraph service, which, both in this country and elsewhere, has been in danger of sinking into quite undeserved disrepute. As the author remarks, the need for a simple printing instrument for the use of renters of private wires between their offices and public telegraph offices has been felt for many years and is now at last met. The same instrument is excellently suited for a direct

intercommunication system, if such a system is wanted by the public. The "start-stop" feature, which has so many advantages, is perhaps not ideal for a switching system to be used outside of office hours. I question whether many people would care to transmit important confidential messages without having received an intimation that they had really been placed in communication with the office they required, and without any acknowledgment of receipt. I rather think that the fear of having got connected to a wrong number, and of giving some useful information to a competing firm, would be a decided deterrent to the adoption of such a system. I am not impressed either with the suitability of the printing-telegraph for sending and receiving service switching instructions. In spite of the attractions of an entirely separate telegraph switching system with multiplexed lines, I think it would be well not to rule out the idea of combining it with the general telephone system, which already provides a great and ever-growing network of switching channels running everywhere. The new system of voice-frequency telegraphy makes it possible for the telegraph to be worked on any circuit that will carry a telephone conversation—with all its equipment of manual or automatic switchboards, transformers, loading coils and speech relays—and the facility of switching at will from the telephone instrument to the printing-telegraph, and vice versa, must prove a great asset. The telegraph instrument must, of course, be suitably designed and equipped from the signalling standpoint. Its line current must be kept very low in order to avoid interference with the telephone system, but that is a condition which must apply in any event, as telephone and telegraph conductors are now inextricably united in the new underground cable system of the country. I might remark also that the author's financial calculations as to remunerative rates, etc., refer to conditions which seem to approach a good deal closer to the ideal, in the matter of steady and continuously sustained traffic, than is ever likely to be experienced. As regards the automatic switching of telegraph circuits, it may interest the author to know that a good many years ago the question of converting the London intercommunication system to automatic switching was under consideration, and a system was designed (on paper) which would have met all the conditions. It was not proceeded with because it was then becoming obvious that the competition of the telephone would, in a comparatively short term of years, do away with the need for maintaining a telegraph switching system for the offices of the London area.

Mr. J. Newlands: The author says that the telegraphs as we know them in this country are slow, costly and inefficient. From the commencement (in about 1846) the telegraphs grew like a tree and the different branches had to be interconnected. It is still much too like a tree; there are far too many different transmitting points, and that is the real cause of this slowness and costliness. In the early days different kinds of apparatus were taken over from different companies, many of which have entirely disappeared. The single-needle system has practically gone out of the Post Office service, as also have the acoustic needle, the A.B.C. and Bright's bell. We have here a paper the author of which tells us candidly that he thinks the day has come when the sounder also ought to go—that it has served its day and generation, and has become more or less obsolete. I am inclined to agree with him, but we must remember that while the sounder is very cheap and easily produced in large numbers, the present cost of the teletype is almost prohibitive. I quite agree with the author that there are too many circuits, and that the terminal facilities are at fault. What is the reason? The apparatus is far too slow; the operators were too slow; many of them are still too slow. I tried for many years to improve the rate of working by what is known as the "average" system; but my efforts fade into insignificance compared with the author's sweeping recommendation to "scrap the lot." As the telegraph business grew, the number of offices on a circuit had to be reduced to 3, 4 or 5. There are very few circuits that I can recall which have more than 5. Now, if the teletype is so constructed that not 5 but twice or three times 5 offices doing a moderate amount of business can be put on a telegraph circuit, then its increased rate of working will enable a great many of the existing circuits to be grouped on to one teletype, and in that way it will effect economies at transmitting offices. I think that is possible. The telegraph distribution system of this country will have to be totally revised if the teletype is to have a really good chance. If the sounder is to go, then I would suggest that the transmitting offices should be roughly something as follows: London (with a wide area), Bristol, Norwich, Birmingham, Nottingham, Sheffield, Leeds, Manchester, Liverpool, Glasgow, Edinburgh, Aberdeen, Belfast, Dublin and Cork; that these larger places should be freely interconnected, and that they should reach all the area around them. This would, I believe, greatly reduce the number of transmissions to and from rural localities, probably to an average of two per message. The author, in endeavouring to show how people sitting in their offices could be connected all over the world, refers to the question of a "bottle-neck" at the cable ends. Now, one of my former operators, Mr. J. B. Heggerty, suggested a reversion to the old Umschalter switch such as is now used in Belgium. He proposed a system of joining through each telegraph office "direct" to any other office it required, each in turn. That is perhaps suitable in a country such as Belgium, where Antwerp and Brussels are within easy reach of the whole system, but Mr. Heggerty's scheme was turned down for the reason that it is impossible to be continuously altering the length of a circuit. The author proposes to switch through direct up to 5 000 miles. The faults which are inherent in our telegraph system would, I think, condemn such a scheme as that; there would be "bottle-necks" all over the country. With regard to a teletype exchange system for London, I do not think there is a real case for that at all. The author admits that the telephone is much better suited for such a populous city, where there is not a great deal of telegraph communication except between the head office and a business firm's works. On the other hand, I think that if there is an

effective demand in the country for a teletype exchange similar to the telephone exchange, it ought to be attached, not to the telephone system, but to the chief or central telegraph office, which, in connection with its phonogram room, should have certain wires put apart. Let me take for illustration the most central town in England. If there is an effective demand on the part of business men or stockbrokers or banks for a teletype exchange from London to Birmingham, I think the department should put one good experimental wire at the disposal of the Central Telegraph Office and see what it can obtain in the way of business. I see great possibilities in the way of the simplification of telegraphy by the adoption of the teletype for speeding up the telegraphs. I see the prospect of great economies on the part of the administration, especially if the cost of the teletype can be lowered, and, if the teletype apparatus can be made in bulk in this country and can be placed at the command of the Post Office, I think that it will make very rapid progress indeed.

Mr. E. H. Shaughnessy: On page 254 the author says: "The circuit facilities will be still greater when half a dozen wireless beams work across the Atlantic each at 300 words a minute." I think that this is even more than wireless engineers will prophesy with any degree of confidence; but on the next page I read that: "Even if this were possible, there are the inaccuracy of wireless, interference troubles and atmospherics, and there is no way of answering back." So that although he is looking forward to wireless to help him, at the same time he says that wireless is no good. When discussing costs, the author speaks of the rapidity with which this scheme will enable telegraphy to be carried on, and on page 260 he says: "A great advantage that the telegraph possesses over the telephone is that a telegraph message can be stored up at any point where there may be a 'bottle-neck,' until its turn comes for transmission." This indicates that a fault of the present telegraph delay owing to bottle-necks is even turned into an advantage in this method. The price of the teletype, or any form of start-stop printer, viz. £90 to £180 as given by the author, must undoubtedly be reduced if the telegraph is to compete with the telephone. It will be a very serious position if a million subscribers are obtained, in each of whose offices an instrument costing £100 will have to be installed. First of all this would involve a capital expenditure of £100 000 000 for instruments alone, and I think that is the sort of development visualized by the author in 25 years' time.

Mr. J. E. Kingsbury: Reading the paper from the telephone point of view I have some doubt whether it will be possible to introduce his method in the way the author suggests. For the purpose of analogy I have compared the conditions with railway traffic, of which there are two kinds, passenger and goods. The passenger traffic we may consider as being of the first importance, and for the purposes of analogy we may call speech the passenger traffic and the written word the goods traffic. Now terminal facilities for goods traffic are usually regarded as a very expensive item, and only to be taken advantage of by those who have a great quantity of goods to despatch. Terminal facilities from the point of view of the telegraph were, we must remember, suggested even earlier than the author records in his paper. Simply as a matter of history I should like to remind him that the first exchange system was that patented by Dumont in 1851. It was there suggested that the telegraph line should be taken into the house or the office of the sender and the receiver. Now if the most is to be made of long-distance facilities the goods must be collected in detail, forwarded in bulk and distributed in detail. In a sense that is what is done by the telegraph of to-day. The author suggests that better results can be obtained only by forwarding direct from the sender to the receiver. To my mind that is all a question of cost and convenience. In the case of a line capable of conveying the number of vibrations shown in Fig. 1 (which are adapted to the machines at either end as at present used, but depend for the economic use of the line telegraphically on the multiplication of a number of machines utilized by different people), economy is dependent upon the simultaneous requirements of a number of people to use that line—and in practice, of course, the requirements will not be simultaneous. The collection of goods at a central depot, from whence they would be forwarded in bulk to some other distributing centre, would enable more traffic to be obtained from the line itself than would the general provision of terminal facilities. On the other hand, there can be no question of the great advantage to certain users of direct telegraphic communication such as the author proposes, but I would suggest that the system should be tried in the first instance in an independent teletype exchange. I think that if the teletype printer were added to the existing telephone system, the telephone subscriber would strongly object to find that his line, which was adapted for passenger service, was being monopolized for goods to the detriment of his passenger service. Again, the cost of the teletype appears to be so high as to justify the further increase necessary to give it a separate line. Therefore I think that the author should amend his estimates by making provision for a separate teletype exchange in order to give the system a fair trial.

Mr. T. B. Johnson: I agree with the author that there is a field for the extension of the telegraph in work for which it is more suitable than the telephone; and I say that in spite of the fact that I am an enthusiastic advocate of the development of telephony, and especially automatic telephony. The crux of the question is to what extent the business man really wants a written record. It is exceedingly creditable that transactions of such importance as are carried on at every moment of the day, depending entirely on the word of the men at the ends of the line, are honoured and carried out, but still there is some need for a written record. Whether the start-stop printers would satisfy the requirements I am unable to say, but if they will—and the author states that they can be transferred from a short to a long line—then I believe that there is a field for them. Broadly speaking, material is cheap and labour is dear; and if we can save labour every day the cost of these machines, which will inevitably fall considerably as their use

extends, will not be a really serious bar. At the present time there is far too much writing down of telegrams in different places. Take Leeds and Bradford, for instance, each of which cities has some smaller telegraph offices connected with it. A telegram from a place near Bradford has to be written down in Bradford; it has to be transmitted in turn to Leeds and to the office near Leeds. Teletype exchanges at these two cities would save a good deal of transmission, and each transmission in addition to the cost also involves an additional risk of error. The author, in his estimates, has not taken sufficient account of the cost of labour at the switching centres. In practice it would be found that the cost of switching of telegrams would be much more than he anticipated, and telephone engineers will agree with me that the cost of switching, no matter what attemps are made to cheapen it, is always appreciable. It would, however, be much less than the present cost of writing down and re-transmitting. I do not agree with the author that farmers will take much advantage of the teletype machines; the English farmer is much too conservative. It is very difficult to persuade him to take a party-line telephone; and when some time ago the Post Office telephone authorities distributed weather forecasts from their rural exchanges, it was found that so few people wanted them that they have been practically discontinued. Another important point is that these machines must be so constructed as to require no adjustment at the subscriber's office. Although I do not think that the sounder will become obsolete, its use will continue to diminish and the tendency which there has been of late years to make the telegraphist either a typist or a mechanic will continue at an accelerated rate. The type printer is bound to supersede the sounder for the greater part. It is rather surprising—as showing the conservatism of the ordinary English user—to find how little the facilities which the telephone administration does give in other directions are made use of. For instance, very few people take advantage of the system whereby a telegram may be addressed to a person's telephone number, thus enabling the message to be telephoned from the main telegraph office and saving the time occupied in delivery.

Mr. A. E. Thompson: In view of the subtlety of the distinction which the author has drawn between the telegraph and the telephone, the fact that the ordinary business man with the telephone at his elbow uses it for much traffic that could be handled more economically by the telegraph is not surprising. Undoubtedly the telegraph has suffered by the want of a satisfactory connecting link between the user and the administration. Instead of being regarded as a normal means of communication, it is only used in extreme necessity and it has thus become associated not with the active side of life but rather with catastrophe, sickness and death. Telegraphy has thus itself become enfeebled. In comparing the relative transmission efficiencies of the telegraph and the telephone, the author states that when the word "Paris" is spoken, 365 waves are transmitted, as against 21 waves when the same word is telegraphed. This assumes that only the fundamental frequency is transmitted in the case of the telegraph, whereas the square-shaped signals necessary for machine speeds are built up from a number of harmonics. The importance of these harmonics is clearly illustrated by the "composite" system of superimposing. In this system the telegraph signals have to pass through a filter network having a fairly sharp cut-off at about 80 periods per second. It is not possible, however, to telegraph at this speed, and in practice the maximum speed obtainable is between 20 and 25 periods, which is sufficiently low to permit the third harmonic to pass freely through the filter. A more direct, and more striking, illustration of the admitted economy of the telegraph, from the line standpoint, is afforded by the Western Electric Co.'s "voice frequency" telegraph system. Take, for example, a 4-wire telephone circuit providing one speech channel in each direction. If the telephone is given up, and if the same line plant is then equipped at its terminals with the Western Electric system, from 10 to 12 independent telegraph channels can be obtained. Each of these channels may, in turn, be equipped with multiplex-quadruplex printing telegraph apparatus, giving a total of 40 to 48 message-channels, or a traffic-carrying capacity of approximately 1 200 to 1 400 words per minute. If only two wires are available the traffic-carrying capacity is reduced to 600 or 700 words per minute, but this is still considerably more than the telephone can handle. In the section dealing with teletype exchanges, the author states that the Bell Telephone Co. is starting to sell telegraph typewriter service to business men in Chicago, on similar lines to the Western Union. This may perhaps give the impression that leased wire telegraph service is a new practice in the United States, whereas the Bell Telephone Co. has, of course, been leasing printing telegraph facilities for a number of years past. The only new feature is that the Illinois Bell Telephone Co. of Chicago is now offering the teletype apparatus for use on its lines. With regard to the telegraphy of the future, a matter which requires some consideration if the telegraphs are to be linked up on an extensive scale is the establishment of a standard 5-unit code. At present three or four different arrangements of this code are in use in Europe, but investigation will probably show that the code used by the "teletype," the Murray multiplex, and the American multiplex and start-stop systems, is the most satisfactory from every point of view. When the administrations adopt a common 5-unit code, then with such developments as the simple typewriter-telegraph, the "composite" system, and the "voice frequency" telegraph system, the author's vision of the new telegraphy should soon be realized. As Mr. John Lee, the Controller of the Central Telegraph Office, so aptly states in his book "Telegraph Practice," "The old mystery of the telegraph is breaking down; the public is no longer to be separated from the organism by the fortification of a counter. The telegraph system is no longer to find its bounds and limits in telegraph offices. It will penetrate into industry itself; it will link up all manner of industries with each other and with whatever centralizing bureau shall yet be evolved."

Major F. H. Masters: A previous speaker has stated that the facilities available for telephone subscribers are not made use of, and complained that it was difficult for the Post Office to advertise those facilities. A body known as the Telephone Development Association has recently been formed, and it would appear that it should be part of their duty to advertise existing facilities. I should like to suggest to the author that some of the advantages which he puts forward for the teletype system could be obtained rather more simply by using the telephone in connection with the telegraph.

Mr. W. J. Thorrowgood: A point of view which does not appear to have entered into the author's calculations concerns the user of this apparatus. It has been said that the user of a telephone does not always know how to manipulate a receiver after he has used it. If he is to use the teletype machine to any extent, I venture to say that the cost to him of learning how to use it will be very considerable. A man operating a typewriter at 40 words a minute must give his whole attention to the work; whereas if he speaks over the telephone he is thinking of what he is saying, and he conveys a good deal by the way in which he says it. The teletype writer to an ordinary user is not so comfortable to use as a telephone, and a telephone lends itself so easily to business men that it seems to me that a teletype has no chance at all—certainly in view of the possible advances that can be made in 25 years, the period mentioned by the author. When calculating the number of words that can be sent by telegraph, or telephone, it must be considered that the unit of telephone communication is not letters, words, or messages, but a conversation, which may consist of several messages, certainly not less than two.

Mr. A. C. Brown: There is one thing which might very easily alter our conception of the whole subject, and that is the "Telephonograph." That, of course, is not a new proposition; it is quite possible now for telephone subscribers to have an instrument which will automatically start when a call is given from the exchange, and which will record the telephone message and deliver it up when it is wanted. I fancy that a considerable use of such apparatus would enable a great many of the difficulties of switching to be avoided, and might possibly considerably affect the number of telegraphs required.

Mr. J. S. Jones: The author appears to base his attack on the existing telegraph service in this country on two paragraphs which appeared in the *Daily News*. The first of these paragraphs, however, has no reference to the British telegraph service and the second is largely incorrect. The alleged system of telephoning express messages from one exchange to another has never existed and the subscriber at Norwood, far from having a new facility in being put through to the Central Telegraph Office, has in fact had that facility for 30 years. I do not think, judging from the evidence at the General Post Office, that the public is dissatisfied with the present telegraph service. The author thinks that there are too many circuits and I take it that he means that the Post Office does not take proper advantage of the devices which exist for superposing and multiplexing. Leaving reserve wires out of account, there are very few telegraph services in this country which require two or more wires, for the reason that multiplex working is in operation on all heavy routes. Presumably the author's view is that more could be done to cut down the number of physical circuits by forming channels by multiplexing, or by the tone-frequency method, and extending them by short-distance physical circuits—for example, by forming a number of such circuits between London and Birmingham and extending them to Nottingham, Manchester, etc. Such a method, however, has the great disadvantage of placing too many eggs in one basket. In any case, expedients of this kind could be applied to very few routes in this country. A system of transmitting centres as advocated by Mr. Newlands was in fact introduced in the British telegraph service nearly three years ago. It had some effect in reducing the number of re-transmissions of telegrams, but it could not reduce the number of re-transmissions per message by 2, as asserted by Mr. Newlands, for the reason that the average number of re-transmissions per message is actually 1·2. The author envisages the telegraph service too much as a business-man's service. It is used by all sorts of people, and the number of persons sending more than, say, three telegrams a day is comparatively small. A very few send large numbers of telegrams and the system of direct telegraphing proposed by the author would be quite unsuitable for them. The author proposes the establishment of a telegraph system practically on the same lines as the telephone service, but such a service would involve the provision of three or four times as many telegraph channels as exist at present. There is unquestionably a field for teletype exchanges, but it is highly improbable that the possibilities of development are as extensive as the author suggests.

Mr. G. F. Findley (*communicated*): It would appear that in order to obtain a true vision a forecast of the telephone development must be placed alongside this forecast of the new telegraphy. In view of recent achievements it is not necessary to consider the telephone development 25 years hence. I think that the development of telephony in the next 10 years will make the present system appear very crude. The improvement in the telephone service provided by the "no delay" conditions created within the London "toll" area, between the Liverpool area and the Manchester area, between the Glasgow area and the Edinburgh area, etc., and the advance in transmission efficiency, manufacture, laying and maintenance of telephone cables and, last but not least, the advance made in the telephone repeater, force me to anticipate a telephone development along the following lines:

(1) It will be possible at moderate charges for calls between all large cities to mature with a maximum delay of 10 minutes and for calls between towns within the vicinities of these large cities to enjoy the same standard of service. In fact, practically the whole of Britain should have a 10-minute service on terminal calls.

(2) The maximum delay on a call from Plymouth to Aberdeen (a through call) should not exceed 20 minutes.

(3) The telephone will become as vital as electric light and power, water, etc.

As the natural way to communicate with one another is to talk, I am unable, in view of my vision of the telephone development, to realize how the author's scheme can live. There will be no necessity to "teletype" when one can "teletalk" without delay and for a moderate charge. Where documentary confirmations are essential—and I am of the opinion that with the advance of telephone education these confirmations will be very few—the post will be sufficiently speedy. The author appears to have overlooked also the ease of correction by telephone as compared with teletype, especially simplex teletype, working. He says that, with the new telegraphy, telegraph instrument rooms will be deserted, as they will become switching centres and the stability of circuit conditions will be established. At present, it would appear that every circuit is worked under different conditions and that any scheme which embodies the word "economy" a sufficient number of times is given prominence and a trial. I think that one of the real planks of economy is efficient standardization and mass production, which will cheapen the article to the consumer. With simple apparatus such as the telephone and a straightforward issue, viz. "The required persons to talk," a delay of 60 seconds is experienced on long-distance calls, after the subscribers' telephonists have answered, before the required persons commence talking. I can see a considerable increase to this delay before "the required persons can type." Therefore in all the circumstances—the main being the development of the telephone—I cannot see the necessity to "teletype" when one can "teletalk" with efficiency and economy.

Mr. T. E. Herbert (*communicated*): The first two parts of the paper may be described as an extension of a paper * read before the Institution of Post Office Electrical Engineers at Manchester on the 3rd March, 1924. In general, the conclusion arrived at in the paper quoted is the same as the author's, viz. that the time has arrived when some form of automatic switching must be adopted. The telegraph ought to be the cheap, speedy and democratic method of conveying messages which cannot suffer the delay of the ordinary post. The cost of the telegraph plant is necessarily much less than that of the corresponding telephone plant required to convey a message over a moderate distance. If the plant or capital charges of telegraphs are compared with trunk-line capital charges, it will be found that the latter are much heavier. The net receipts from telegraphs are higher than for telephone trunk lines, and yet the former consistently register a loss and the latter a profit. The operating costs, including the cost of delivery of messages, are very high. By eliminating the re-transmission of messages, not only is the cost reduced but greater expedition is secured. It is, of course, a matter of opinion as to whether the business community can make use of a quick telegraph service, but it is certain that present-day business could not be conducted without our present means of rapid communication and transport, mechanical and electrical. It therefore seems reasonable to suppose that increased rapidity has a definite monetary value, and it scarcely seems idealistic to suppose that in time greater expedition in business arrangements will become, not a luxury, but a necessity. This greater rapidity will have to be paid for, but if the results are commensurate the extra cost of telegraphing letters as compared with the ordinary post will assume very minor proportions. The telephone trunk conversation is regarded as essential for personal communications and personal discussions of urgency, and from the enormous use made of trunk lines it is clear that this aid to business is fully appreciated. The interruptions by telephone-calls on relatively minor matters are, however, sometimes serious and would be avoided by the use of a telegram—the caller has not to obtain a telephone connection, nor is the called person interrupted in his occupation of the moment. The telegram is received and dealt with in the called person's office, and the consultation which may be necessary for the reply is effected in the least possible time, since all the data are available when the matter is to be decided. All this, however, postulates a service which is cheap and extremely rapid. Close and careful investigation is called for, and from the large number of papers on the subject of telegraphs now appearing in various technical publications, and from discussions by telegraph and telephone societies, I think it is certain that the problems can and will be solved—to this end the author has contributed a most valuable piece of constructive criticism. On page 247 he states that it is hopelessly idealistic to suppose that the telegraphs have value for short distances. It is by no means certain that the value of the written record and the avoidance of interruption to, and by, important executives has no recognized value. In the event of the main telephone exchange in a town or city being destroyed by fire, the telegraphs would serve to mitigate the disaster since there would be no difficulty whatever in providing a relatively large traffic-carrying system at short notice. The restoration of the exchange would necessarily occupy weeks or months, according to the size and nature of this damage. The "engaged" difficulty referred to on page 259 could be met in yet another way. The message might be received on a receiving perforator allied with a transmitter which would seize a waiting point for the line required and, when this was free, proceed to transmit the message. The point to be appreciated is that this machinery standing idle waiting to re-transmit the message saves human labour, and it is the cost of such labour which necessarily keeps up the cost of telegrams. I am disposed to think that special circuits for telegraphs, rather than the joint use of local subscribers' lines save for very small users, is the most probable development. The failure of the London intercommunication switch is not a valid argument against the suggestions now made. It depended on manual switching and on the skill of morse operators at small offices. Also, it seems possible that the area served by each office for delivering messages was too small for economical operation. The first step (p. 264) should, I think, be in the direction of providing an automatic switching system such that no manual re-transmission of messages should take place between telegraph offices. In conclusion, I am by no means in agreement with the author's suggestion that

* T. E. Herbert: "The Problem of the Telegraphs," *Telegraph and Telephone Journal*, 1924, vol. 10, p. 126.

telegraph clerks will disappear. It will be precisely as with automatic telephone exchanges where a large number of women are always necessary for special switching, accounts work, and many other duties. So with telegraphs, a large staff will always be required and if the volume of the work increases under the new conditions I think it more than probable that the functions of the staff may be changed but that great displacement will not occur.

Mr. Donald Murray (*in reply*): I am glad the Institution has given me so much liberty in the preparation of this paper, because I might have been asked, quite fairly, to make it more technical in tone and substance. In view, however, of the importance of attracting public attention to the idea of teletype exchanges, it would have been unfortunate if any restriction had been imposed on the popular journalistic method of presentation that I have adopted. Technical men would also have been justified in complaining of the length of the paper; but it has been well said by Sir Oliver Lodge that "effective exposition cannot be done crisply and compactly." For these and other reasons I expected a good deal of adverse criticism, and I have therefore been agreeably surprised at the very friendly tone of the discussion and the considerable degree of approval given to the scheme advocated in the paper.

It is most encouraging to hear from Colonel Purves that the British Post Office is keenly interested in the proposals which I have put forward, and that steps are being taken to investigate the scheme with a view to giving it a practical trial. I am also glad to hear from the Engineer-in-Chief of the British Post Office that on the engineering side the scheme presents no serious difficulties, and that it is essentially an economic problem. That is a point upon which I have laid emphasis in the paper, and I am glad to have it confirmed by so high an authority. Colonel Purves makes a good point about the relative efficiencies of the receiving appliances in the case of the telephone and telegraph, in the one case the enormously sensitive and intelligent human ear, and in the other case inanimate and comparatively insensitive telegraph apparatus. My reply is that vacuum tubes now far exceed in sensitiveness the human ear, and that there is no reason why all the telephone methods (including vacuum tubes) should not be applied to telegraphy. It is a physical impossibility to avoid the consequences of the facts displayed in Fig. 1. In any case the margin of about 100 to 1 in favour of the telegraph and against the telephone is so great that heavy discounts can be allowed in respect to points such as that to which Colonel Purves has referred.

Another point made by Colonel Purves is that he is not impressed with the suitability of the printing-telegraph for sending and receiving service switching instructions, and he is evidently not prepared to shut out the possibility of combining the teletype and telephone, switching from the one to the other at will. I am glad to hear that, and two French inventions appear to make it practicable to work start-stop printers through ordinary telephone exchanges in conjunction with telephones.

The criticisms by Mr. Newlands are also very helpful. I agree with him that the present cost of start-stop printers is far too high. It is a new industry, however, and the preliminary expenses have been heavy. When the industry begins to pay its way, prices will come down. That has been the experience in all industries. It is very encouraging to have the opinion expressed by Mr. Newlands that when prices come down, as the result of bulk manufacture of start-stop printers in this country these machines will make very rapid progress indeed. Mr. Newlands refers to what I have called "bottle-necks" —points where telegraph messages accumulate and have to wait their turn. That, of course, would prevent direct communication; but the telegraph service at present is full of bottle-necks, with consequential delays and waste of labour in writing down telegrams, and it is one of the attractions of the printing-telegraph exchange idea that it will greatly reduce the number of bottle-necks, and possibly in time abolish them altogether.

I admit that to work over 5 000 miles with the teletype is rather idealistic under present conditions; but it is not impossible, because the Western Union Company is working six multiplex installations on six telegraph wires right across the American continent, a distance of about 3 300 miles. Each of these wires is carrying 100 words a minute simultaneously in each direction. Under these circumstances, to work the teletype at 40 words a minute over 5 000 miles presents no technical difficulty at all. In fact, on wires 3 000 miles long it will be easy to have two teletype channels simultaneously in each direction on one wire, a result eight times cheaper than the telephone, even if the telephone could work over such a distance with no more costly technical appliances than the telegraph, a thing that it certainly cannot do.

The points raised by Mr. Shaughnessy are also good. Certainly the price of start-stop printers will have to come down very much before there can be any great extension of their use; but the present high prices are the main factor that will render it possible by and by to get the price down to a point much below the present rate. Capital must be accumulated to make cheap manufacture possible, and the manufacture of such machines must first reach the remunerative stage. That condition has not yet been fulfilled.

Mr. Kingsbury's remarks are specially interesting because they express the telephone point of view. His analogy with passenger and goods traffic on railways is illuminating and is rather adverse to the teletype exchange scheme, though he agrees that it is a question of cost and convenience. It is very instructive to hear that the telegraph exchange plan was patented as far back as 1851, because it is remarkable to note how many good ideas have been published and forgotten long ago, the time not having been ripe for them. In my paper I have taken the same line as Mr. Kingsbury in favouring separate teletype exchanges; but it is a point about which there appears to be considerable difference of opinion, especially in view of the two French inventions to which I have referred and in view of the wonderful capabilities of vacuum valves.

One point mentioned by Mr. Johnson is the difficulty

about switching over from short to long lines. This certainly makes it difficult to apply the duplex balance in every instance; but in the case of simplex working there is no more difficulty in switching the teletype rom short to long lines than in the case of the morse key and sounder. I am glad that Mr. Johnson draws attention to the waste of labour, inevitable under the present system, of writing down telegrams and rewriting them several times. That is one of the strong points in favour of the teletype exchange. As for the cost of labour at switching centres, referred to by Mr. Johnson, it seems to be not unlikely that automatic telephone exchange machinery will take care of this difficulty.

An important point was raised by Mr. Thompson about my comparison of telephone and telegraph signalling in Fig. 1. The harmonics giving practically square-shaped telegraph waves certainly would reduce the ratio of 365 : 21; but telegraphy with the fundamental frequency only and without any serious admixture of upper harmonics is possible, and has indeed been advocated by Rowland, Squier and others. In any case the number of different harmonics in line A, Fig. 1, must of necessity be very large, and line D makes some approach to one fundamental frequency. The unavoidable difficulty, so far as telegraphy is concerned, appears to me to be not harmonics but the changes of phase in the waves, which have to be made in order to transmit signals, because a pure sine-wave alternating current cannot transmit intelligence. For instance, in line D (Fig. 1) a half wave has been suppressed at P, thus throwing the succeeding waves completely out of step. In the next letter, A, a half wave has been reversed from negative to positive. These changes of phase cannot be good for telegraphy when filter methods are employed; but telegraphy is impossible without either such changes of phase or changes in amplitude. Experience has shown that the latter are inadmissible, so we are left with changes of phase as the only practicable method of telegraphy. Just what effect this has on the comparison in Fig. 1 I do not know; but the facts mentioned by Mr. Thompson indicate that it may be considerable. The figures given by him, in regard to the number of channels into which a telegraph wire can be split up by the Western Electric Co.'s methods, are astonishing and confirm the arguments in the paper. Mr. Thompson raises another important point, namely, a universal 5-unit telegraph code. That is a matter which will have to receive the attention of the telegraph administrations in the near future.

Major Masters, in suggesting that the telephone-telegraph combination would give some of the advantages which I have put forward for the teletype exchange scheme in a more simple manner, appears to me to have overlooked the economic consequences of Fig. 1 and the saving in labour in telegraph offices by the teletype combined with teletype exchanges. That is impossible of achievement by the telephone-telegraph combination.

Mr. Thorrowgood raises the point about the difficulty of using the teletype, compared with the telephone. The same argument applies to the typewriter. Business men do not use typewriters: they dictate their letters and telegrams now, and the only change will be that they will dictate more telegrams and fewer letters, and their typists will be as expert on the keyboards of the teletypes as they are now on the same keyboards of typewriters.

Mr. Brown's suggestion about combining the phonograph with the telephone is unfortunately not practicable, and it also disregards the economic consequences of Fig. 1.

Mr. Stuart Jones pointed out that the first newspaper paragraph quoted by me does not apply to the British telegraph system. In reply I may point out that my paper deals with telegraphy throughout the world, and not only with the British and one or two other telegraph services which are relatively good. I am sorry to say Mr. Stuart Jones is right in asserting that the British public (and, I may add, also the American) are not dissatisfied with the telegraph service. My point is that they ought to be, and my paper has been written to inspire the public with a little divine discontent on the subject. I want to galvanize the public into demanding something far better not only for themselves but also for the telegraph administrations.

Mr. Stuart Jones makes a good point about the danger of putting all one's eggs into one basket; but the risk depends on the kind of basket. Underground circuits are wonderfully reliable and weatherproof. As I have pointed out in reply to another speaker, it is not business men but their typists who will do the telegraphing.

Mr. Findley, like several other speakers, has concentrated his attention too much on England. I wrote for the world and not only for Great Britain; I took a cosmopolitan view. Several speakers expressed doubt about the farmer ever using the teletype. Mr. Johnson, for instance, said that English farmers are too conservative to use the teletype; but if he will refer again to pages 254 and 255, he will find that I expressly exempted the British farmer and mentioned farmers in other parts of the world, particularly in America, as probable very large users of the teletype. Again, a careful study of the economic consequences of Fig. 1 will show Mr. Findley the need for teletyping, in spite of our being able to teletalk with efficiency and economy. Distances are short in Great Britain, and there is no reason why Mr. Findley's visions of a greatly improved telephone service in this country should not be realized; but the great new countries of the world, the United States, Canada, South Africa, Australia, Russia, Siberia and South America have very long distances, which make the economic consequences of Fig. 1 very important indeed.

I welcome the support given to my forecast of telegraph development by Mr. Herbert, whose paper was most suggestive. It made no mention, however, of the idea of getting every business man to do his own telegraphing, just as he does his telephoning, direct to his correspondents through teletype exchanges. That is the essence of my paper. Mr. Herbert stresses the fact that it is the cost of labour that makes telegrams costly. Obviously the remedy is to abolish the costly labourers—the middlemen workers—and transmit and receive tele-

grams direct. I note with interest that Mr. Herbert, like many other Post Office engineers, is a supporter of automatic switching for the proposed teletype exchanges.

In conclusion, I should like to draw attention to a probable method of using the teletype efficiently through teletype exchanges, namely, storing up messages and sending them through by teletype on one call. Business men already do this in the case of long-distance telephone calls, when these are a daily occurrence. They note down beforehand points for discussion when the telephone call is put through, and it seems likely that telegrams to be sent by the teletype through exchanges will be typed ready to be sent through on one call, which may last for 10 or 12 minutes. In that time two expert typists would easily exchange 500 words between two offices 1 000 miles apart, and on a line equipped with the duplex balance the number of words could be raised to 1 000. This method of working would greatly increase the efficiency of the teletype exchange by increasing the ratio of profitable working time compared with the time spent in getting connected.

THE PREDETERMINATION OF THE PERFORMANCE OF INDUCTION MOTORS.*

By D. B. HOSEASON, Associate Member.

(*Paper first received 1st September, and in final form 23rd October, 1924.*)

SUMMARY.

The accuracy with which the performance of induction motors can be forecast in actual practice has not yet reached that attained in connection with other types of machines. An indication of this lies in the recognized tolerances on guarantees, especially those on power factor. The inaccuracies do not arise from ignorance of the conditions on the designer's part but rather from lack of time to take into account all the factors.

This paper is intended to describe a quick yet accurate means of predetermining the performance of induction motors. A group of accurate formulæ is developed on the basis outlined by Steinmetz and is given alongside the corresponding approximate formulæ which have hitherto been much used on account of their simplicity. Curves are then drawn showing the difference between the results given by the two groups of formulæ, the ratios being expressed as correction factors. It is thus possible to obtain results approaching the accuracy of the more involved systems of calculation, by using the simplest formulæ and applying the appropriate correction.

Finally, two examples are given indicating the accuracy obtained by the use of the curves.

TABLE OF CONTENTS.

TABLE OF CONTENTS—*continued.*

(1) INTRODUCTION.

It has often been pointed out that by using the graphic method of "inversion," or the exact mathematical method outlined by Steinmetz, the performance of induction motors can be predetermined with greater accuracy than by using more common methods. The labour involved, however, in using either system has so far prevented their adoption in the engineering and design departments of most firms.

The circle diagram in its simplest form is based on a constant value of magnetizing current from standstill to synchronism and also takes no account of the change in phase angle between the mutually induced E.M.F. in the primary winding and the applied voltage. The calculation of the performance of a motor on a basis of this simple circle diagram can be easily and rapidly carried out and has already been reduced to the application of a number of well-known formulæ.

The method here suggested for predetermining the performance of an induction motor is an endeavour to obtain the accuracy of the more involved systems with the rapidity of application of the simplest.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

(2) The Polyphase Induction Motor Equivalent Circuit.

It is perhaps advisable to refer to the terms used and to show their relationship. Fig. 1 shows the equivalent circuit diagram of a polyphase induction motor. r_1 and x_1 combined correspond to the primary self-inductive impedance, x_1 relating to that flux which links the primary winding only and more commonly called primary leakage flux. r_2 and x_2 similarly correspond to the secondary self-inductive impedance, where x_2 relates to that flux which links the secondary winding only, generally termed secondary leakage flux. r_m and x_m correspond to the mutual inductive impedance, or the impedance of the magnetizing circuit. r_m is the wattful component required for iron losses, and x_m relates to the flux linking both windings, generally termed main flux.

The actual values of r_2 and x_2 are expressed in terms of the primary winding, and in the case of x_2 also in terms of the supply frequency. The secondary reactance is a variable quantity depending on the frequency of

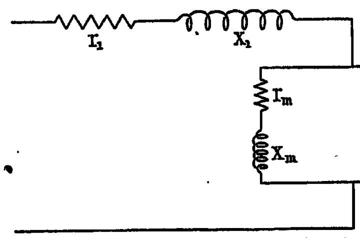

Fig. 1.—Equivalent circuit diagram for a polyphase induction motor.

the secondary currents and thus the slip s. Then we have :—

Primary self-inductive impedance $= r_1 + jx_1 = \dot{Z}_1$*
Secondary self-inductive impedance $= r_2 + jsx_2 = \dot{Z}_2$
Mutual inductive impedance $= r_m + jx_m = \dot{Z}_m$

the following example, which shows the method of deducing the primary current at any slip.

If $\dot{I}_1$ = primary current ; $\dot{E}_1$ = applied voltage ;
$\dot{I}_2$ = secondary current ; $\dot{E}_2$ = mutually induced E.M.F. in the primary winding

Then $$\dot{E}_1 = \dot{E}_2 + \dot{I}_1(r_1 + jx_1) \quad . \quad . \quad . \quad (1)$$

$\dot{I}_1$, however, has two components, the secondary current and the magnetizing current, and

$$\dot{I}_1 = \dot{I}_2 + \frac{\dot{E}_2}{r_m + jx_m}$$

The E.M.F. generated in the secondary, due to the secondary conductors slipping back through the field, is $s\dot{E}_2$.

Then $$\dot{I}_2 = \frac{s\dot{E}_2}{r_2 + jsx_2}$$

and $$\dot{I}_1 = \frac{s\dot{E}_2}{r_2 + jsx_2} + \frac{\dot{E}_2}{r_m + jx_m}$$

$$= \dot{E}_2\left[\frac{s}{r_2 + jsx_2} + \frac{1}{r_m + jx_m}\right] \quad . \quad . \quad (2)$$

Substituting this value of I_1 in equation (1) we have :—

$$\dot{E}_1 = \dot{E}_2 + \dot{E}_2(r_1 + jx_1)\left[\frac{s}{r_2 + jsx_2} + \frac{1}{r_m + jx_m}\right]$$

$$= \dot{E}_2\left[1 + \left\{\frac{s(r_1 + jx_1)}{r_2 + jsx_2} + \frac{(r_1 + jx_1)}{r_m + jx_m}\right\}\right]$$

$$\dot{E}_2 = \frac{\dot{E}_1}{\left[1 + \left\{\frac{s(r_1 + jx_1)}{r_2 + jsx_2} + \frac{r_1 + jx_1}{r_m + jx_m}\right\}\right]}$$

Substituting in Equation (2) we obtain :—

$$\dot{I}_1 = \dot{E}_1\frac{s(r_m + jx_m) + (r_2 + jsx_2)}{(r_2 + jsx_2)(r_m + jx_m) + (sr_1 + jsx_1)(r_m + jx_m) + (r_1 + jx_1)(r_2 + jsx_2)}$$

$$= \dot{E}_1\frac{(sr_m + r_2) + j(sx_m + sx_2)}{[r_2(r_m + r_1) + s(r_1r_m - x_mx_t - x_1x_2)] + j[r_2(x_m + x_1) + s(r_mx_t + r_1x_m + r_1x_2)]}$$

For convenience of expression let

$$r_1 + r_2 = r_t$$
$$x_1 + x_2 = x_t$$
$$\dot{Z}_1 + \dot{Z}_2 = \dot{Z}_t$$

(3) The Primary Current of an Induction Motor.

Col. 1 of the table (p. 282) gives a number of formulæ corresponding to the simple circle diagram already mentioned, while col. 2 shows the more accurate formulæ which take full account of the change in magnetizing current and change of phase angle between the mutually induced E.M.F. in the primary and the applied voltage with change of speed. The general method of obtaining these expressions is indicated in

* Symbolic values are denoted $\dot{Z}_1$, $\dot{Z}_2$, etc., and virtual values Z_1, Z_2, etc.

The denominator of this expression occurs repeatedly throughout all the various equations relating to the motor, and for convenience the individual items are expressed by the following constants :—

$\alpha = r_2(r_m + r_1)$; $\beta = r_1r_m - x_mx_t - x_1x_2$;
$\rho = r_2(x_m + x_1)$; $\mu = r_1x_m + r_mx_t + r_1x_2$.

Then $$\dot{I}_1 = \dot{E}_1\frac{(sr_m + r_2) + j(sx_m + sx_2)}{(\alpha + \beta s) + j(\rho + \mu s)}$$

the virtual value of which is

$$I_1 = E_1\sqrt{\left[\frac{(sr_m + r_2)^2 + (sx_m + sx_2)^2}{(\alpha + \beta s)^2 + (\rho + \mu s)^2}\right]}$$

The torque formula is obtained in a similar manner

TABLE.

INDUCTION-MOTOR PERFORMANCE FORMULÆ.

	(1) APPROXIMATE FORMULÆ	(2) CORRECT FORMULÆ
Primary current at any slip s ..	$E_1\sqrt{\left[\frac{(r_2+sr_1+sr_m)^2+(sx_t+sx_m)^2}{(r_2r_m+sr_1r_m-sx_mx_t)^2+(sr_mx_t+sr_1x_m+r_2x_m)^2}\right]}$	$E_1\sqrt{\left[\frac{(sr_m+r_2)^2+(sx_m+sx_2)^2}{(\alpha+\beta s)^2+(\rho+\mu s)^2}\right]}$
Secondary current at any slip s ..	$\frac{sE_1}{\sqrt{[(r_2+sr_1)^2+s^2x_t^2]}}$	$\frac{sE_1Z_m}{\sqrt{[(\alpha+\beta s)^2+(\rho+\mu s)^2]}}$
Torque at any slip s	$\frac{sE_1^2r_2}{(r_2+sr_1)^2+s^2x_t^2}$	$\frac{sE_1^2r_2Z_m^2}{(\alpha+\beta s)^2+(\rho+\mu s)^2}$
Maximum torque	$\frac{E_1^2}{2[r_1+\sqrt{(r_1^2+x_t^2)}]}$	$\frac{E_1^2r_2Z_m^2}{2\{\alpha\beta+\rho\mu+\sqrt{[(\alpha^2+\rho^2)(\beta^2+\mu^2)]}\}}$

Maximum power	$\frac{E_1^2}{2(Z_t+r_t)}$	$\frac{E_1^2r_2Z_m^2}{2\left\{\alpha\beta+\rho\mu+(\alpha^2+\rho^2)\left[1+\sqrt{\left(\frac{(\alpha+\beta)^2+(\rho+\mu)^2}{\alpha^2+\rho^2}\right)}\right]\right\}}$
Slip at maximum power	$\frac{r_2}{Z_t+r_2}$	$\frac{1}{1+\sqrt{\left[\frac{(\alpha+\beta)^2+(\rho+\mu)^2}{\alpha^2+\rho^2}\right]}}$

Z_1 = Primary self-inductive impedance.
Z_2 = Secondary self-inductive impedance.
Z_m = Mutual inductive impedance.

$Z_1 = r_1 + jx_1$; $Z_1 + Z_2 = Z_t$
$Z_2 = r_2 + jx_2$; $r_1 + r_2 = r_t$
$Z_m = r_m + jx_m$; $x_1 + x_2 = x_t$

$\alpha = r_2(r_m + r_1)$
$\beta = r_1r_m - x_mx_t - x_1x_2$

$\rho = r_2(x_m + x_1)$
$\mu = r_mx_t + r_1(x_m + x_2)$

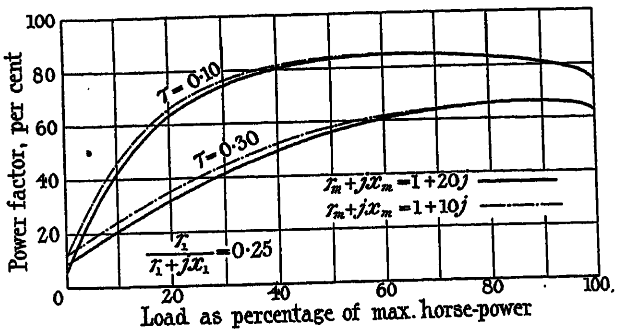

FIG. 2.—Curves showing the effect of iron loss on the power factor of an induction motor (short-circuit power factor = 0·25).

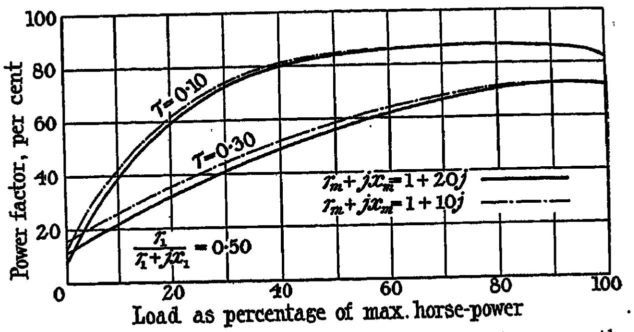

FIG. 3.—Curves showing the effect of iron loss on the power factor of an induction motor (short-circuit power factor = 0·5).

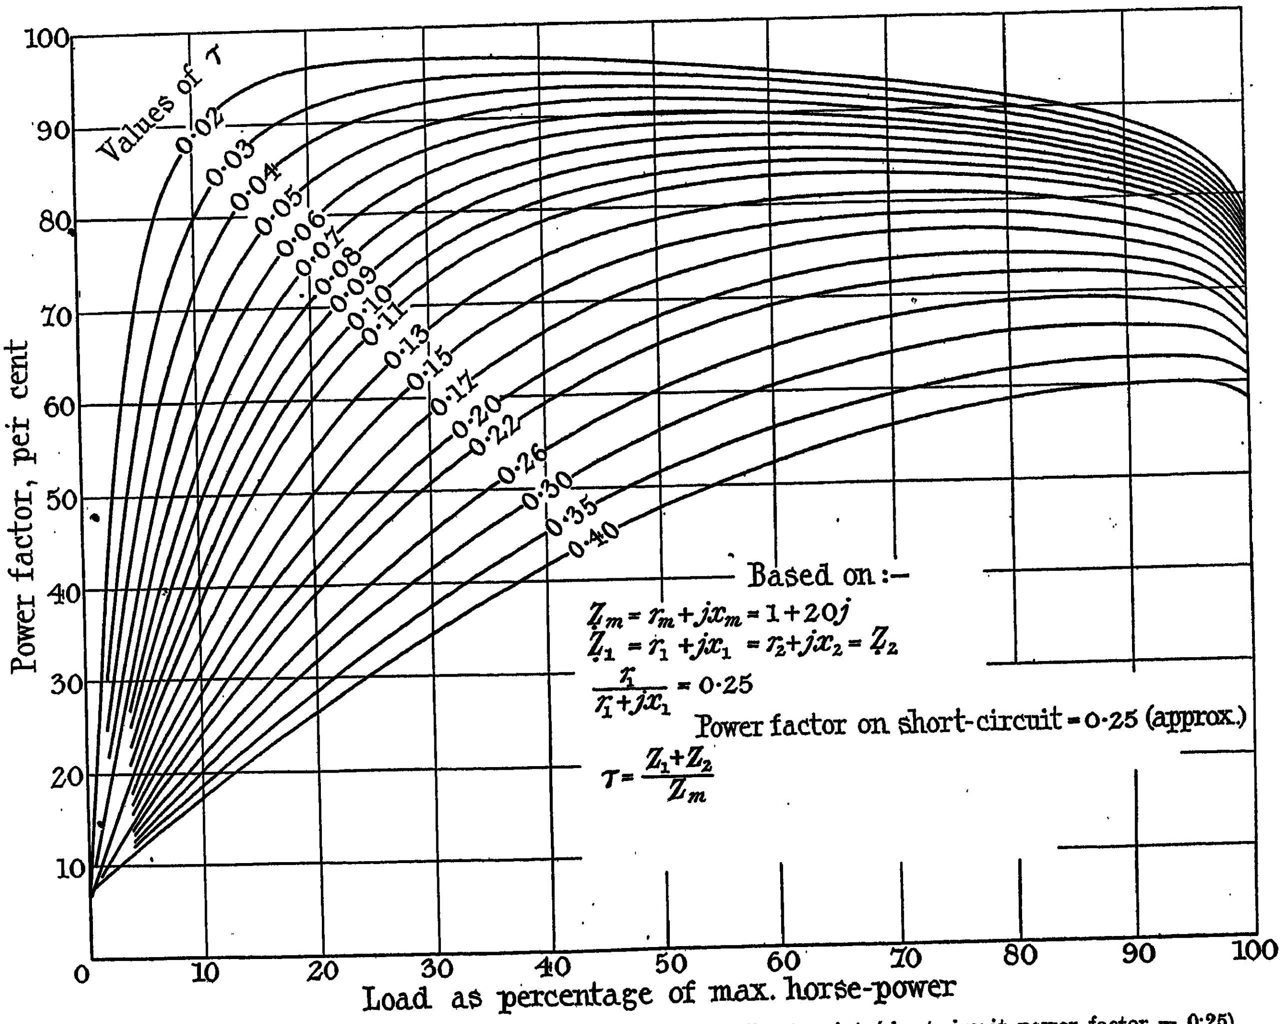

FIG. 4.—Induction-motor power factor curves from no-load to pull-out point (short-circuit power factor = 0·25).

and from this, by differentiation, the slip for maximum torque, and thus the maximum torque is also deduced. By multiplying by $(1 - s)$ an expression for power output is obtained from the torque formula, and, again by differentiating, the slip for maximum power is obtained and thus the maximum power.

(4) INDUCTION-MOTOR PERFORMANCE CURVES.

The extent of the difference between the results given by the two groups of formulæ depends on the ratio of working out the power factors from the primary current formula in column 2 of the table for the various sets of conditions, a complete group of curves can be produced which will enable the power factor of a motor to be determined at any load. These curves would take into consideration all the conditions governing the motor power factor, such as change in magnetizing current due to primary impedance drop, and change of phase angle of the primary back E.M.F.

In order to produce the curves mentioned above,

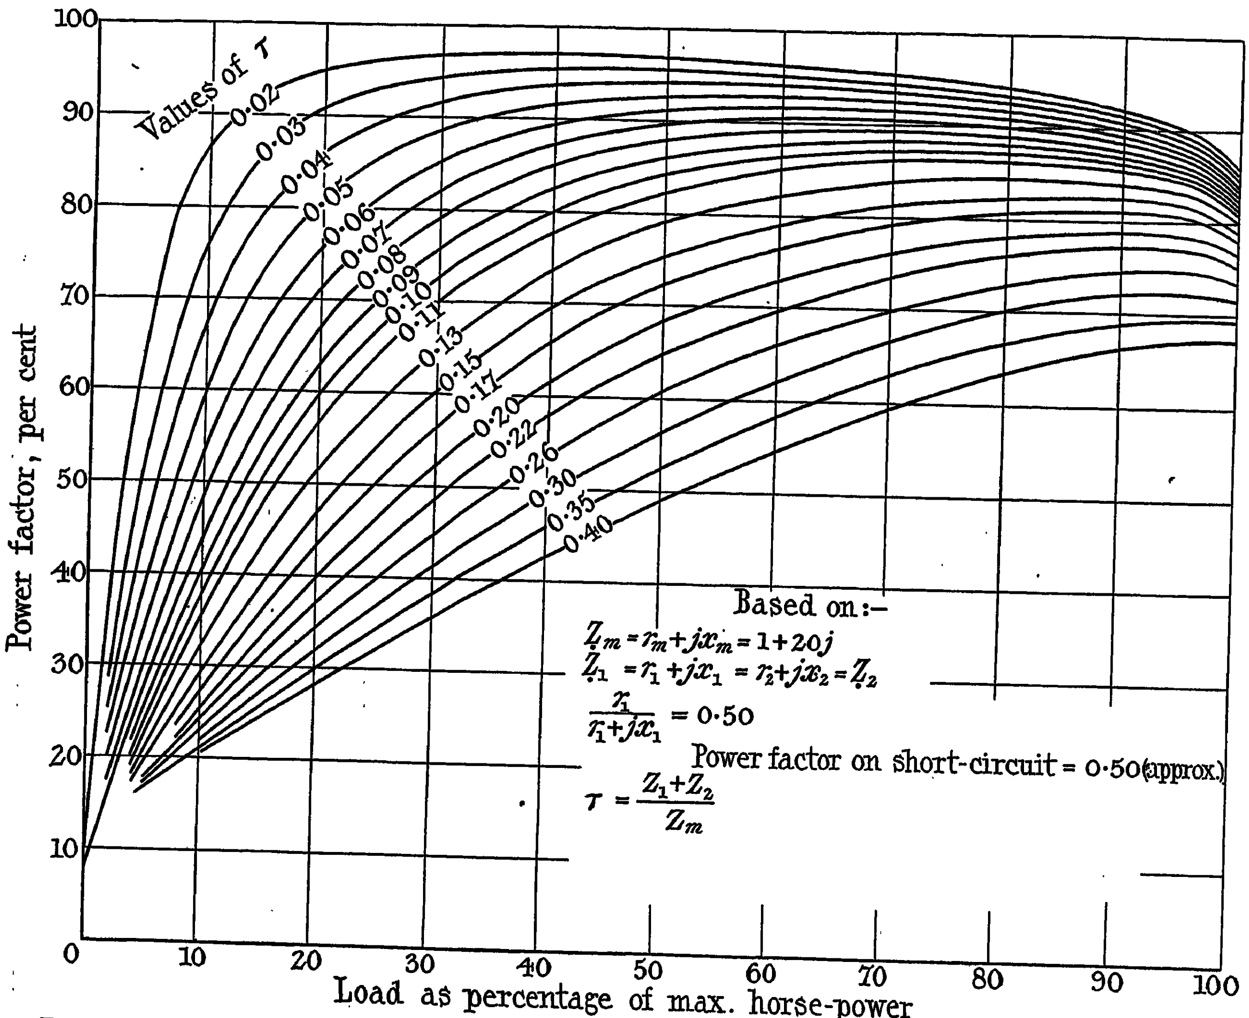

FIG. 5.—Induction-motor power factor curves from no-load to pull-out point (short-circuit power factor = 0·5).

the mutual inductive impedance to the total self-inductive impedance. For example, in the case of a motor with a comparatively small magnetizing current the results obtained will be almost the same from both formulæ. For machines with a large amount of magnetizing current, however, the results obtained may differ widely. If curves are plotted on the basis of the ratio of the mutual to the total self-inductive impedance, it is possible to obtain a series of correction factors for the approximate formulæ which will enable the correct figures to be obtained. Furthermore, by certain assumptions must be made. First, the primary and secondary impedances at the line frequency are assumed to be equal. This is usually not far wrong, and the errors likely to occur from the assumption will be small. Secondly, the power factor in the magnetizing circuit must be fixed. An analysis has been made of a number of tests on machines varying from ½ h.p. to 200 h.p. and the limits of power factor variation in the magnetizing circuit appear to be from 0·05 to 0·10. This power factor is really an indication of the proportion of iron loss in the machine, and its effect

on the overload capacity and short-circuit current of the motor will be negligible. The effect on the total power factor is shown in Figs. 2 and 3 for two values of τ in each case, where $\tau = Z_t/Z_m$.

The majority of the tests analysed were nearer the power factor of 0·05 than 0·10, and as this figure causes the estimated results to be slightly on the low side it has been used in compiling the remaining curves.

A third assumption which must be made is the power factor of the self-inductive circuits at the supply frequency. This usually lies between 0·25 and 0·50. If, then, two sets of curves are available for power factors of 0·25 and 0·5 respectively, by using both curves and making allowance for the difference according to the exact figure for the self-inductive power factor, comparatively accurate results can be obtained.

On the basis of the above assumptions two sets of curves have been drawn in Figs. 4 and 5, giving induction-motor power factors at all loads from no load to the "pull out" point and for values of τ from 0·02 to 0·40. Similarly the maximum powers have been worked out, using the two formulæ given in cols. 1 and 2 of the table, and the relationship is plotted in Fig. 6. The maximum power calculated from formula (1) has been called the "apparent" maximum, and that obtained by formula (2) the "actual" maximum. In the case of these curves and with the higher values of τ it will be observed that quite an appreciable reduction in estimated overload capacity occurs. To take an extreme case, a motor might have an apparent overload capacity of 1·75 times full load momentarily, whereas the actual figure could be as low as 1·35 to 1·40 times full load. Fig. 7 has been drawn with the object of indicating the effect of the magnetizing-current component of the short-circuit current. It is generally stated that the short-circuit current is given by dividing the impressed voltage by the total self-inductive impedance, or, alternatively, that the total

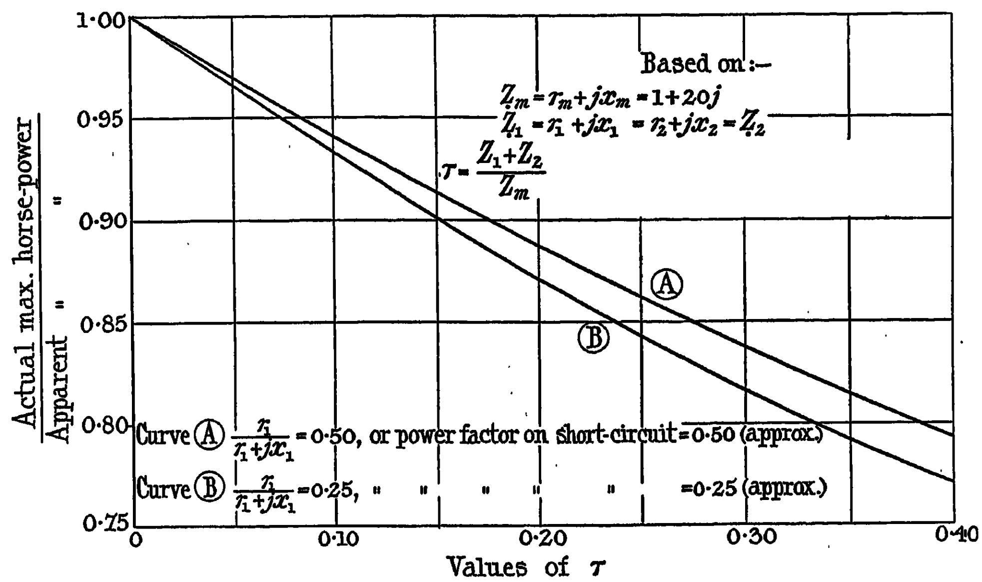

FIG. 6.—Curves showing actual and apparent maximum horse-power.

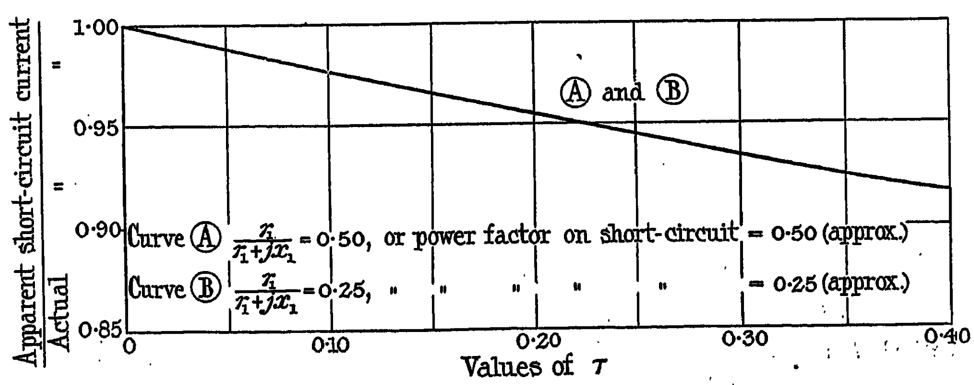

FIG. 7.—Curves showing actual and apparent short-circuit current.

self-inductive impedance is given by dividing the impressed voltage by the short-circuit current. This statement has generally been qualified by assuming a normal relationship between Z_t and Z_m, and it has been pointed out that some of the current measured on short-circuit is actually magnetizing current. In Fig. 7 the current obtained by dividing the impressed voltage by Z_t has been termed "apparent" short-circuit current, while that obtained by working out the formula in col. 2 of the table for $s = 1 \cdot 0$ has been termed "actual" short-circuit current. The results indicate that this point is of no very great consequence, as the actual numerical values in the worst case are only about 8 per cent in error. The variations in self-inductive impedance due to differences in manufacture are often of this order or greater.

The method of applying the curves in actual practice is as follows. After the completion of the customary preliminary designs and when the actual windings have been fixed, the magnetizing current and leakage flux are estimated in the usual way. The iron loss is then determined and the values of r_m and x_m are found. It should be noted that when the power factor is as low as $0 \cdot 05$ to $0 \cdot 10$ the numerical difference between the reactance and impedance is so small that the ohmic values of r_m and x_m are given by :—

$$r_m = \frac{P}{I_m^2}; \quad x_m = \frac{E}{I_m}$$

where E = the voltage considered in estimating P and I_m,
I_m = the estimated magnetizing current, and
P = the estimated iron loss, in watts.

The resistances of the primary and secondary windings are next calculated and that of the secondary referred to the primary. From the leakage flux the total motor reactance is determined, and finally the total self-inductive impedance Z_t and the value of τ. The apparent maximum horse-power is calculated in line with col. 1 in the table and then from Fig. 6 the appropriate correction factor is determined. Using the actual maximum horse-power and knowing the value of τ, the motor power factor at any load can be found from Figs. 4 and 5. The remainder of the performance data, i.e. slip, losses and efficiency, are determined in the usual way.

(5) Tests and Conclusions.

The two following examples indicate the results obtained by the application of the curves. The results given under method 1 are obtained by using the approximate formulæ given in col. 1 of the table, and those under method 2 show the effect of applying the correction factors.

(1) $3\frac{1}{2}$ *h.p., three-phase, 50-period, 400-volt, 715-r.p.m. slip-ring motor for crane service.* Half-hour rating.

$$r_m + jx_m = 2 + 38j; \quad Z_m = 38$$
$$r_t + jx_t = 4 \cdot 6 + 9 \cdot 0j; \quad Z_t = 10 \cdot 1$$
$$r_t/Z_t = 0 \cdot 46; \quad \tau = 0 \cdot 266$$
Volts per phase = 231.

	Method 1	Method 2	Test
Maximum horse-power	2·08 × full load	1·75 × full load	—
Full-load power factor	0·55	0·63	0·65
$\frac{3}{4}$ load power factor ..	0·46	0·54	0·55
$\frac{1}{2}$ load power factor ..	0·35	0·42	0·43

(2) 60 *h.p., three-phase, 50-period, 415-volt, 322-r.p.m. slip-ring motor.* Standard 6-hour rating.

$$r_m + jx_m = 1 \cdot 14 + 15 \cdot 6j; \quad Z_m = 15 \cdot 6$$
$$r_t + jx_t = 0 \cdot 50 + 2 \cdot 56j; \quad Z_t = 2 \cdot 6$$
$$r_t/Z_t = 0 \cdot 19; \quad \tau = 0 \cdot 166$$
Volts per phase = 415.

	Method 1	Method 2	Test
Maximum horse-power	1·86 × full load	1·65 × full load	—
Full-load power factor	0·74	0·76	0·77
$\frac{3}{4}$ load power factor ..	0·69	0·71	0·73
$\frac{1}{2}$ load power factor ..	0·58	0·60	0·62

In using the curves the assumptions upon which they are based should be kept in view as, although accurate results are obtained over a wide range, occasional cases will occur in which, for example, the primary impedance differs considerably from the equivalent secondary impedance, or the iron loss is excessive. The friction, windage and tooth-frequency iron losses all require an output torque from the secondary and should consequently be added to the load to obtain the total secondary output. In highly saturated machines the power factor will be slightly higher than that given by the curves, as a small increase in the primary drop will result in considerable reduction in magnetizing current.

A NEW TYPE OF SQUIRREL-CAGE INDUCTION MOTOR WITH HIGH STARTING TORQUE.

By T. F. WALL, D.Sc., D.Eng., Associate Member.

(*Paper first received* 15*th July, and in final form* 26*th November*, 1924; *read before the* SHEFFIELD SUB-CENTRE 17*th December*, 1924.)

SUMMARY.

This paper contains an account of tests made on a new type of squirrel-cage induction motor with high starting torque. Each conductor of the rotor winding is a compound bar of which the characteristic property is that the resistance increases with the frequency of the alternating current flowing in it.

The compound bars are each built up as follows: There is a central core of copper, which is surrounded by a sleeve of steel. Outside the steel sleeve is a skin of copper, the outer copper skin and the central copper core being brought into good electrical contact at each end. When alternating current flows through the compound conductor the portion passing through the central copper core produces in the steel sleeve a magnetic flux which induces a back E.M.F. tending to choke the current out of the core. The result is that the current will flow chiefly through the high-resistance copper skin outside the steel sleeve. The greater the frequency of the alternating current the greater will be the back E.M.F., and the effective resistance of the compound bar will be correspondingly increased.

If a squirrel-cage rotor winding is formed from these compound conductors, then, at starting, since currents of the full supply frequency will flow in the bars, the effective resistance and the starting torque will be high. When running normally, the currents in the rotor bars will be at the very low frequency of slip and hence the resistance will be correspondingly low; in fact, it will be practically the same as the resistance as measured by direct current.

The paper contains the results of tests made on a squirrel-cage rotor built with compound conductors in accordance with the author's proposals, and also the test-results on a standard rotor, the same stator being used in each case.

TABLE OF CONTENTS.

INTRODUCTORY.

The squirrel-cage induction motor is probably the simplest, most robust, and cheapest machine yet invented for transforming energy. The great defect, however, under which this type of machine suffers and which is seriously retarding its full exploitation, is the fact that if it is started by being switched directly on to the supply mains there will be a heavy initial rush of current in the line. Since this starting current has a low power factor the voltage regulation of the supply mains might be seriously affected if no limitations as to the size and number of such squirrel-cage motors were to be enforced.

The electric supply undertakings in this country and on the Continent are not favourably disposed to the installation of squirrel-cage induction motors in any but the smallest sizes unless means are provided for limiting the rush of current in the line at starting.

The standard methods used in practice for complying with this requirement result in a very poor starting torque, so that the motor cannot start under full load. It therefore becomes necessary either to provide a fast-and-loose pulley arrangement, or to fit some form of centrifugal clutch so that the load is not applied until the motor reaches full speed or nearly full speed. Such accessories, however, cannot but deprive the squirrel-cage motor of its most striking inherent characteristics of cheapness, simplicity and robustness, and consequently this type of motor has not taken the place to which it is naturally entitled in the industrial applications of the electrical drive.

In this paper the author describes a new method of providing a squirrel-cage motor with a high starting torque without necessitating a prohibitively large starting current in the line. It is hoped that these proposals may point the way to the definite solution of this long-standing and troublesome practical problem.

THEORY.

It is generally recognized that the proper solution of the problem of high starting torque and low starting current is the use of a high resistance in the rotor circuit at starting. An inspection of the formula* for the torque of an induction motor shows that the starting torque is, within limits, almost directly proportional to the rotor resistance, and it is also obvious that the starting current will be reduced as the rotor resistance is increased.

When a wound rotor provided with slip-rings is used, it is a simple matter to introduce resistances in series with the rotor winding at starting and to cut them out as the motor runs up to speed, so that eventually —when the motor has attained full speed—all the starting resistances have been cut out and the rotor winding has been short-circuited. The superior starting characteristics of wound rotors give them almost the monopoly of use in this country and on the Continent for all motors except those of the smallest sizes.

* *Journal I.E.E.*, 1923, vol. 61, p. 129.

For many years, attempts have been made to produce a squirrel-cage rotor which shall have a high effective resistance at starting and a low effective resistance when running, so that the good starting characteristics

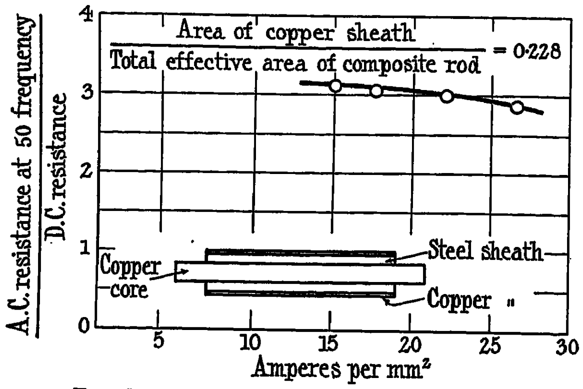

FIG. 1.—Current density in composite rod.

are not obtained at the expense of poor efficiency when running. References to the literature of the subject will show what a great variety of proposals have been made for this purpose but, so far as the author is aware, none of them has yet established itself in practice.

FIG. 2.

NOTE: The zero lines of the two waves are not coincident.

In the present paper, attention is concentrated on a method recently developed by the author which is considered to have advantages not possessed by any previous proposal. A number of test data have been obtained, which it is hoped may form the basis of the design of squirrel-cage rotors for any required practical conditions. The data given later in the paper have been obtained from an actual experimental motor of 57 b.h.p. built in accordance with the author's proposals by Messrs. J. H. Holmes and Co. and tested by them at their works in Newcastle-on-Tyne.

Before proceeding to the consideration of the rotor construction as proposed by the author, a short review of previous cognate work will be given.

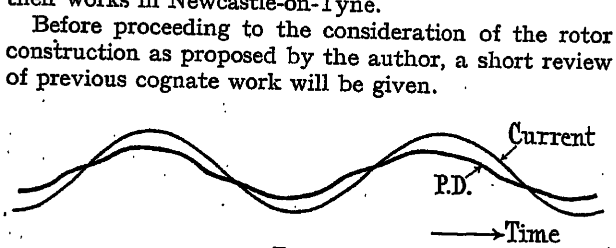

FIG. 3.

NOTE: The zero lines of the two waves are not coincident.

In the year 1900 H. M. Hobart proposed to make use of the "skin effect" in iron for improving the starting characteristics of squirrel-cage rotors, and for this purpose he proposed the use of iron rotor bars. The idea was that at starting, the frequency of the rotor currents being the full supply frequency, the skin effect in the iron conductors would cause them to have a high effective resistance at starting. When, however, the motor is running at full speed, the frequency of the currents in the rotor bars will be the frequency of the rotor slip, and will therefore be so small that the skin effect becomes very slight, so that the resistance of the rotor winding is not much different from the value which would be obtained if measured for direct current. In accordance with this proposal, therefore, the rotor resistance would be automatically altered in accordance with the requirements and the rotor construction would lose none of its robustness, simplicity or cheapness.

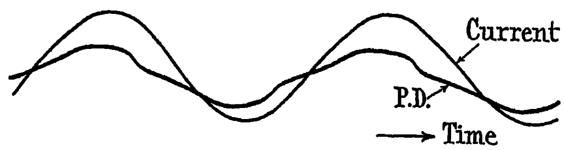

FIG. 4.

NOTE: The zero lines of the two waves are not coincident.

For several reasons this proposal has not met the practical requirements and, so far as the author is aware, has not been used on a commercial scale.

In 1915 Elihu Thomson proposed to make use of the

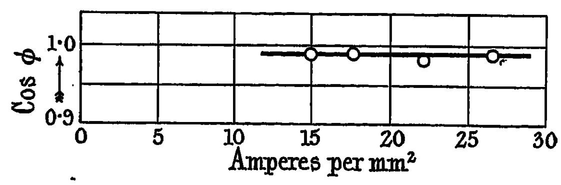

FIG. 5.—Current density in composite rod.

skin effect by means of special compound bars for the rotor winding. The bars were to be constructed of a central copper core surrounded by a steel sheath. At starting, the high-frequency currents, by reason of the back E.M.F. induced in the central copper core and

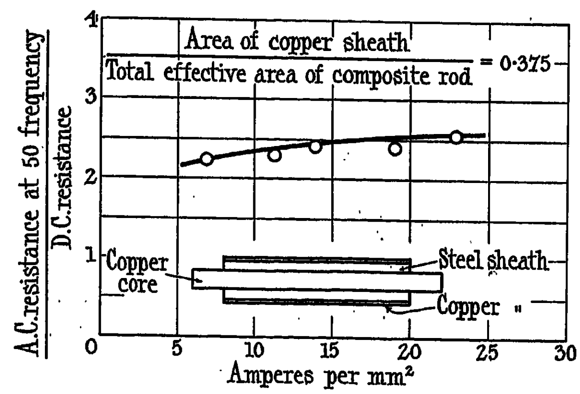

FIG. 6.—Current density in composite rod.

due to the magnetic field in the surrounding steel sheath, would be forced into the steel sheath so that very little current would flow in the central copper core. In this way the composite bar would be caused to have a high effective resistance when the motor was starting. When the frequency of the rotor currents

was reduced to the frequency corresponding to the rotor slip, the back E.M.F. induced in the central copper core would be correspondingly reduced so that practically all the current would flow in the central copper core, thus giving a low resistance when the motor is running.

Although this was a great advance on Hobart's original proposal, it has not met the practical requirements and the author believes that it has not been used to any extent. The reasons for this will be more apparent after a consideration of the test data given below, which have been obtained from an actual composite conductor constructed in accordance with the principle just stated.

The essential features of the method proposed by the author were described in a preliminary paper read before Section G of the British Association at Liverpool in 1923. Briefly stated, each rotor conductor is in effect a simple form of auto-transformer. It is well known, from the theory of transformers, that when the secondary winding is short-circuited the effective resistance of the primary winding is given by the expression

$$R_1 + \frac{M^2 R_2 \omega^2}{(L_2\omega)^2 + R_2^2}$$

where R_1 = resistance of the primary winding, in ohms,
R_2 = resistance of the secondary winding, in ohms,
L_2 = inductance of the secondary winding, in henrys, and
$\omega = 2\pi \times$ supply frequency.

This expression for the effective resistance of the primary winding shows that the resistance *increases* as the supply frequency increases.

Further, the effective inductance of the primary winding when the secondary is short-circuited is given by the expression

$$L_1 - \frac{L_2 M^2 \omega^2}{(L_2\omega)^2 + R_2^2}$$

where L_1 = inductance of the primary winding.

This expression shows that the effective inductance of the primary winding when the secondary is short-circuited *decreases* as the supply frequency increases.

Actually, each rotor bar is constructed as follows: A central copper core is surrounded by a steel sheath of suitable thickness which may or may not be in electrical contact with the copper core. The steel sheath is then covered with a copper skin of suitable sectional area and this outer copper skin is brought into good electrical contact at each end with the central copper core. A diagrammatic sketch of the composite rod is shown in Figs. 1 and 6. As already stated, such a composite conductor is, in effect, a simple form of auto-transformer with short-circuited secondary winding. The central copper core forms the primary winding, the steel sheath is the magnetic core, and the outer copper skin is the secondary winding.

If a squirrel-cage rotor is constructed with such composite bars, then, at starting, the frequency of the currents induced in the bars being of the full supply frequency, the effective resistance will be relatively high in accordance with the expression given above. When the rotor is running normally, the currents in the rotor bars will be of very low frequency corresponding to the rotor slip; consequently, the effective resistance of the composite bars will be correspondingly reduced and will, in fact, be practically the same as that found by direct-current measurement.

The relative thicknesses of the central copper core, the steel sheath, and the outer copper skin, are of great importance in determining a satisfactory performance and, in order to obtain a basis for the design and the predetermination of performance, a large number of tests have been carried out on composite rods of various proportions. A selection of these test-results are given below.

TESTS A.

Determination of the Influence of the Thickness of the Outer Copper Skin on the Characteristics of the Composite Rod.

For these tests the central copper core and the steel sheath were kept the same throughout and measurements were made of the characteristics for several different thicknesses of the outer copper skin. The dimensions of the central copper core and the steel sheath were as follows:

Diameter of central copper rod	5·9 mm
Cross-sectional area of central copper core	27·3 mm²
Radial thickness of steel tube	2·95 mm
Cross-sectional area of steel tube	84·0 mm²
Length of steel tube	20·3 cm

The steel tube was brought into good electrical contact with the central copper core at each end by soldering, so that the steel tube was effective in carrying a portion of the current, particularly at the very low frequencies.

The specific resistance of the steel used was 11 times that of copper, so that the equivalent area of the steel tube when referred to the conductivity of copper was 7·6 mm².

The total effective area of the central copper rod and the steel tube was therefore 34·9 mm².

(i) *Area of the outer copper skin* = 10·3 *mm*².—The total effective area of the composite rod in this case was consequently 45·2 mm², so that the ratio

$$\frac{\text{Area of outer copper skin}}{\text{Total effective area of composite rod}} = 0\cdot 228.$$

Tests were made of the effective resistance and the power factor of the composite rod when supplied with current of 50 frequency. The resistance measurements were made by means of a vacuum thermo-junction and galvanometer which was used to determine the potential difference across the rod when the alternating current was flowing, the thermo-junction and galvanometer being afterwards calibrated by direct current. The values of the power factor were ascertained from the oscillograms of the P.D. and current waves.

In Fig. 1 is shown the relationship between the ratio (A.C. resistance at 50 frequency)/(D.C. resistance) and the effective current density in the composite rod,

the effective current density being obtained by dividing the current by the equivalent area of 45·2 mm² as calculated in the foregoing.

These tests were made with values of the effective current density up to 27 amperes per mm², which

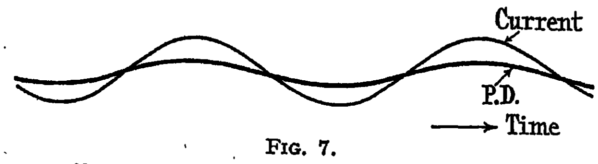

Fig. 7.
Note: The zero lines of the two waves are not coincident.

fully covers the range concerned in the starting conditions of squirrel-cage motors. Usually the normal full-load current density in practice is about 6 to 7 amperes per mm². During the starting period, however, the current density will be many times greater than the

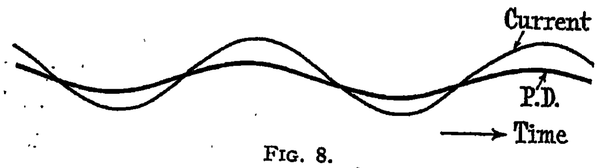

Fig. 8.
Note: The zero lines of the two waves are not coincident.

normal full-load value, and hence it is necessary that the tests should be made over a sufficiently wide range to cover the maximum current density likely to be obtained.

Reference to Fig. 1 shows that the effective resistance

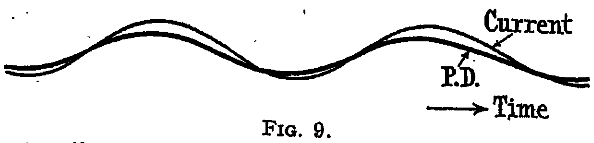

Fig. 9.
Note: The zero lines of the two waves are not coincident.

with alternating current at 50 frequency *decreases* slightly with the current density, the average value of the effective resistance being about 3 times the resistance as measured with direct current.

In Figs. 2, 3 and 4 are given the oscillograms of the

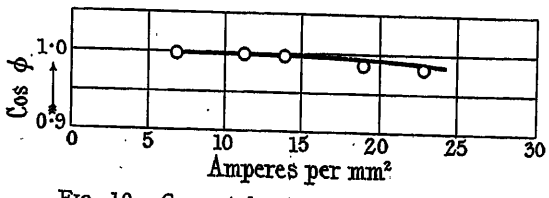

Fig. 10.—Current density in composite rod.

P.D. and current waves for current densities of 17·6, 22·1 and 26·6 amperes per mm² respectively. From these oscillograms the curve of Fig. 5 has been deduced, showing the power factor as a function of the current density, and it will be seen that the average value of the power factor in this case is about 0·987.

(ii) *Area of the outer copper skin* = 20·9 *mm*².—The total effective area of the composite rod in this case was therefore 55·8 mm², so that the ratio (Area of outer copper skin)/(Total effective area of composite rod) is 0·375.

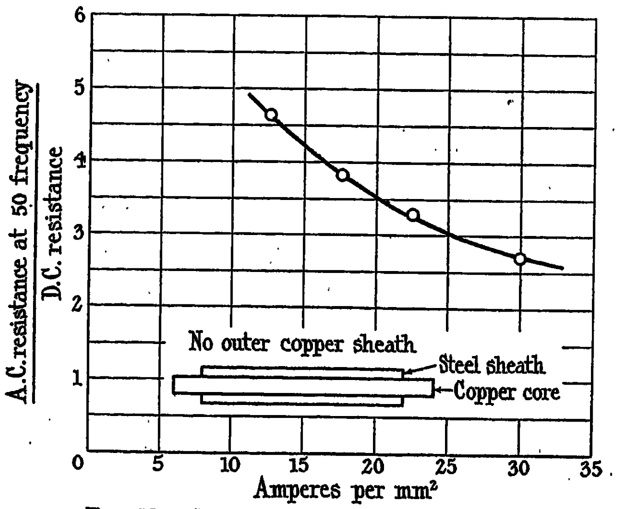

Fig. 11.—Current density in composite rod.

In Fig. 6 is shown the relationship between the ratio (A.C. resistance at 50 frequency)/(D.C. resistance) and the effective current density in the composite rod.

Fig. 12.
Note: The zero lines of the two waves are not coincident.

It will be seen that in this case the effective resistance *increases* slightly with the current density, the average value of the effective resistance for the range tested

Fig. 13.
Note: The zero lines of the two waves are not coincident.

being about 2·5 times the resistance as measured with direct current.

In Figs. 7, 8 and 9 are given the oscillograms showing the P.D. and current waves for current densities of 13·9, 19·0 and 22·9 amperes per mm² respectively. From these oscillograms the curve of Fig. 10 has been deduced showing the power factor of the composite

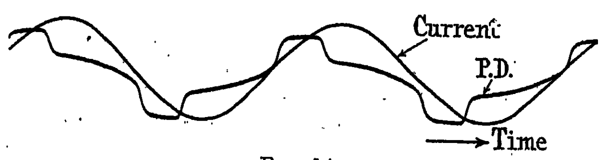

Fig. 14.
Note: The zero lines of the two waves are not coincident.

rod as a function of the current density, and it will be seen that the power factor for current densities up to about 15 amperes per mm^2 is very close to unity.

(iii) *No outer skin used.*—The composite rod comprising merely a central copper rod and a steel sheath corresponds to the proposal made by Elihu Thomson, to which reference has been made in the foregoing.

In order to ascertain for comparative purposes what the characteristics of this type of composite conductor are, tests were made with the composite rod detailed in the foregoing but with the outer copper skin removed.

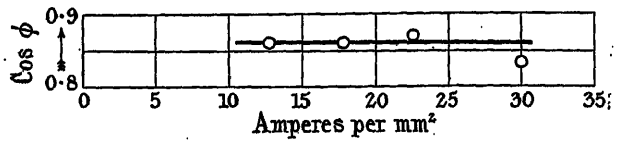

FIG. 15.—Current density in composite rod.

In Fig. 11 is shown the relationship between the ratio (A.C. resistance at 50 frequency)/(D.C. resistance) and the effective current density in the composite rod. It will be seen from Fig. 11 that the resistance decreases to a very marked degree with an increase of current density. That is to say, the rod has to some extent a negative resistance characteristic, which may result in an unstable condition so that the current may increase to an unduly large value.

In Figs. 12, 13 and 14 are shown the oscillograms for the P.D. and current waves for current densities of 17·75, 22·6 and 30 amperes per mm^2. From these oscillograms the curve of Fig. 15 has been deduced

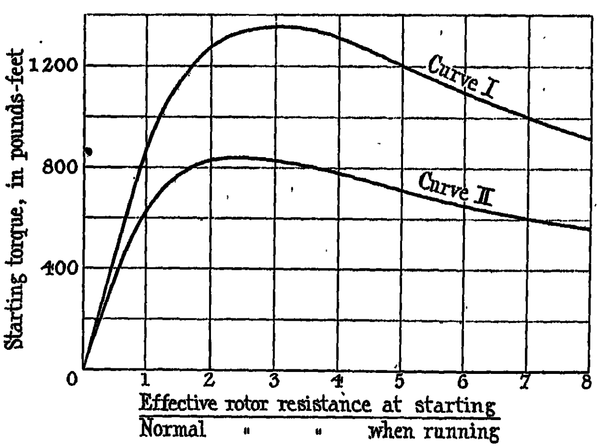

FIG. 16.

showing the relationship between the power factor of the composite rod and the current density, and it will be seen that the average value of the power factor in this case is about 0·865. This is a very low value and appears to the author to be one of the chief reasons why the use of such composite conductors (that is, without any outer copper skin) has not been found satisfactory.

In order to show the great significance of the power factor on the starting characteristics of the motor, the curves given in Fig. 16 have been calculated for the case of the motor for which the specification is given later in this paper. These curves show the relationship between the starting torque and the ratio (Effective rotor resistance at starting)/(Normal rotor resistance when running). Curve I refers to the case in which the increased rotor resistance at starting is obtained by means of conductors which have unity power factor, and Curve II refers to the case in which the increased rotor resistance at starting is obtained by means of conductors having a power factor of 0·86. It will be seen that for a given effective rotor resistance at starting the starting torque when the power factor is 0·86 is not much more than one-half the torque when the power factor of the resistance is unity. This shows in a very striking way the importance of obtaining the increase of the starting resistance at as high a power factor as possible.

The composite conductors with an outer copper skin have a further advantage over composite conductors without an outer copper skin, in that the power factor of the former when the rotor is running at normal speed will be considerably greater than the power factor of the conductors which have merely a steel sheath. The reason for this is that a large proportion of the current can flow through the outer copper skin when such is provided and, of course, in so far as the outer copper skin is concerned, the steel sheath has no effect on its inductance.

A further important deduction which can be made from Curve I of Fig. 16 is that the maximum starting torque obtainable by increasing the rotor resistance is reached when the increased rotor resistance is only about three times the normal running resistance.

TESTS B.

DETERMINATION OF THE INFLUENCE OF THE THICKNESS OF THE STEEL SHEATH ON THE CHARACTERISTICS OF THE COMPOSITE ROD.

In order to ascertain the effect of the influence of the thickness of the steel sheath on the characteristics

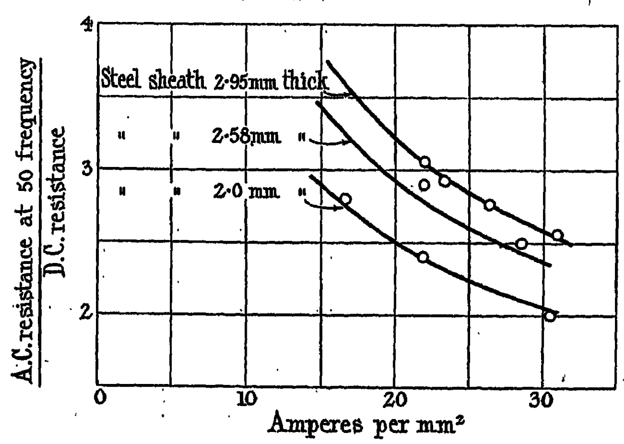

FIG. 17.—Current density in composite rod.

of the composite rod, tests were made with three rods, each having a different thickness of steel sheath. The

data of these rods and the results obtained from the tests are as follows :—

Composite Rod " A."

Thickness of steel sheath	2 mm
Diameter of central copper rod	6·1 mm
Area of central copper rod	29·4 mm^2
Radial thickness of steel sheath	2 mm
Length of steel sheath	20·2 cm
Effective cross-sectional area of steel sheath reduced to conductivity of copper ..	4·75 mm^2
Area of outer copper skin	6·30 mm^2
Total effective area of composite rod ..	40·45 mm^2

$$\frac{\text{Area of outer copper skin}}{\text{Total effective area of composite rod}} = 0{\cdot}155.$$

In Fig. 17 the results of the resistance tests on this rod are plotted as the lowest of the three curves there

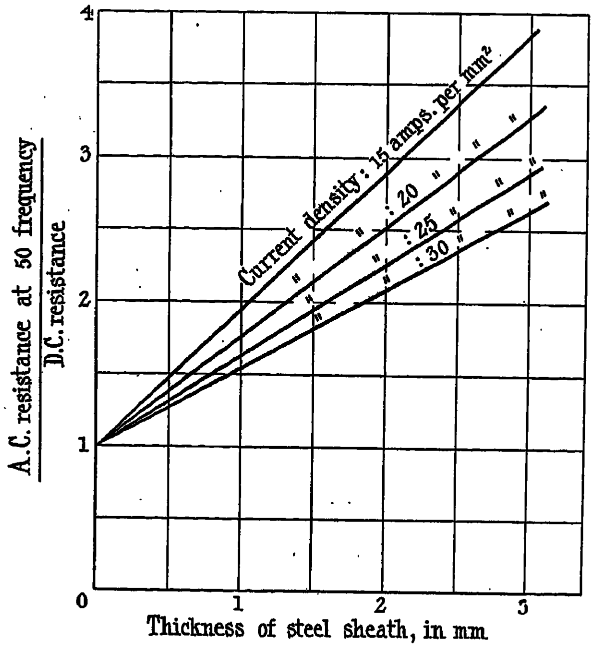

FIG. 18.

given. This curve shows the relationship between the current density in the rod and the ratio (A.C. resistance at 50 frequency)/(D.C. resistance).

Composite Rod " B." Thickness of steel sheath 2·58 mm.

Diameter of central copper rod	6·3 mm
Area of central copper rod	31·5 mm^2
Radial thickness of steel sheath	2·58 mm
Length of steel sheath	20·2 cm
Effective cross-sectional area of steel sheath reduced to conductivity of copper ..	6·63 mm^2
Area of outer copper skin	5·08 mm^2
Total effective area of composite rod ..	43·21 mm^2

$$\frac{\text{Area of outer copper skin}}{\text{Total effective area of composite rod}} = 0{\cdot}118.$$

In Fig. 17 the results of the resistance tests on this rod are given in the middle curve.

Composite Rod " C." Thickness of steel sheath 2·95 mm.

Diameter of central copper rod	5·9 mm
Area of central copper rod	27·3 mm^2
Radial thickness of steel sheath	2·95 mm
Length of steel sheath	20·2 cm
Effective cross-sectional area of steel sheath reduced to conductivity of copper ..	7·63 mm^2
Area of outer copper skin	5·7 mm^2
Total effective area of composite rod ..	40·63 mm^2

$$\frac{\text{Area of outer copper skin}}{\text{Total effective area of composite rod}} = 0{\cdot}14.$$

In Fig. 17 the results of the resistance tests on this rod are given in the highest of the three curves.

From the results given in the three curves of Fig. 17 the relationship between the thickness of the steel sheath and the ratio (A.C. resistance at 50 frequency)/(D.C. resistance) has been deduced and plotted in Fig. 18. This relationship has been deduced for the following values of the current density, viz. 15, 20, 25 and 30 amperes per mm^2 respectively. It is interesting to note in Fig. 18 that the a.c. resistance of the composite rod increases proportionally to the thickness of the steel sheath.

TEST-RESULTS OBTAINED FROM A SQUIRREL-CAGE ROTOR BUILT WITH COMPOSITE CONDUCTORS IN ACCORDANCE WITH THE AUTHOR'S PROPOSALS.

In order to obtain some practical test data as to the extent to which the results detailed in the foregoing could be usefully applied in the actual construction of a squirrel-cage rotor with high starting torque, Messrs.

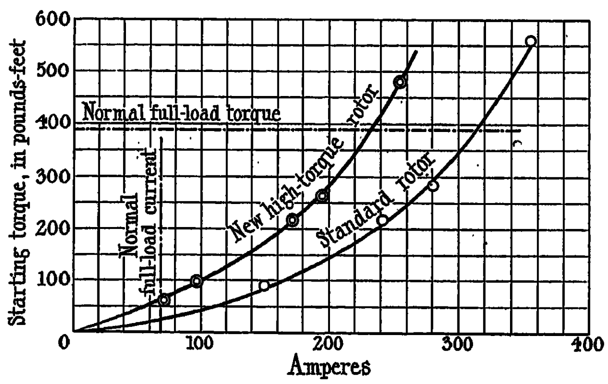

FIG. 19.—Starting-torque curves.

J. H. Holmes and Co., Ltd., in collaboration with the author, built a sample squirrel-cage rotor and tested it in a standard stator. The test data so obtained are given in the form of a series of curves (see Figs. 19 to 25).

A standard squirrel-cage rotor was then tested under the same conditions and with the same stator, the test data so obtained being also shown in Figs. 19 to 25. Each test-point obtained with the author's new high-torque rotor is shown in Figs. 19 to 25 by means of concentric circles, whereas each test-point obtained with the standard rotor is shown by a single circle.

Standard motor.—The specification of the standard motor used for the tests is as follows: 57 b.h.p.,

440 volts, 40 frequency, 6 poles, synchronous speed 800 r.p.m.

Stator :—72 semi-enclosed slots, 4 slots per pole per phase. Each slot contains 5 conductors of 0·29 in. × 0·18 in. compressed stranded copper arranged for star connection. The winding is the two-range or concentric type.

Rotor :—75 conductors, each 0·50 in. × 0·18 in.
Length of rotor bars, each 15·4 in.
Full-load current per bar, 360 amperes.
Short-circuit current per bar, 2 800 amperes.
Rotor core diameter, 13·44 in.
Rotor core length, 11·4 in.
Section of each end-ring, 0·30 square inch.

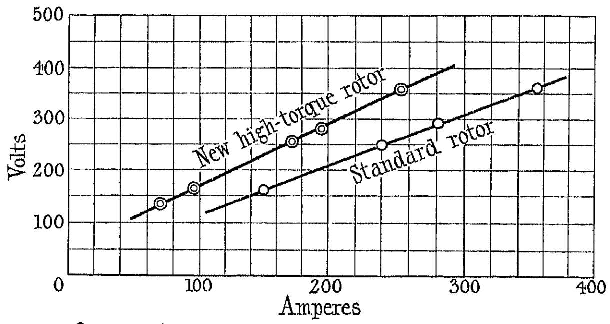

FIG. 20.—Short-circuit tests.

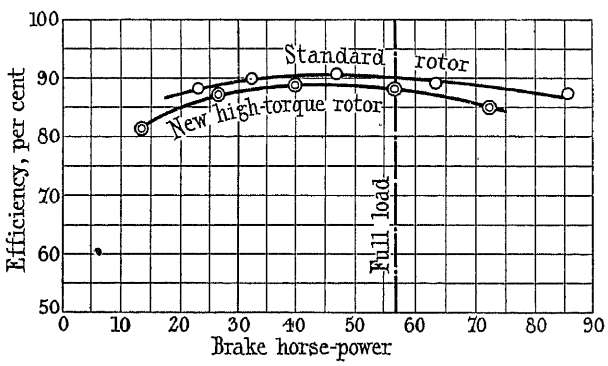

FIG. 21.—Efficiency curves.

New high-torque rotor with composite conductors.—60 circular semi-enclosed slots.

Each conductor is built up as follows (see Fig. 26) :

Diameter of central copper rod ..	..	0·236 in.
Internal diameter of steel sheath	..	0·251 in.
External diameter of steel sheath	..	0·485 in.
Thickness of outer copper skin	..	0·010 in.

The length of the steel sheath and the outer copper skin is 12 inches. The central copper rod was brought into good electrical contact with the steel sheath and the outer copper skin at each end. Each end-ring is of 0·90 square inch sectional area.

It will be observed that the diameter of the central copper rod is appreciably less than the internal diameter of the steel sheath. This was due to irregularities in the bore of the steel tube, which made it impossible to insert a copper rod of diameter larger than 0·236 inch. If the bore of the steel tube could be obtained dead true, it would be possible to avoid the waste space inside the steel tube (see Fig. 26) and thus obtain a composite rod of lower resistance. In this way the efficiency of the motor would be improved without impairing the starting conditions.

It was not considered desirable to punch more than 60 slots in the rotor for the composite bars, since this

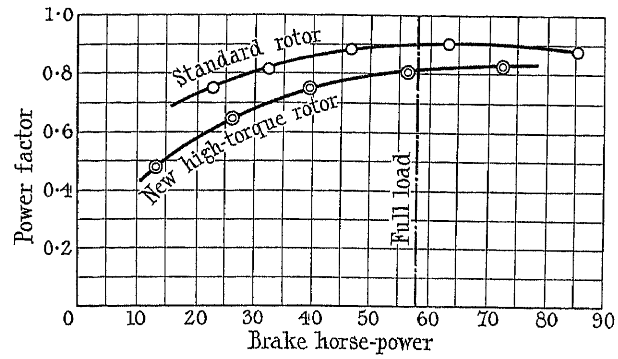

FIG. 22.—Power factor curves.

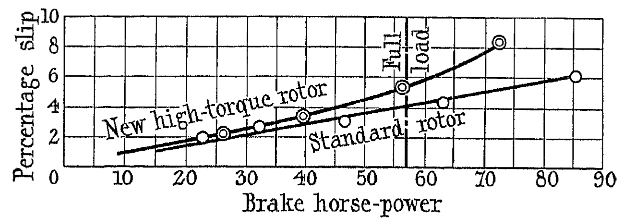

FIG. 23.—Percentage-slip curves.

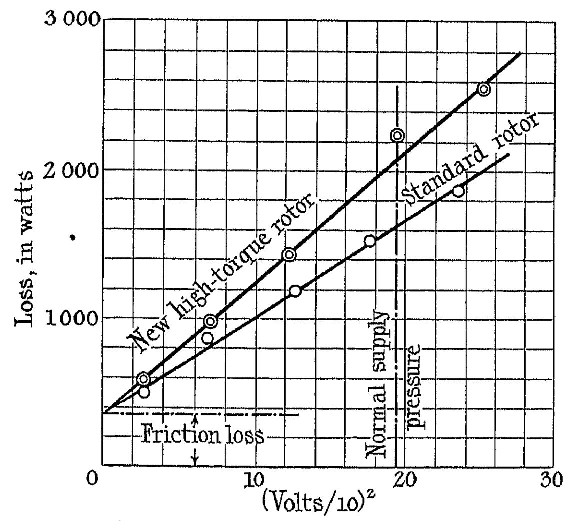

FIG. 24.—Core and friction losses.

would render the minimum section of the teeth too small for mechanical strength.

The relative performances of the new type of rotor and the standard rotor are clearly shown in Figs. 19 to 25.

The striking improvement in the starting conditions when the author's new high-torque rotor is used may be deduced from the curves of Figs. 19 and 20. For instance, to obtain the full-load torque at starting, with the author's new type of rotor, a current of

230 amperes is necessary (Fig. 19), and the applied voltage at the stator terminals will be 320 volts (Fig. 20).

If an auto-transformer is used for starting, the line current will be

$$\frac{320}{440} \times 230 = 167 \text{ amperes.}$$

Since the normal full-load current is 68 amperes, the full-load starting torque is obtained with a line current of only 2·45 times the full-load current.

If a similar calculation is carried out for the standard

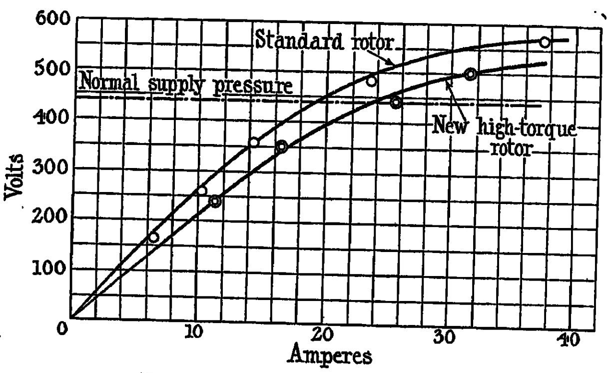

FIG. 25.—Magnetization curves.

rotor it will be seen that, in order to obtain full-load starting torque, the line current must be 3·37 times the full-load current.

As regards the efficiency, reference to Fig. 21 shows that the efficiency of the new type of rotor is slightly lower than that of the standard rotor. This is largely

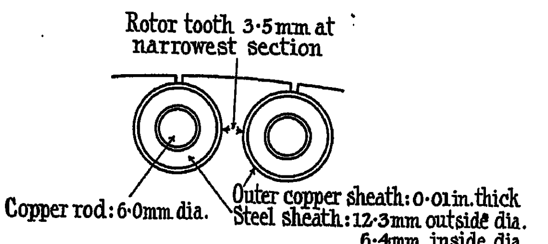

FIG. 26.—Showing the composite conductors in the new high-torque rotor.

No. of rotor slots = 60
Rotor diameter = 34·2 cm.
Air-gap = 0·75 mm.

due to the fact that the central copper rods of the composite conductors do not quite fill up all the space inside the steel sheaths, as was pointed out in the earlier part of the paper. This can be obviated in future and the efficiency at full load thus brought practically equal to that of the standard rotor.

APPENDIX.

Reduction of a Squirrel-Cage Winding to an Equivalent Winding having the Same Number of Phases and the Same Number of Turns per Phase as the Stator Winding.

A squirrel-cage winding is a polyphase winding of m_2 phases, where $m_2 = Z_2/p$, Z_2 being the total number of rotor bars and p the number of pairs of poles.

A squirrel-cage winding contains only one bar per phase, so that the number of turns per phase is $w_2 = \frac{1}{2}$.

Let r_r = resistance of the segment of one end-ring between two rotor bars (that is, the resistance of the segment A B in Fig. 27).

x_r = reactance of the segment of one end-ring between two rotor bars for a frequency equal to the stator supply frequency.

r_b = resistance of one rotor bar.

x_b = reactance of one rotor bar for a frequency equal to the stator supply frequency.

Then the effective resistance of one rotor bar plus the two end-ring segments is

$$r_2 = r_b + \frac{2r_r}{[2 \sin (\pi/m_2)]^2}$$

The reactance of one rotor bar plus the two end-ring segments is

$$x_2 = x_b + \frac{2x_r}{[2 \sin (\pi/m_2)]^2}$$

The actual squirrel-cage winding containing m_2 phases and w_2 turns per phase is equivalent to a winding

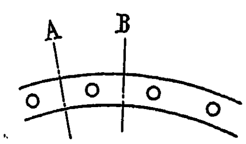

FIG. 27.

having m_1 phases and w_1 turns per phase and of which the resistance per phase is

$$r_2' = r_2 \frac{m_1(w_1 f_1)^2}{m_2(w_2 f_2)^2} = \frac{4m_1(w_1 f_1)^2}{Z_2} pr_2$$

where f_1 = winding factor of the m_1 phase winding,
f_2 = winding factor of the m_2 phase winding.

Since the squirrel-cage winding comprises only one bar per phase, the winding factor for such a winding is always equal to unity. As already stated, $w_2 = \frac{1}{2}$.

Similarly the reactance of the m_1 phase winding which is equivalent to the actual squirrel-cage winding is

$$x_2' = x_2 \frac{m_1(w_1 f_1)^2}{m_2(w_2 f_2)^2} = \frac{4m_1(w_1 f_1)^2}{Z_2} px_2$$

Discussion before the Sheffield Sub-Centre, at Sheffield, 17 December, 1924.

Mr. D. B. Hoseason: The author points out the advantages of the squirrel-cage motor as compared with all other types of machines, and his proposal is intended to overcome the great objection to these machines in the matter of starting performance. It is well known that the standard squirrel-cage induction motor takes a high starting kVA per unit of starting torque developed, and although the author has termed his machine "a squirrel-cage induction motor with high starting torque" it would have been more effective to have called it a "squirrel-cage induction motor taking a low starting current." In my opinion there is a demand for a squirrel-cage induction motor which will permit the starting gear to be simplified. Only a few applications can be started by means of star-delta starting alone and it is usually necessary to employ either an auto-transformer starter or a star-delta starter with a centrifugal clutch. The star-delta starter and clutch is more expensive than the auto-transformer starter and it is generally the auto-transformer starter which is installed. This operates on about its 75 per cent tapping, and may cost as much as 33 per cent of the total cost of the installation; it has in all probability only half the life of the motor and, in addition, it is often a constant source of trouble to the maintenance engineer. It is worth while to examine the various methods which have been put forward in the past to improve the starting characteristics of squirrel-cage motors without appreciably affecting their normal running performance. Two of these mentioned by the author are the iron conductor and the copper-core steel-sheath conductor proposed by Elihu Thomson. There have also been a number of other patents generally on the lines of these two. In almost every instance the main principle of operation has been the equivalent of a high-resistance, low-reactance circuit in parallel with a high-reactance, low-resistance circuit in the rotor of the machine. At standstill with full line frequency being generated in the rotor the high-reactance, low-resistance circuit will pass very little current and give negligible torque, while the high-resistance, low-reactance circuit will pass appreciable current and give fairly high torque such as would be supplied by a slip-ring motor with a resistance inserted in the rotor circuit. At full speed the frequency in the rotor falls and the low-resistance circuit now has a much lower impedance than the high resistance circuit and carries the greater portion of the current. This low resistance would result in about the same slip on full load as a standard squirrel-cage motor. The reason for the comparative failure of the various methods put forward in the past is that no proper control over the ratios and values of the resistance and reactance of the two equivalent circuits is possible with the mechanical construction employed in the various cases. It is obvious that to obtain the fullest control and the best adjustment of these the two circuits should be completely separated. This is obtained in what has been called the double-wound squirrel-cage rotor. In this there are two distinct windings, an outer squirrel cage having a high resistance and low reactance, and an inner squirrel cage having a high reactance and low resistance. The values of reactance and resistance in each case can be adjusted to give the best possible performance. In the summary to the paper, the author says: "When alternating current flows through the compound conductor the portion passing through the central copper core produces in the steel sleeve a magnetic flux which induces a back E.M.F. tending to choke the current out of the core. The result is that the current will flow chiefly through the high-resistance copper skin outside the steel sleeve." It is suggested then that the proposals contained in the paper are essentially another variation of the double-circuit method, and furthermore that while this latest device may be a distinct improvement on the iron conductor or the composite conductor of Thomson, it is still inferior to the motor with two separate windings on the rotor. In fact it is a step back from the double-wound rotor machine. That this is the case is borne out by the fact that double-wound rotor machines can be designed and built to have far better starting and running characteristics than those of the 57-h.p. motor given in the paper.

Mr. G. H. Fletcher: The idea of utilizing the "skin effect" of conductors has been exploited for many years by design engineers, especially in connection with squirrel-cage motors. The majority of induction motor designers have been lured by the apparent possibilities, but my own investigations in this field, and consideration of other investigations which have been made from time to time, have resulted in a rather sceptical frame of mind, and the test-results given in the paper have destroyed the last vestige of my faith in the idea. Before referring to the general analysis of the test-results of the sample induction motor—which are, after all, the most important points—I wish to point out that these results, while showing the standard motor in a very favoured light as compared with the motor built up with composite bars, are hardly fair to the standard motor, owing to the fact that while the slip of the new rotor is 5½ per cent at full load the slip of the standard rotor is given as only 4·1 per cent. If the slip of the standard motor had been the same at full load as that of the new motor, the starting torque per kVA input would not have been much inferior. On comparing the efficiency and power factor of the standard motor against the power factor and efficiency of the motor with the new rotor, it will be seen that for a full-load current of 69·5 ampères the output of the standard motor is 57 h.p., whereas for the new type of rotor the output is actually less than 48 h.p. for the same total losses. This, of course, is a very serious matter because of the increase in weight and cost per h.p. Quite apart from their effect on the size of the motor, however, the reduced power factor and efficiency are quite serious in themselves, from the point of view of current consumption. A careful analysis will show that the inferior characteristics are not accidental but are inherent in the new rotor winding.

The power factor is reduced, partly due to the increased magnetizing current as shown in Fig. 25 (no doubt on account of the reduced iron section of the rotor teeth), but largely due to the increased leakage in the rotor bar, that is, the leakage flux which passes round the steel tubes surrounding the centre rod. So far as I can gather from the paper the detail tests of the composite bar have been made with the bar unsurrounded by iron. This condition, of course, is different from that under which the composite bar is actually used. Naturally, if a composite bar is tested in air the inductance of the outer copper section would be very much lower than that of the inner rod. When the composite bar is enclosed, or partially enclosed, in an iron core, the conditions are very different, the outer section itself then being inductive. This no doubt explains why the promising tests shown in the first part of the paper do not materialize when applied to an actual motor. The reduced efficiency is apparently due to an increase of 30 per cent in iron loss and an increase of 26 per cent in primary copper loss due to the increased primary current and 33 per cent increase in secondary copper loss. This latter loss, however, is useful in so far as it increases the starting torque of the motor. There are many important practical considerations such as cost and reliability, and it is quite certain that such a rotor must be more expensive than the standard rotor wound with copper bars and copper rings, and is more dependent upon efficient workmanship for reliable operation. As an alternative to the author's suggestion I would propose to increase the rotor resistance of the standard motor and thereby increase the slip from 4·1 per cent to 6 per cent. It is well known that the starting torque of an induction motor varies approximately in proportion to the full-load slip. In other words, if one were to take the standard motor as described in the text and increase the slip from 4·1 per cent to 6 per cent the starting torque would be increased proportionately. The kVA necessary to start this motor against full-load torque would be rather less than in the case of the high-torque motor. In other words, by the use of a suitable auto-transformer the current required to start would be approximately 165 amperes and, therefore, this motor would be at least as good as the rotor wound with composite bars from the point of view of starting, and on every other point the results would be very much superior. In Table A I give figures based on the figures given in the text for motors fitted with such rotors.

TABLE A.

	Rotor with composite bars	Standard rotor with 6 % slip
Output	48 h.p.	56 h.p.
Current to start against 57 h.p. load..	174 amps.	165 amps.
Power factor at start ..	0·42	0·48
Full-load power factor at 57 h.p.	0·81	0·90
Full-load efficiency at 57 h.p.	87·5 %	88·5 %
Maximum output	115 h.p.	155 h.p.
Stator current at rated output	78·2 amps.	69·5 amps.

In conclusion I would suggest that the new type of rotor might be considerably improved if the outer copper sheath were omitted altogether, the composite bars being composed simply of the inner copper core and the iron sheet. In this case the current would pass along near the surface of the steel tube, which, having a higher resistance than copper, would provide a path of higher resistance and therefore an increased starting torque. Even then it is doubtful if the results would be so much better than the ordinary standard method as to justify the increased complications.

Mr. E. A. Binney: Anyone familiar with the unfavourable position of the squirrel-cage motor in this country as compared with the United States must feel that a more lenient attitude towards this very useful motor should be taken by the power supply undertakings in this country. It is not reasonable to expect that all the advance towards assisting the more general application of the squirrel-cage motor should be made by the designer. At the same time, any step towards producing a squirrel-cage motor more favourable to the requirements of the power supplier should be encouraged. Various attempts to do this have been made in the past and the present paper should at least stimulate further effort along similar lines. At first glance the test-results on the composite bar lead one to expect very much better results than those shown by his test data on the experimental motor. The author shows that with his composite bar, presumably not assembled in a rotor slot, the current will flow with practically no lag, whereas the bar having no outer sheath shows a decided current lag. He deduces from this that, quite apart from other considerations, a material improvement in starting torque is to be expected. However, once the bar is surrounded by iron, as it is when assembled in the slot, this favourable condition disappears so that this factor would hardly enter into whatever improvement he finally obtains. The effect of the composite-bar construction on the effective resistance when currents at full frequency are carried, is an encouraging feature of both types of bar investigated, since it would appear that a very considerable increase in the rotor resistance at standstill could thereby be obtained without increasing the slip when operating at full speed. There appears to be no advantage in the author's additional copper sheath in this respect. However, unless the tests were carried out with the bars assembled in slots the results may be misleading. Unfortunately, the experimental tests indicate that the sample motor works with a higher slip at full load, which makes a direct comparison with the standard motor impossible. The power factor readings obtained with locked rotor would have given some clue to the actual increase in rotor resistance realized. It is unfortunate that the two motors compared were not identical in all respects with the exception of the rotor bars. The number of slots in the standard rotor is greater, and this would affect the results. The standard motor appears to have rectangu-

lar bars ; this is a more economical shape than the round bar adopted for the experimental motor. The latter has very heavy end-rings as compared with the standard motor, which alters the ratio of ring and bar resistance in the two cases. These factors all tend to make fair comparison of the two motors difficult to anyone not well versed in the design of induction motors. It would appear that the composite type of bar causes a great increase in the rotor slot leakage, which is reflected in the greatly reduced overload capacity of the motor. This is an unfavourable feature and in my opinion detracts materially from any advantage gained in the starting performance. Unless the increase in effective rotor resistance during starting can be obtained without materially increasing the leakage, it does not seem that really outstanding results are likely to be obtained.

Mr. H. W. Walker : Previous speakers have referred to the restriction by various supply authorities of the use of moderately large squirrel-cage motors. Whilst this is generally true, I know of a certain municipal power station which uses 125-h.p. squirrel-cage motors to drive the rotary pumps on the condensers. The author's high-torque rotor, in my opinion, may not come into general commercial use so as to displace entirely the present simple and robust type of squirrel-cage rotor. With a little improvement they will mostly be used for directly driving high-speed rotary pumps and blowers, etc., which require abnormal torque to accelerate.

Mr. H. E. Yerbury : Every engineer is, I think, agreed that if squirrel-cage motors could be designed for high starting torque and low starting current a big field would be open for their use. The author rightly says that for simplicity and robustness they cannot be equalled. The tests of his 57-h.p. motor show, unfortunately, that power factor and efficiency are lower than on an ordinary type of motor. These are serious drawbacks as they are evident throughout the full range of the tests and are shown clearly in the curves. Full starting torque was attained on the test motor with a line current of 2·45 times the full-load current. It therefore appears necessary to provide an auto-starter which incidentally is nearly double the price of a secondary starter for a slip-ring motor. It would be unfair to expect a general electricity supply department to provide plant and cables greatly in excess of the full load connected ; hence it is customary to specify that a motor should not take more than about $1\frac{1}{4}$ times full-load current at starting. On a power supply or railway and tramway supply only, it would not be deemed serious and would be scarcely noticeable if the supply voltage fluctuated from 5 to 10 per cent. Whether the effects of a large starting current are serious or not is of course dependent on the location of the motor on the supply network, and an intermittent diminution of voltage on a lighting circuit is most undesirable and in fact prohibitory. In short, low starting current is of more importance to a supply department than high starting torque, the application of which has, I think, only a limited field. The commercial aspect cannot be ignored, and it would be interesting to learn the relative cost of the author's new machine. A slip-ring motor of, say, 55 h.p., costs about 25 per cent more than a squirrel-cage motor, but until the author goes further and designs a motor which will reduce the starting current to, say, $1\frac{1}{2}$ times full-load current, the consumer will still be burdened with an extraneous device to effect this desired result, and this starter will cost twice as much as for a slip-ring motor. Finally, therefore, there is not more than 10 per cent difference in capital costs, but the maintenance costs are obviously lower on a squirrel-cage motor. As with the author's motor an auto-transformer has to be inserted to reduce the current, is not the object of his new design thereby partly defeated ? Further, for what purposes, apart from lift and crane motors, does he think his special motor is required, and does he not think that there is more likelihood of the insulation deteriorating, and that any type of motor would have a shorter life if the full or nearly full voltage of the supply were impressed upon it at each starting period ?

Prof. E. W. Marchant (*communicated*) : The ingenious device of building a squirrel-cage rotor for an induction motor with composite rods having a copper core surrounded by an iron sheath, which in turn is covered by a thin outer copper sheath (thus increasing the effective resistance of the rotor bars for the relatively high-frequency currents which are induced when starting the motor), is an important improvement in the design of induction motors. The circuit of a rotor constructed with bars of this character has a much higher power factor than one made with steel-covered copper bars such as were described by Elihu Thomson. This has been shown clearly by Dr. Wall's experiments, and the importance of this result is demonstrated very clearly in Fig. 16. With a ratio of effective rotor resistance at starting, to rotor resistance when running, of 3, the starting torque when the power factor of the rotor is unity is 1 350 lb.-ft., whereas with a power factor of 0·86 the starting torque is about 820 lb.-ft. It is interesting to note also that no gain in starting torque is obtained when the ratio of resistance at start to running resistance is greater than 3. The circle diagram shows that there must be a limit to the gain in starting torque obtained by increasing the rotor resistance, and the author's figure for the best ratio should be useful to designers. He has designed a motor which should be of great service where a robust motor with high starting torque is needed. It has all the advantages of the squirrel-cage motor in simplicity of construction, with a starting torque of the same order of magnitude as that obtained with the much more complicated, wound rotor. This result has been obtained at the expense of a relatively small loss in efficiency and power factor.

Dr. T. F. Wall (*in reply*) : In the course of the discussion, reference has been made to the double-wound rotor of Boucherot. This type of motor is, of course, subject to deficiencies of an exactly similar nature, viz. reduced efficiency and power factor, as are shown in the test-results given in the paper for the composite conductor rotor. The double-wound rotor has, however, the further disadvantages that its size and cost for a given output must obviously be considerably greater. I have given a fully worked out example of the performance of a Boucherot motor in *Engineering*, August 10, 1923.

The machine of which the test data are given in the present paper is the first of this size to be completed and tested. So far as I am aware these test data are the first yet published for a rotor built with composite conductors. It is therefore obvious that the results obtained are not submitted as giving the best possible performance of which motors built in accordance with this invention are capable. For example, the performance would have been appreciably improved if it had been possible to choose a larger number of rotor slots, as would have been the case if rectangular conductors had been employed. Such rectangular composite conductors would be practicable if the steel sheath were formed from rectangular "washers" stamped out of laminated iron and threaded on the central rectangular conductor, the whole being covered with the copper skin.

A further consideration as regards the field of application of this new type of rotor is that in many cases it would be feasible to use series starting resistances, instead of an auto-transformer, when it is necessary to reduce the starting current to a value still lower than that obtained by switching the motor directly on to the line. Series starting resistances provide the cheapest form of starting gear, and this item would be similar to the starting resistance of a wound rotor, with the exception, of course, that it would be connected in the stator circuit instead of in the rotor circuit.

In designing a standard line of these motors it would be possible to design machines that would have appreciably better starting characteristics than those of the experimental sample specified in the paper. It is, however, hoped that these results will form the basis from which further advances may be made.

Mr. Fletcher seems to me to have formed a gloomy opinion of the possibilities of this invention which is certainly not justified by any test-results given in the paper. If his pessimism is based on experience with the simple steel-sheathed conductor I can understand it. I consider, however, that the addition of the outer copper skin introduces an entirely new and beneficial factor in the design of composite conductors and brings them within the realm of practical application. Mr. Fletcher states that "for the same total losses" the new high-torque rotor will give less than 48 h.p. as compared with 57 h.p. by the standard rotor. He then proceeds to increase the rotor resistance of the standard motor by about 45 per cent, and draws up Table A in which the standard motor is allowed to have appreciably greater total losses than the new high-torque motor for the specified ratings. The data given in Mr. Fletcher's Table A are wrong in important respects. Increasing the slip of the standard rotor from 4·1 per cent to 6 per cent, i.e. by about 45 per cent, will raise the torque curve in Fig. 19 by a corresponding amount, but even then the torque curve is markedly below that of the rotor with composite bars, and the starting current at full-load torque is appreciably higher than that of the composite-bar rotor. In view of these facts, I consider Table A to be of no value as a criticism of the new high-torque rotor.

As regards the applicability of the tests on single isolated composite rods, there seems to be a misapprehension. The tests on the isolated composite rods give the inherent characteristics of these rods, and this information is the essential feature in considering the possibilities of such rods when used as rotor conductors. The comparison of the test-results for single isolated composite rods with outer copper skins and single isolated plain steel-sheathed copper rods is a perfectly legitimate one, and the great advantages shown by the former will be evident in test-results from rotors constructed respectively from these two types of composite conductors. There is, however, a further very important consideration to bear in mind, viz. that whereas the plain steel-sheathed copper rods will most seriously (and, I think, prohibitively) increase the slot leakage, the composite rods with outer copper skins will cause nothing like this increase in slot leakage, for the simple reason that the flux passing through the steel sheath will also cut the outer copper skin and is therefore not leakage, although it may give rise to a certain amount of eddy-current loss in the copper skin. This may, in fact, partly account for the slightly lower efficiency of the composite-rod rotor as shown in the test-results given in the paper. In view of the considerations already detailed and also in view of the test-results given in the paper, the suggestion that plain steel-sheathed copper rods would be preferable to the steel-sheathed copper rods with outer copper skins seems to me to be wholly unsupported either on logical or on experimental grounds.

Mr. Yerbury points out that the composite-bar rotor will draw more than 1½ times the full-load current from the line if switched directly on to the line at starting. This is quite true, but I think that the time has arrived when electric supply undertakings should relax their ruling that induction motors shall not take more than about 1½ times full-load current when starting. Designers should be met at least half-way in this respect and I submit that not to do so is putting difficulties in the designers' way which are largely unnecessary. There seems to be very little real justification for this severe restriction on the amount of starting current.

It is not expected that the cost of rotors with composite conductors will show up advantageously in all cases as compared with normal squirrel-cage rotors. Investigation shows, however, that there is a range of motors of medium output for which the cost of this new type of rotor will compare favourably both as regards slip-ring rotors and normal squirrel-cage rotors.

That there is a real and definite need for a satisfactory squirrel-cage induction motor with high starting torque is, I think, most conclusively proved by the fact that such a large number of electrical engineering firms in this country, on the Continent, and in the United States, have made such persistent efforts to solve the problem. That this is so is borne out by reference to the Patent Office records and to the technical Press.

I am not quite clear as to what Mr. Yerbury refers with regard to possible insulation troubles. It is not necessary to have any insulation in the rotor slots. As is so often the practice with normal squirrel-cage rotors, the conductors may be laid directly in the rotor slots.

I much appreciate the remarks of Prof. Marchant. I thank him for calling attention to some of the salient facts given in the paper, and for his appreciative view of the proposals on which the paper is based.

EFFICIENCY OF END CONNECTIONS, AND THE SHORT-PERIOD RATINGS OF LARGE-CURRENT SHUNTS.*

By S. W. MELSOM, Associate Member, and H. C. BOOTH.

[FROM THE NATIONAL PHYSICAL LABORATORY.]

(*Paper first received* 22*nd August, and in final form* 21*st November,* 1924.)

SUMMARY.

The efficiency of the end connections, which was discussed by a Committee of the British Engineering Standards Association when considering the standardization of shunt ends and switchboard connectors, has been investigated. The results show that with brass lugs the contact resistance is considerably higher than with copper, and also that with brass ends the pressure-drop across the two joints is of the order of 20 mV as compared with 75 mV across the shunt itself. With copper ends the voltage-drop is only 3 mV.

The temperature-rise of the resistance elements of shunts carrying overloads was investigated. The amount of overload which a shunt will carry during short periods before a given temperature excess is reached depends almost entirely on the heat capacity of the metal of which the shunt is composed, the effects of radiation and convection under these circumstances being negligible by comparison. Formulæ for the evaluation of short-period overloads were deduced from the dimensions of typical shunts for a given value of the temperature excess, and were checked by results obtained from actual overload tests.

INTRODUCTION.

In connection with the work of the Instrument Committee of the British Engineering Standards Association, it was considered desirable to investigate before they were definitely adopted for standard practice the proposed standard sizes for shunt ends and other apparatus used on or with switchgear.

Three shunts, designated A, B and C, were kindly lent by Messrs. Elliott Brothers, Ltd., and Messrs. Nalder Brothers and Thompson, Ltd. These all had the standard pressure-drop of 75 mV and were for normal maximum currents of 2 500, 3 000 and 5 000 amperes respectively.

In their general shape and design these three shunts were very similar, and the total cross-section of the metal in the resistance elements was proportional to the current to be carried, so that there is no reason to ascribe any variations in the behaviour of the end contacts to this factor.

The principal dimensions of these three shunts are given in Table 1, and in Fig. 1 they are shown drawn to the same scale. The 2 500-ampere shunt A was fitted with copper lugs, the other two shunts with brass.

The proposed standardizing of the dimensions related only to the size and spacing of the bolt holes; the thickness, overall width and length of the lug being left to the individual maker. In the three shunts tested the actual width, length and thickness were so dimensioned that small variations would probably not greatly affect the results.

For the purpose of the tests the shunts were connected with copper busbars of the same width as the lug, one on each side of the lugs. The thickness of each of the strips was ⅜ in. for the 2 500-ampere and 3 000-ampere shunts, and ½ in. for the 5 000-ampere shunt. Thus the sectional area of the copper connecting-pieces

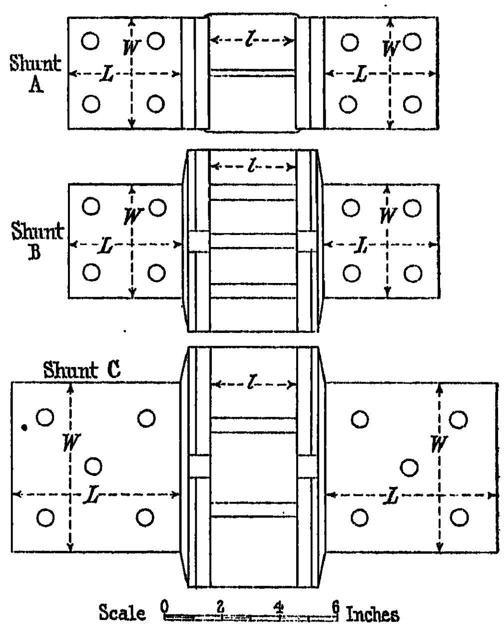

FIG. 1.

was 3 sq. in. for the two smaller shunts and 6 sq. in. for the 5 000-ampere shunt.

RESULTS OF TESTS.

As regards the number and arrangement of the bolt holes, previous work had indicated that an intermediate fifth bolt did not improve the contact, and this was again confirmed in the case of shunt C (Fig. 1). The fifth bolt hole would therefore appear to be unnecessary.

The question as to what constitutes an efficient joint for the purpose of a shunt is a matter of some doubt. The definition used by the authors in their previous

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

work * was as follows: "An efficient joint is one in which the total resistance of the length comprising the joint is not greater than that of an equal length of the straight conductor," and this probably holds for all ordinary switchboard practice, though for a shunt it may be argued that a pressure-drop of 20 mV across the two joints is small in comparison with the drop across the shunt itself. For the present purpose, however, the authors have again adopted this definition.

The results for the three shunts are set out in Table 1. It will be noted that the efficiency of shunt A fitted with copper lugs is very good, the resistance of the joint being considerably less than that of an equivalent length of the straight (copper) conductor. On the other hand the efficiency of contact of the brass lugs is somewhat low, being of the order of 37 per cent.

It will be seen from the table that the copper lugs in the small shunt are thicker than the brass lugs for the larger shunts; thus the actual metallic resistance given in the table for this shunt is lower in proportion than that of the other shunts. The higher efficiency of the joints of shunt A as compared with B and C, however, arises only in a small measure from this cause. As will be seen from the values given for R_C, the contact resistance of copper to copper is very much less than that of copper to brass. This point has been noticed before, but has not yet been fully investigated.

The fact that the thermal conductivity of copper is at least 3 or 4 times as great as that of brass, although the effect of it is not apparent in the present connection, requires, however, to be noticed as being a factor of considerable practical importance, since better thermal conductivity of the parts involved will help materially in dissipating the localized heating which is developed at the place where the resistance elements are soldered into the shunt-ends.

TABLE 1.

Shunt	Current	L	T_1	T_2	W	Voltage-drop (one joint) of overlap at full load	$R = R_M + R_C$	t	R_M	R_C	R_B	R_L	Joint efficiency, $100R_L/R$
	amps.	in.	in.	in.	in.	mV	microhms	°C.	microhms	microhms	microhms	microhms	
A (copper)	2 500	4	$1\frac{1}{4}$	$\frac{3}{4}$	4	1·48	0·59	62	0·42*	0·17	0·264	1·058	179
B (brass) .	3 000	4	$\frac{3}{4}$	$\frac{3}{4}$	4	8·04	2·68	41	0·82	1·86	0·245	0·980	36·5
C (brass) .	5 000	6	1	1	6	10·3	2·06	45	$0·61_2$	$1·44_8$	0·126	0·758	37·3

L = length of overlap.
T_1 = thickness of lug.
T_2 = thickness of the double busbar.
W = width of lug and busbar.
R = resistance of overlap.
t = temperature of overlap.
R_M = resistance of metal parts of overlap.
R_C = resistance of contact surface of overlap.
R_B = resistance of 1 in. of double busbar.
R_L = resistance of length L of double busbar.

Note.—In computing R_M the resistivity of the brass was taken as 3·0 microhms per inch cube with a temperature coefficient of 0·001 per deg. C., and the resistivity of the copper as 0·678 microhm per inch cube with a temperature coefficient of 0·004 per deg. C.

* The thickness of that portion of the busbar which formed the overlap was in this instance reduced to $\frac{11}{32}$ in.

SHORT-PERIOD OVERLOAD RATINGS OF SHUNTS.

The following investigations were carried out on the three shunts A, B and C, in which the pressure-drop at full load was 0·075 volt, and also on a 5 000-ampere shunt D, in which the pressure-drop was 0·2 volt at full load. The object of these investigations was to find how far shunts for heavy current could be overloaded for short periods without the temperature-rise becoming excessive and endangering the soldered joint or changing the resistance of the shunt.

In the case of a simple conductor the problem might be solved from a general knowledge of the heat-capacity and heat-emissivity characteristics of the conductor, but in the case of shunts the factors involved are too complex to permit of any general solution of the problem being arrived at on these lines, except under certain special circumstances to be discussed later. The general treatment of the problem which is applicable in the case of a simple conductor is possible only because certain simplifying assumptions can be made. It is permissible, for instance, to regard the conductor as thermally homogeneous so that when it is carrying current the heat generated will be uniformly distributed within the metal and uniformly dissipated to the surrounding medium, and not to any appreciable extent through or into the end connections. The surrounding medium may also be assumed to remain throughout at an approximately invariable temperature and not to be affected by the rising temperature of the heated body. Under these conditions, and assuming that over a limited range of temperature difference the heat is dissipated at a rate proportional to the temperature excess, the relation of temperature-rise to time will then be of the simple form

$$\theta = m\,(1 - \epsilon^{-t/\gamma}) \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where, for any given current,

θ = the temperature excess of the conductor above the surrounding air,
m = the final maximum temperature excess produced by the given current,
t = the time which has elapsed since the current was switched on,
γ = the time-constant of the conductor, i.e. the ratio of the heat capacity to the rate at which heat is lost to the surrounding medium for a unit temperature excess.

In a shunt, however, because of its more complicated structure, the conditions are substantially different. The heat developed by the current is carried off, not only by radiation and convection into the surrounding medium, but also, and to a very considerable extent, by direct conduction through and into the end pieces and connections to which the shunt is attached. The temperature of these end pieces rises both in consequence of the local effects of the current and of the heat that flows into them from the resistance element.

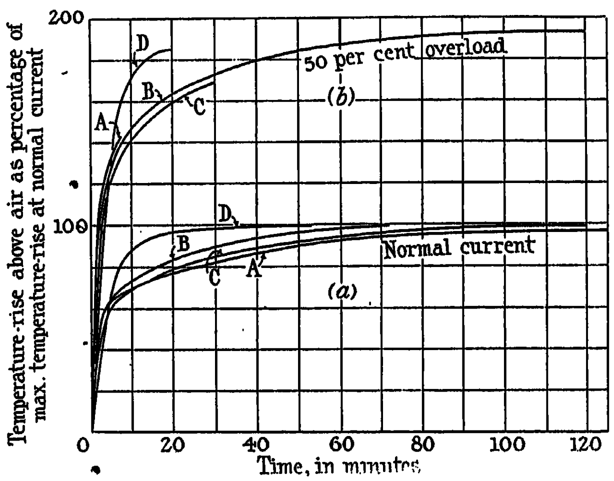

FIG. 2.—Comparison of temperature-rise of four shunts, (a) at normal rating and (b) at 50 per cent overload.

Where, however, the simple relation expressed by Equation (1) holds, the rise of temperature for any such simple conductor, at any given period after switching on the current, will in every case be in the same ratio to the final maximum value. Thus under two different conditions of loading for which the final maximum temperatures would be M_1 and M_2 respectively, the two corresponding values of the temperature excess at any time t_0 before the final temperature is attained would also be in the ratio of M_1 to M_2. In cases of this kind, therefore, the theoretical determination of the time that will elapse before the temperature excess reaches any prescribed value could easily be calculated if the thermal characteristics of the conductor were approximately known.

The extent to which the thermal behaviour of the resistance elements of a heavy-current shunt departs from this simple relation will be seen from Table 2, which gives in the case of the three shunts B, C and D the temperature excess (a) for normal loading, (b) for a 50 per cent overload, and (c) the ratio of these two sets of values taken at various intervals during the first portion of the heating curve. It will be seen that neither for the same shunt at different parts of the curve nor for different shunts at the same time-interval after switching on, is the ratio constant. The temperature-rise curves of these three shunts, together with that of shunt A, are also shown in Fig. 2, in each case as a percentage of the final temperature. The rapid rise of temperature in shunt D is no doubt chiefly due to the fact that though larger and heavier than the other three shunts the voltage-drop is 0·2, whereas in the others it is 0·075.

TABLE 2.

An approximate indication of the length of time during which an overload is permissible is given in Fig. 3, which shows the rise of temperature in shunt A with normal current, and with 50 per cent, 100 per cent and 200 per cent overload respectively. The heating of the positive and negative ends for normal current and 50 per cent overload is also given. It will be seen that with 200 per cent overload a temperature excess of 200 deg. C. in this instance is reached in about 1 minute after the current is switched on, but with a 100 per cent overload this temperature is not reached until the current has been flowing for about 6 minutes. The ends of shunt A were of copper and the positive end during the first 10 minutes did not attain to more than 20 per cent of the temperature-rise of the hottest of the

resistance strips, to the behaviour of which the temperature curves in all cases refer, except where otherwise stated. In B, a 3 000-ampère shunt with brass ends, the temperature-rise of the ends was relatively greater, and during the first 10 minutes attained to about 50 per cent of the temperature of the hottest strip. This must have a very direct effect on the rate of temperature-rise of the resistance elements themselves,

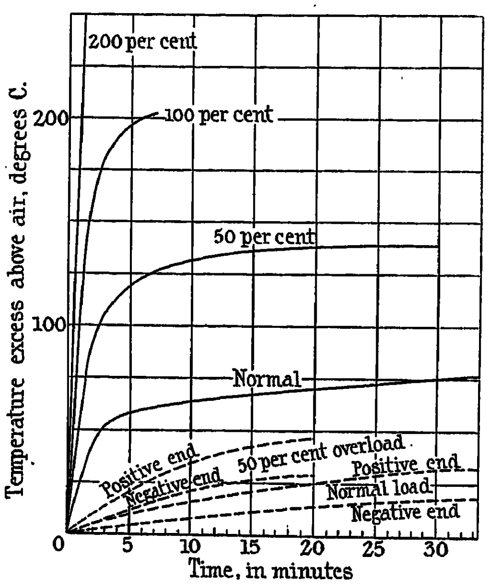

FIG. 3.—Temperature of resistance element and ends of a 2 500-ampere shunt with various overloads.

and it is probable that to this effect are chiefly to be attributed the differences in the character of the temperature-rise curves, especially during the first few minutes. These differences are well exemplified in Fig. 2, from which it will be seen that the time taken to reach a given temperature (the final maximum temperature for normal rating being in all cases approximately the same) may vary by as much as 100 per cent.

Where the maximum permissible temperature-rise is reached in a few seconds—this happens when the shunt carries a very heavy overload—the problem becomes amenable to a very simple method of treatment. During such periods very little of the heat developed will have time to escape, either by radiation and convection, or by conduction. For practical purposes it will therefore be sufficiently correct to assume that, for a very short period after switching on, the whole of the heat energy developed in the resistance elements goes to raise the temperature of the metal. The rate of temperature-rise will therefore depend entirely upon the voltage-drop and current on the one hand, and the mass, resistivity and specific heat of the metal on the other. If constant values are assumed for these quantities it is then possible to obtain a general formula.

Let it be assumed that the resistance elements are of manganin and that the mean resistivity $\rho = 42$ microhms per cm cube, the density $d = 8 \cdot 4$, the specific heat $s = 0 \cdot 50$ (in electrical measure), l = the length of the resistance element in cm, M = mass of the resistance elements in grammes, and R = resistance in ohms. Then, on the assumption that there is no escape of heat, the temperature-rise θ when a current I has been passing for t seconds is

$$\theta = \frac{RtI^2}{Ms}$$

If the voltage-drop is $0 \cdot 075$ when I', the normal rated current, is passing, then

$$R = 0 \cdot 075/I' = \rho l/A$$

and

$$M = dlA$$

A being the total cross-section of the resistance material.

We therefore have

$$\frac{I}{I'} = \frac{l}{0 \cdot 075}\sqrt{\left(\frac{\rho d s \theta}{t}\right)}$$

If we assume an initial temperature of 20° C. and that 200° C. is the maximum, then $\theta = 180$, and if, as is frequently the case, $l = 7 \cdot 5$ cm (approximately 3 in.) on substituting the numerical values given for ρ, d and s the formula reduces to

$$I/I' = 17 \cdot 8/\sqrt{t}$$

which is the overload factor; or

$$t = 317\left(\frac{I'}{I}\right)^2$$

which gives the time during which the overload current may be carried.

TABLE 3.

Ratio of overload to normal rated current	1·5	1·7	2·0	2·5	3·0	5·0	10
Time in seconds to attain 200° C. assuming that shunt							
(a) was previously cold	141	109	79	51	35	12·7	3·2
(b) had been running at normal current	78	61	44	28	20	7	1·7

But these formulæ are based on the assumption that, when the overload is switched on, the shunt had previously been carrying no current. If the shunt for some time previously has been carrying the maximum rated current and under these conditions is then suddenly called upon to carry an overload, the temperature-rise can no longer be taken as 180 deg. C. but as the

difference between 200° C. and the temperature which the shunt attains at full-load current. If this latter be taken as approximately 100° C., θ becomes 100 deg. C. and the formulae become

$$\frac{I}{I'} = \frac{13 \cdot 3}{\sqrt{t}}$$

or

$$t = 176\left(\frac{I'}{I}\right)^2$$

With this assumption a series of short-time ratings corresponding to various overloads was calculated by the use of the formula and is shown in Table 3.

This would indicate that if the overload period does not exceed 1 minute an overload of 130 per cent above the normal rating current would be permissible if the shunt started cold, but that an overload of 70 per cent could be allowed if the shunt had previously been running at full load. Reference to the curves for 200 per cent and 100 per cent overload in Fig. 3 will show that this is approximately correct.

Note.—In all the shunts tested the temperature-rise for normal maximum continuous loading was of the order of 100 deg. C., and in discussing the effect of overloads and the application of the formula in the examples worked out the authors have considered a value of 200 deg. C. This latter figure is purely arbitrary and was taken as being rather below the melting-point of soft solder. It is not suggested that this or any and every type of resistance alloy that might be used could safely be raised to this temperature without permanent injury or change, or that this value should be adopted as standard practice.

DISCUSSION ON
"A NEW NETWORK THEOREM." *

Mr. A. Morris (*communicated*): Mr. Rosen's paper is of considerable general interest and of great practical utility to engineers and others who are concerned with electrical networks. The title of the paper indicates that the theorem is new; this, however, is not the case. Mr. George A. Campbell published it in perhaps an even more general form—in the *Bell System Technical Journal*, July 1922 (vol. 1, No. 1), in an article entitled "Direct Capacity Measurement." This article contains the following statement: "Generalizing, we have the following definition: The direct capacities of an electrical system with n given accessible terminals are defined as the $n(n-1)/2$ capacities which, connected between each pair of terminals, will be the exact equivalent of the system in its external reaction upon any other electrical system with which it is associated only by conductive connections through the accessible terminals." I quite believe that Mr. Rosen was without knowledge of Campbell's article when he submitted his paper for publication and that he has in fact worked out the theorem quite independently. The theorem is, however, of such importance, and would appear to be so little known, that its publication in the pages of the *Journal*, two years after its having been first enunciated, is probably fully warranted.

The following example of the use of the theorem applied to impedance operators will doubtless prove of interest. This example involves the use of the star to mesh and also the mesh (triangular) to star (three ray) transformations. The network concerned arises in connection with the localization of a certain class of dielectric fault occurring in electric cables.* Fig. A shows the magnitude of the impedance of each network-member, as well as its arrangement. PQSL and VUTL represent the separate conductors of the faulty cable circuit, which are joined together at the end L for the purpose of localization. ZQ and ZU represent the normal insulation resistances to earth of the conductors, whilst ZS and ZT represent the resistances of the "earth" faults existing at the points S and T respectively. PH and HW represent ratio arms, G a galvanometer, HZ an earthed battery and WV a resistance which can be adjusted until balance of the galvanometer is secured. The fault on the cable circuit is situated at a point x ohms from the end V of the conductor VUTL. The resistance of each conductor

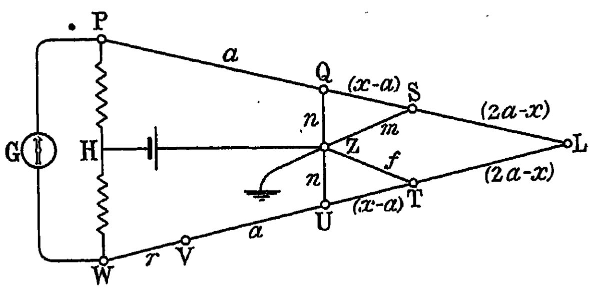

Fig. A.

* Paper by Mr. A. Rosen (see vol. 62, p. 916).

* A. Morris and R. M. Chamney: "Considerations relating to the Murray Loop Test," *Journal of the Institution of Post Office Electrical Engineers*, 1918 vol. 11, part 1; also H. T. Werren: "The Localization of Low Insulation Faults in Underground Cables," British Post Office Research Report No. 1672, November, 1922.

is $2a$ ohms, whilst the normal insulation resistance and the fault resistances are n, m and f ohms respectively. The magnitude of the adjustable resistance WV, when a balance has been secured, is r ohms.

In order to derive the condition for balance of the network by the usual methods, it would be necessary to solve a seven-row determinant. By the use of the theorem the equation for balance may be written down at once if the network is first simplified.

In the expressions about to be derived the following abbreviations will be used :—

(i) For $[m + f + 2(2a - x)]$ write $1/g$.
(ii) For $[a - x + 2mg(2a - x)]$ write $1/h$.
(iii) For $[a - x + 2fg(2a - x)]$ write $1/k$.
(iv) For $[mfg(h + k) + 1]$ write s.
(v) For $[mfg(h + k) + nh + 1]$ write t.
(vi) For $[mfg(h + k) + nk + 1]$ write u.
(vii) For $[mfghkn(u + t) + ut]$ write w.

The simplification is effected as follows :—

(*a*) Replace the two members SL, TL by the single member ST; whence ST $= 2(2a - x)$.

(*b*) Transform the triangular mesh ZST into the three-ray star YZ, YS, YT; whence YS $= 2mg(2a - x)$; YT $= 2fg(2a - x)$; YZ $= mfg$.

(*c*) Transform the star SY, SQ into the member YQ, and the star TY, TU into the member YU; whence :—

$$YQ = a - x + 2mg(2a - x) = 1/h$$
$$YU = a - x + 2fg(2a - x) = 1/k$$

(*d*) Transform the star YQ, YZ, YU into the mesh ZQ, QU, UZ; whence :—

$$ZQ = \frac{mfg(h + k) + 1}{h} = \frac{s}{h}$$
$$QU = \frac{mfg(h + k) + 1}{mfghk} = \frac{s}{mfghk}$$
$$UZ = \frac{mfg(h + k) + 1}{k} = \frac{s}{k}$$

(*e*) Combine the two parallel ZQ members and also the two parallel ZU members, thus :—

$$ZQ = \frac{ns}{nh + s} = \frac{ns}{t}$$
$$ZU = \frac{ns}{nk + s} = \frac{ns}{u}$$

(*f*) Transform the triangular mesh ZQU into the three-ray star OZ, OQ, OU; whence :—

$$OZ = \frac{n^2mfghks}{w}; \quad OQ = \frac{nsu}{w}; \quad OU = \frac{nst}{w}$$

The simplified network is then as represented in Fig. B, where the magnitude of the impedance members PQ, WV, VU is as shown and the magnitude of the members OZ, OQ, OU as given in paragraph (*f*) above.

The condition for balance of the resulting Wheatstone bridge network (for equal ratio arms) can now be written down, observing that the member OZ is in series with the battery feed and that its magnitude will not affect the equation for balance, thus :—

$$a + \frac{nsu}{w} = r + a + \frac{nst}{w}$$

$$\text{i.e.} \quad r = \frac{ns}{w}(u - t) = \frac{n^2s}{w}(k - h)$$

The advantage of the above method of treatment from the point of view of the saving of labour in the work of obtaining the condition for balance is very considerable. The reduction of the complicated network to the simple four-arm bridge is also of practical advantage, by reason of the clear picture thus presented of the balancing conditions to be met when arranging the testing apparatus.

The equation given above will require to be evaluated for x. In doing this the work is simplified by reason of the fact that in practice n, m and f are of an order

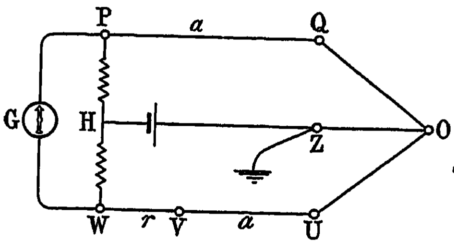

FIG. B.

10^4 to 10^5 times that of a and x. Furthermore, if a similar equation is obtained for the balancing condition (balancing resistance r') when testing from the end of the line remote from PW (this can be written down from analogy), then expressions involving n, m and f can be eliminated, and the equation for the distance (x) to the fault becomes

$$x = \frac{2ar'}{r + r'}$$

Mr. A. Rosen (*in reply*): I am grateful to Mr. Morris for drawing my attention to G. A. Campbell's article in the *Bell System Technical Journal* of July 1922, with which I was previously unacquainted. From the fact that it is not quoted in more recent articles on the subject, and also that Mr. Morris is the only one who has commented on the matter, it is evident that the theorem is new as far as engineers in this country, and no doubt in Europe generally, are concerned.

The instance given by Mr. Morris is interesting, not only as an example of the application of the star-mesh conversion, but also as a method of locating faults in underground cables which will be appreciated by cable engineers. Since the publication of the paper, I have found further instances of the more extended form of the theorem, in the development of a general theory of the interference between circuits in telephone cables.

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE: CHAIRMAN'S ADDRESS

By H. H. Harrison, Member.

"THE ART OF COMMUNICATION ENGINEERING."

(Abstract *of Address delivered at Liverpool, 3rd November,* 1924.)

In taking for my subject to-night that of Communication Engineering, I need hardly remind the members that our Institution originally existed as the Society of Telegraph Engineers and that its interests were then entirely devoted to this, the earliest, branch of our profession.

Communication engineering embraces telegraphy and telephony, either wire or radio, and also such electrical means of communication as control the movements of trains, i.e. railway signalling. Fundamentally the three sections have the same object, viz. the control from one point by one individual, or a group, of the actions of another person or collection of persons situated some distance away. The links over which the control is exercised range from a few miles to three or four thousand, and it is partly this question of distance which determines the type of link used.

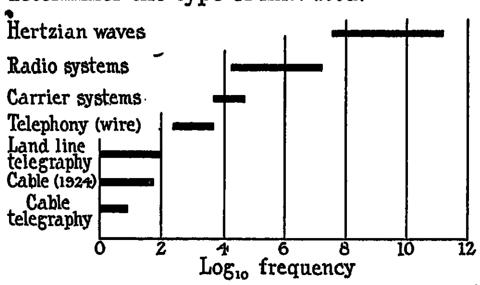

Fig. 1.—Frequency bands of different forms of communication.

To the student of these matters two tendencies have revealed themselves in the last 10 years. One is the replacement, as far as possible, of the human element by the machine. This is evidenced by the rapid growth in the adoption of printing-telegraphs, in which the telegraphic art is reduced to the mere pressing of buttons; while switching mechanisms, remotely controlled by the subscriber, are fast taking the place of the manually operated telephone exchange. This movement is in evidence over the entire world, but perhaps more so in the United States. This is partly explained by the size of that country and by the number of big cities at relatively great distances apart. In Europe, since the war, great strides have taken place in the directions indicated.

The second tendency to be noted is the gradual overlapping in technique of land-line, cable and radio telegraphy and of land-line and radio telephony due to each borrowing methods which have been developed in bringing the others to their present stage of usefulness. The interconnection of land-line and radio-telephone channels is an example of this, and both wire telegraph and telephone engineers are crossing the frontier line dividing them from the radio engineer. The common medium of exchange is the three-electrode valve and its associated circuits.

It is perhaps useful at this stage to glance at the communication frequency spectrum. Fig. 1 shows the various frequency bands used by the different systems. The plots represent the logarithms of the numbers corresponding to the width of the bands.

I propose in this address to give illustrated descriptions of the following:—

Signalling methods employed in communicating intelligence.
Various multiple methods of signalling.
The fundamentals of telephony.
The current patterns of elementary signals.
The characteristics of long and short conductors, cable and land line.
The siphon recorder.
Automatic transmission on cables.
Telephone circuits.
The advantages and disadvantages of loading.
Methods of loading in use.
Combination of loading with repeaters.
Arrangements at repeater stations.
Radio-telephony.
The band filter.
Carrier-current telegraphy and telephony.
Interlinking of wire and radio channels.

Land-line telegraphy has, except for the application of several frequencies to multiple operation, remained stationary for many years. The process of substitution of machines for manual methods of operation is steadily proceeding and manual telegraphy is dying, but dying hard.

Two recent developments in automatic telegraphy possess features which make them of some interest. Quadruplex telegraphy which provides for the simultaneous transmission of two groups of signal in one direction, and also two groups of signals in the opposite direction independently of each other, is based on a combination at each station of the single-current and double-current duplex systems. The single-current portion of the system permits of the transmission of one group of signals in each direction through changes in current intensity, and the double-current system permits of a similar additional transmission through changes of current direction irrespective of current strength. The latter is called the "A," and the former the "B" channel. The "B" signals are superposed on the "A" signals, as will be clear from Fig. 2 (*a*) in which letters F and L are set out on a current-time chart.

It will be noted from Fig. 2 that the requirements for the "A" side signals result in several reversals in direction of the current while "B" signals are in progress. These reversals produce a moment of no current

in the line. This has no influence on the "A" side relay, since this is polarized and its armature remains where last placed. The "B" side relay is, however, non-polarized and is provided with a controlling spring. With no current, its armature commences to leave the working position and return to the normal or resting position. This return movement ceases as soon as the current is re-established, but in the meantime the "B" signal has been broken, or "split" as it is termed. This is shown at the points indicated by arrows in the figure. This splitting tendency seriously limits the distance over which quadruplex operation is possible and also prevents high-speed operation of the "B" channel, although this is practicable on the "A" channel.

which also involves the connecting in phase of the several transmitters by shafting and gears has been developed. Two separate independent channels are shown in Fig. 3, but there is no limitation and three or four channels may be employed. The principle on which the method depends for obtaining more than one channel is that of division of the line time. A time unit is taken, say that of a dot impulse, and the line is given to each transmitter in turn for one-half, one-third, or one-quarter of the time unit. The transmitter star-wheels are geared together and to a revolving brush arm, which sweeps over circularly disposed contacts in pairs and gives the line to each transmitter lever TL, TL_2 in turn. The current-time chart at the right-hand side

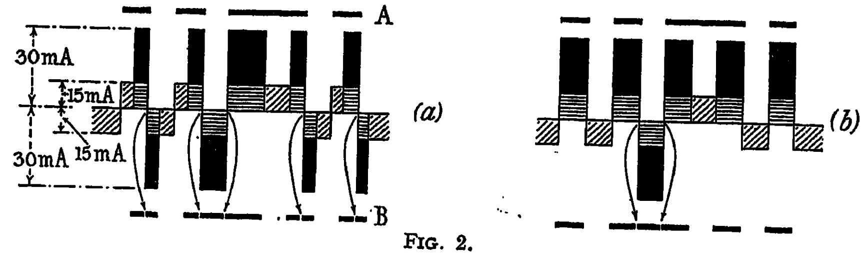

FIG. 2.

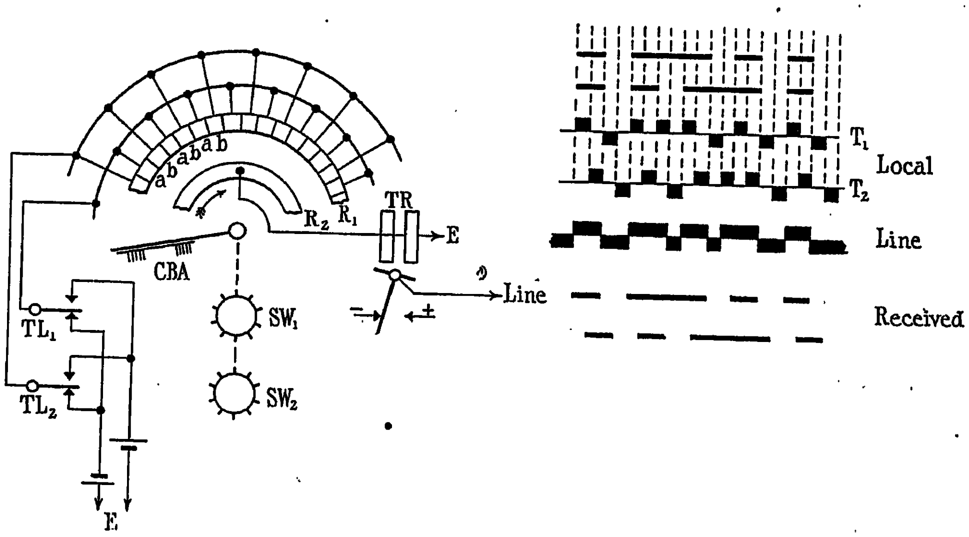

FIG. 3.

In Fig. 2 (*b*), matters are so arranged that the dot signals on both channels commence and terminate together. When this is effected—and it is secured by using automatic transmitters on both channels and gearing them together—split dot signals are impossible on the "B" channel and the dashes are only split at intervals a dot space apart. These can be bridged over by any of the known devices for this purpose, and we have a quadruple system which is capable of operating at high speeds on both channels. This ingenious step in quadruplex operation is due to Creed and Willson and constitutes a considerable advance; 130 words per minute per channel, or, together, 260 words per minute have been transmitted between London and Manchester.

Another recent contribution to land-line telegraphy

shows how the two sets of signals dovetail into each other for the letters "L" and "F." Their resultant in the line is unreadable and the system may be considered to be untappable. At the receiving end a synchronous rotary commutator is used to select the two sets of signals and distribute them to their appropriate receivers, which must be polarized.

In submarine cable telegraphy developments have taken two directions: (1) Improvements in terminal apparatus, and (2) improvements in the design and construction of the cables themselves. The first-named improvement takes the form of some amplifying device.

Most cable amplifiers consist of the siphon-recorder arrangement without the recording siphon. Three examples are given in Fig. 4.

Fig. 4 (*a*) shows the well-known Heurtley hot-wire magnifier. The receiving coil controls the movement of two fine platinum wires. Adjacent to these are two fixed wires, the system being heated by current from a local battery. When the relative positions of the wires are altered by the movements of the coil, their mutual heating effect is modified. The temperature and, therefore, the resistance of the wires in one arm of the bridge are increased and the bridge balance is upset; causing a current to flow in the local recorder.

Fig. 4 (*b*) shows an arrangement in which the magnifying means is the thermionic valve. The receiving coil has two windings, one in the cable circuit as usual

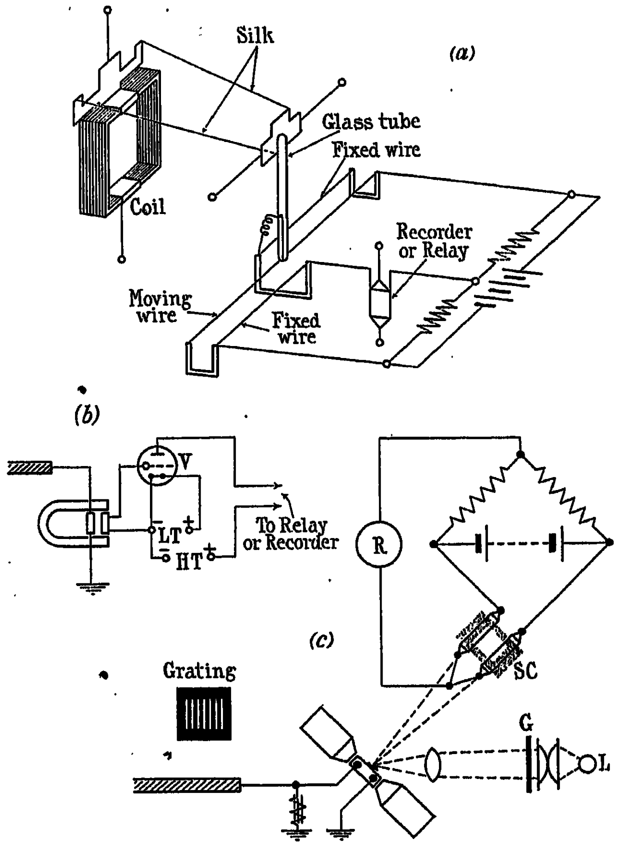

FIG. 4.

and the other so mounted that the coupling between the two coils is negligible. As the coil system oscillates in response to the cable signals, minute electromotive forces are induced in the second coil and these operate on the grid of the valve in the usual way. This amplifying arrangement is stated to give very good results; since the coil has no harness of any kind attached to it the response is very rapid and far in excess of what is actually needed. It would not, however, be applicable to block signals.

Fig. 4 (*c*) shows the arrangement of Cox's selenium-cell amplifier as used by the Pacific Cable Board. The local relay recorder (R) is in a balanced Wheatstone bridge, of which two groups of selenium cells form the third and fourth arms. By means of the optical arrangement shown, the image of a grating (G) is thrown on the two sets of cells. Minute movements of the cable receiver-coil cause abrupt variations between light and darkness and, in accordance with the well-known property of selenium, the conductivity of one bridge arm is increased while the other is decreased. An inductive shunt is placed across the cable receiver-coils. This allows the quick-acting portion of the signal elements to pass through the coils while the slowly varying part or the tail is shunted. The final signals are thus greatly improved in definition. This "shaping" is an old, well-known feature of cable telegraphy.

Amplifiers are, however, not an unmixed blessing. A long, single-wire conductor is very liable to any disturbances which prevail, and making the receiver more sensitive seriously increases this liability. Also the more sensitive the receiving apparatus, the greater is the difficulty in getting a balance which will give satisfactory duplex or two-way working. We cannot, in fact, avail ourselves of all the magnification possibilities which lie to our hands.

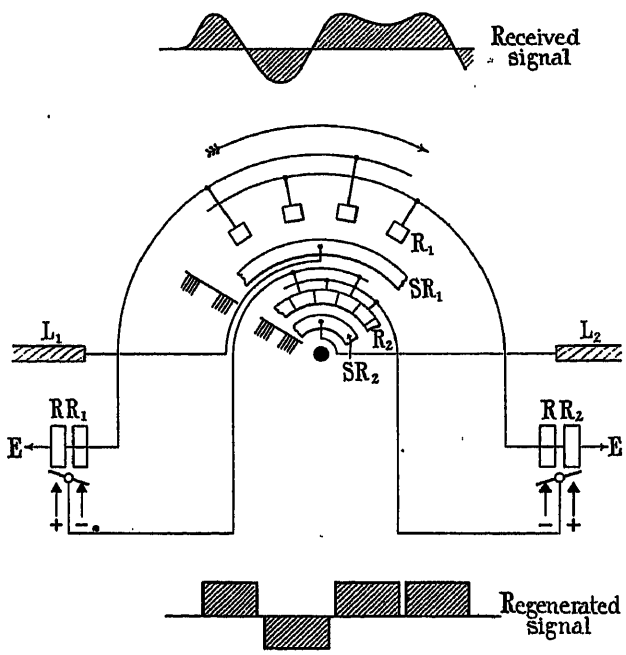

FIG. 5.

A further and more recent development in cable technique is the adoption of regenerative repeaters. The regenerative repeater is due to the eminent French telegraph engineer, the late Emile Baudot. In the ordinary form of repeater the incoming signals operate a relay which sends out current impulses from a battery or other source to the second section of the line. On long and difficult circuits this method is defective because the arriving signals at the repeater station are distorted and the relay there repeats them with further distortion, which it adds itself.

Fig. 5 shows a regenerative repeater inserted between two sections of cable and employing the cable form of morse code. At the top the letter "1" is shown as received from the cable L_1. Alternate signal elements are diverted to two receiving relays, RR_1 and RR_2 via the

solid ring (SR_1) of a rotary commutator or distributor and the short segments of ring R_1. These segments are shortened so as to pick out the middle portion of each received signal element. When a relay has been set by a signal impulse it applies current from a battery to the second line (L_2) via the segments of ring R_2 and solid ring SR_2.

It will be noted that while one relay is being set the other one is transmitting the previously received signal impulse. The setting and transmitting cycles of each relay do not overlap and good contact is assured before a signal is repeated. The rotating brush arm is driven at a constant speed, equal in segments per second to that at which the originating transmitter sends out the signal elements.

The regenerated signal, restored to its correct shape and length, is shown at the bottom of Fig. 5. This type of repeater has been carried to a high state of development by the Western Union Telegraph Co. and is in use on this company's cables. It enables the provincial offices to become extensions of the cable, and direct communication involving no retransmission is possible between Liverpool or other provincial centres and New York or Chicago.

The year 1924 has been marked by the laying of two submarine cables which have a speed of transmission, measured in letters per minute, far in excess of any previous cable. The first has been laid by the Commercial Cable Co. between this country and New York and gives a total speed of 1 200 letters per minute—600 in each direction—which is nearly twice as much as any deep-sea cable in operation at the time of laying. No particulars are available of the design, but presumably an extra heavy copper core has been provided and the electrostatic capacity kept down as much as possible.

The second cable is that between New York and the Azores, laid by the Western Union Co. This cable is loaded on the continuous plan by means of the nickel-iron alloy known as "permalloy," which has a permeability about 30 times that of the best Swedish iron. The speed obtained is 1 700 letters per minute in one direction, nearly six times that ordinarily attained. Writing in 1917, Dr. Malcolm in his book "The Theory of the Submarine Telegraph and Telephone Cable" said: "The possibilities in the future of cable telegraphy in its own sphere are as brilliant as are those of wireless telegraphy. Although the difficulties in the way of their realization must not be underestimated, none appear to be insuperable . . . there can be but little question that cable telegraphy is about to enter upon a period in which all its past achievements will be excelled." His prophecy has not been long in its fulfilment.

The submarine telephone cable has quite recently undergone a radical change in design, as evidenced by the laying of the Anglo-Dutch cable between Domburg, Walcheren and Aldeburgh (Suffolk) which was completed on the 29th August, 1924. Its length is 86 miles, and it consists of eight pairs of continuously loaded conductors, insulated with dry paper and lead-covered and armoured. The submersion was successfully accomplished and it fully met the conditions laid down in the specification. In an editorial comment the *Electrician* truly pointed out that the successful completion of this undertaking solves one of the principal engineering problems involved in the development of an international telephone service, which, when established, will play an important part in promoting better political and commercial relations between Great Britain and continental countries.

A great deal of experimental work has been conducted in Germany recently on carrier-current telegraphy. The German engineers have adopted audio frequencies of the same order with respect to amplitude as speech currents in ordinary telephony. Thus it is possible to take a pair or pairs in existing telephone cables. Repeater stations are of the same type as used for telephone purposes. In this way, six separate telegraph transmissions of 166 words per minute, say 1 000 words, over a loaded cable with an *al* of 2·3 have been obtained. The sending voltages are approximately 1 volt and no disturbance is caused to the telephone pairs in the same cable. Germany appears to be the first administration to employ audio-frequency multiple telegraphy in loaded cables, and we might prophesy that in future, at all events in countries where the distances are comparatively short, the telegraph network will be formed of twisted pairs run in telephone cables.

Radio telegraphy has progressed and is progressing. It is still not without its problems, but we cannot suppose that the large band of workers engaged in this branch of the art will be content to stand still. The "beam" system recently announced by Dr. Marconi is full of possibilities. If it realizes all the expectations of its sponsors, radio telegraphy will once again catch up with the progress recently made in wire telegraphy. Radio and wire channels interlinked will permit of international telegraphy and telephony on a scale not contemplated hitherto. At no period in the development of the communication art has progress been so rapid as it is to-day. This results from the intensive research work carried on continuously by the workers in the different fields.

No paper dealing with this subject should omit a reference to the extraordinary development taking place in the replacement of manually operated telephone exchanges by machine-switching methods. It is no secret that London is being converted from manual to machine operation. The work of installation has already commenced and will occupy from 15 to 20 years before it is complete. The transition period has given rise to serious problems, which have been satisfactorily solved by the Post Office and other engineers who are members of this Institution. Tokio is about to undergo conversion, while Buenos Aires has been in course of conversion for some years.

To the younger members I should like to address a few remarks: I hope that I have been able to show that communication engineering is interesting. It is more than this. It involves just as much engineering consideration as the heavy and, perhaps, more spectacular branch of our profession. While it has been the subject of good-humoured contempt in the past, it is rapidly acquiring a standing and dignity to which it is fully entitled. For many years to come it will offer to the young trained engineer an opening for his talents, and it is not without its prizes too.

WIRELESS TELEGRAPH VALVE TRANSMITTERS EMPLOYING RECTIFIED ALTERNATING CURRENT.

By G SHEARING, B.Sc., Member.

(*Paper received 7th August, and read before the* WIRELESS SECTION *3rd December*, 1924.)

SUMMARY.

The paper describes the development of some of the valve transmitters employing rectified power for naval purposes, from December 1918, onwards. The earlier work is briefly reviewed and general considerations of design for ship conditions are dealt with.

A description is given of the method of calculation of the geometry of the rectifying valve electrodes and of the power loss.

Some of the types of transmitter circuits employed are described, also detail circuit improvements for satisfactory working.

Arrangements of valves in series and the use of coupled circuits for drying-out wet aerial systems, also separate grid-excitation circuit arrangements, are dealt with.

Experimental circuits for the reduction of harmonic interference, also the arrangements adopted for signalling by grid potential control, are discussed.

Finally, the design of the transmitting valve electrodes is dealt with and the question of valve rating is discussed.

TABLE OF CONTENTS.

INTRODUCTION.

This paper deals with some of the valve wireless telegraph transmitters and power supply circuits utilizing rectified current, which have been developed in the Experimental Department of H.M. Signal School for naval purposes from December 1918, onwards. The earlier experimental work, which is briefly reviewed, had indicated that the valve transmitter would supersede both arc and spark transmitters for naval purposes, and this conclusion has since been confirmed by the results obtained, in experimental and routine working, from valve transmitters installed during and since 1919 in the Fleet and in Admiralty shore stations.

SECTION 1.

Earlier work.—The experimental war work * on transmitting valves and circuits carried out from 1915 to 1918 led up to the successful production early in 1918 of a valve transmitter for continuous-wave transmissions which could compete fairly satisfactorily with an arc transmitter of 5 kW supply power from d.c. mains on the same range of wave-lengths as regards received signal strength and distance, and was much superior as regards speed of working. This transmitter employed one glass transmitting valve, type T4 and, later, T4A, of 400 watts anode rating. An alternative design of increased power, which was used in a few cases, employed two T4A valves in parallel. Also, prior to these, valve transmitters of smaller powers had been successfully employed in ships.

The source of h.t. power supply for the T4A valve was the spark-telegraphy alternator and single-phase transformer, the high-voltage direct current required for the anode of the transmitting valve being obtained from a two-wave rectifier unit with smoothing condenser. No special switching arrangements were supplied for interrupted continuous wave (I.C.W.) transmissions, but the change from continuous waves (C.W.) to I.C.W. could be made when required, either by cutting the rectifier unit out of circuit or by disconnecting the smoothing condenser.

For small ships and for the second offices of heavy ships the usual installations were either (1) a spark transmitter supplied from a rotary converter and h.t. transformer and an arc transmitter of 5 kW d.c. input, or (2) the spark set together with the valve C.W. transmitter having one T4A valve. In this case the valve set received its power via the spark h.t. transformer.

* C. L. FORTESCUE: *Report of the British Association for the Advancement of Science*, 1919, and *Radio Review*, 1919, vol. 1, p. 83; B. S. GOSSLING: *Journal I.E.E.*, 1920, vol. 58, p. 670; G. STEAD: *Ibid.*, 1920, vol. 58, p. 107.

Two C.W. valve transmitters of increased power, employing three T4A valves in parallel, were designed and built at the Signal School towards the end of 1918, and were installed at Aberdeen and Ipswich in January and March 1919, respectively. These sets have since been in continuous use for routine work; at Aberdeen an aerial current of 50 amperes was obtained on a wave-length of 3 100 m during the tuning trials in January 1919, the aerial capacity being 2·8 jars.

The results obtained with these sets at shore stations and at sea were so satisfactory that a demand arose during 1919 for valve transmitters of increased power and robustness of design which would not only cover the required range of C.W. wave-lengths but also be suitable for I.C.W. transmissions on the spark range of wave-lengths. In this way the dual arrangement of spark and C.W. valve, or alternatively spark and arc, was replaced by a single-valve transmitter capable of working at a greatly increased speed, the keying of the circuits being arranged for the operator to listen-through during the intervals of his transmission signals.

General considerations.—Arising out of the results obtained with the above sets, the further development of medium-power and high-power valve transmitters for routine work which was put in hand during 1919–20 may be summarized as follows:—

(*a*) Transmitters for Fleet use capable of supplying power of from 2 kW to 10 kW to the aerial under normal conditions and occupying the minimum possible space for satisfactory routine operation in existing wireless telegraph offices; and

(*b*) Transmitters for shore stations for aerial powers up to 30 kW of much more open design.

In addition, certain transmitters of much higher power than (*b*) have been developed.

In the majority of cases the transmitter has been designed to utilize already existing sources of power supply. In this respect it has been fortunate that the power plant for the old spark-telegraphy transmitters was usually suitable for a valve transmitter. The change-over from spark to valve has for this reason been very economical, bearing in mind the advantages obtained from the installation of the valve transmitter.

The main conditions to be aimed at in the design of the valve sets may be enumerated as follows:—

(1) Reliability of working under seagoing conditions, including gunfire.
(2) Satisfactory operation with the insulation of the aerial oscillatory circuit subjected to severely wet conditions.
(3) Robust design of component parts.
(4) Change of wave-length in short time.
(5) Simplicity of control apparatus.
(6) Reasonably efficient working over a very wide range of wave-lengths.
(7) Protection of h.t. power plant and component parts of transmitter from breakdown.
(8) Ready access to each component part.

The total space available has usually been very limited in naval ships and it has been difficult to design a set capable of accommodation so that the required aerial power could be obtained over a wide range of wave-lengths without sparking to earth from the oscillatory circuits. The solution was largely assisted by the successful introduction of the silica valve during 1920; this required less space for the required anode dissipation compared with glass transmitting valves.

The valve transmitters evolved up to 1918 had their apparatus mounted on wood panels to which the valves and other components were fixed. This method was not considered sufficiently robust, and panels of transmitters were developed whose sides were usually composed of angle metal with the component parts bolted to straps of metal or insulation as required, the panel fronts being enclosed with expanded metal capable of removal when necessary. Usually these panels required subdivision to enable them to be readily passed down the hatchways of ships. This system, introduced by Mr. H. Morris-Airey at the end of 1918, has facilitated the standardization, transport and installation of transmitters in ships in the various dockyards.

SECTION 2.

The production of h.t. power.—The majority of the C.W.–I.C.W. transmitters use rectified single-phase

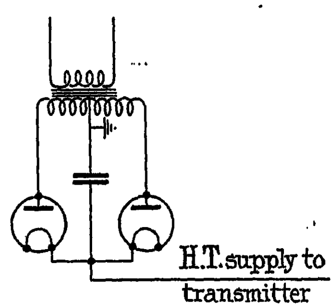

FIG. 1.

alternating current employing two-wave rectification as in the simple circuit shown in Fig. 1. For high powers multiphase rectification is employed.

The single-phase circuit has been described by Prof. C. L. Fortescue, who has deduced formulæ * for design calculations based on the assumption that the saturation current flows through the rectifying valve for the time of each period of the a.c. supply when the anode is positive to the filament.

This assumption was valid for the earlier valve transmitters employing h.t. power supply considerably less than the full power output of the alternator and transformer and having rectifying-valve filaments of small electronic emission. With increase of the aerial power requirements it has been found essential to obtain as high an efficiency of rectification as possible, as the motor-alternators installed were of limited output. The rectifying valves have been designed with liberal filament emission so that, with normal circuit adjustments corresponding to full power, filament saturation

* *Proceedings of the Physical Society*, 1919, vol. 31, p. 319.

does not occur. The increase of filament power required, usually obtained from an auxiliary motor-alternator, has been small in comparison with the gain resulting from the increase of rectified power available for the transmitter.

The exact calculation of the efficiency of a rectifier unit is complex, as has been pointed out by other writers, due to the effects of the transformer impedance and the shape of the anode current/voltage characteristics of the valves. Other factors are the ripple on the rectified potential and the impedance of the transmitting network. The following approximations for a two-wave single-phase supply have enabled design calculations for the valves to be made sufficiently accurately.

As regards the valve itself, the well-known formula for the space current, assuming a filament of infinite emission, is

$$i = 2 \cdot 93 \times 10^{-5} \frac{v^{3/2}}{d_a} l \quad . \quad . \quad . \quad . \quad (1)$$

where d_a = diameter of anode or plate;
l = effective length of anode; and
v = anode-filament P.D.

For the case of hard valves, however, it is found in practice, for the maximum P.D.'s in use for valve as conductor* and with filaments of limited but considerably greater emission than the maximum required, that the relation between the P.D. and anode current may be expressed approximately by :—

$$i_r = \frac{V \sin \omega t - (k + v)}{r} \text{ when } V \sin \omega t > (k + v) \,. \quad (2)$$

where i_r = anode current;
$V \sin \omega t$ = anode potential, assumed sinusoidal;
k = constant;
v = filament potential; and
r = apparent resistance of valve.

The ripple of the smoothing-condenser voltage is strictly dependent on exponential and sinusoidal functions. As, however, the ripple is of small magnitude relative to the mean potential, the assumption has been made, for calculating the rectifier power loss, that the ripple can be represented by straight lines covering each period of the a.c. supply. Referring to Figs. 1 and 2, let :—

$V \sin \omega t$ = instantaneous transformer line voltage to mid-point;
r = apparent resistance of each rectifying valve;
i_r = instantaneous valve current;
V_0 = mean rectified voltage;
C = smoothing condenser capacity;
I_0 = mean current output of condenser;
R = equivalent load resistance, assumed non-inductive;
v_c = permissible maximum ripple about mean value V_0; and
$v_1 = V_0 - v_c$; $v_2 = V_0 + v_c$.

For the instant of minimum condenser voltage, the current through one rectifying valve is equal to that in the transmitting network.

* That is, when the anode potential is positive to that of the filament.

$$\text{Hence } \frac{V \sin \theta - (k + v_1)}{r} = \frac{v_1}{R};$$

$$\sin \theta = \frac{1}{V}\left\{\frac{v_1(R + r)}{R} + k\right\} \quad . \quad (3)$$

$$\text{Similarly} \quad \sin \alpha = \frac{1}{V}\left\{\frac{v_2(R + r)}{R} + k\right\} \quad . \quad . \quad . \quad (4)$$

The current i_r for the angle ωt between the angles θ and α

$$= \frac{V \sin \omega t - [k + v_1 + 2v_c(\omega t - \theta)/(\alpha - \theta)]}{r} \quad (5)$$

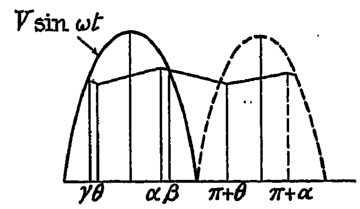

FIG. 2.

The energy used in the rectifying valves for the time between the angles θ and α is

$$\frac{1}{r\omega}\int_\theta^\alpha \left[\left\{V \sin \omega t - \left(k + v_1 + 2v_c\frac{\omega t - \theta}{\alpha - \theta}\right)\right\}\right.$$
$$\left.\left\{V \sin \omega t - \left(v_1 + 2v_c\frac{\omega t - \theta}{\alpha - \theta}\right)\right\}\right] d\omega t$$
$$= \frac{1}{r\omega}\left[\frac{V^2}{2}(\alpha - \theta - \sin \alpha \cos \alpha + \sin \theta \cos \theta)\right.$$
$$+ V(k + 2v_1)(\cos\alpha - \cos\theta) - 4Vv_c\left(\frac{\sin\alpha - \sin\theta}{\alpha - \theta} - \cos\alpha\right)$$
$$\left. + \{kv_1 + kv_c + v_1^2 + 2v_1v_c + \tfrac{4}{3}v_c^2\}(\alpha - \theta)\right] \quad . \quad . \quad (6)$$

and the rectified energy is

$$\frac{1}{r\omega}\int_\theta^\alpha \left[\left(v_1 + 2v_c\frac{\omega t - \theta}{\alpha - \theta}\right)\right.$$
$$\left.\left\{V \sin \omega t - \left(k + v_1 + 2v_c\frac{\omega t - \theta}{\alpha - \theta}\right)\right\}\right] d\omega t$$
$$= \frac{1}{r\omega}\left\{Vv_1(\cos\theta - \cos\alpha) + 2Vv_c\left(\frac{\sin\alpha - \sin\theta}{\alpha - \theta} - \cos\alpha\right)\right.$$
$$\left. - (kv_1 + kv_c + v_1^2 + 2v_1v_c + \tfrac{4}{3}v_c^2)(\alpha - \theta)\right\} \quad . \quad . \quad (7)$$

To determine the angles β and γ for zero current we have as an approximation

$$V \sin \beta = k + v_2 - 2v_c\frac{\beta - \alpha}{\pi + \theta - \alpha} \quad . \quad . \quad (8)$$

$$V \sin \gamma = k + v_1 + 2v_c\frac{\theta - \gamma}{\pi + \theta - \alpha} \quad . \quad . \quad (9)$$

The energy expended in the rectifying valves for the times between the angles θ and γ and the angles β and a is approximately

$$\frac{1}{4r\omega}(V\sin\theta - k - v_1)^2(\theta-\gamma) + \frac{1}{4r\omega}(V\sin a - k - v_2)^2(\beta - a) \quad . \quad (10)$$

and the energy supplied from the transformer for these times is approximately

$$\frac{1}{2r\omega}\int_{\gamma}^{\theta}(V\sin\theta - k - v_1)(V\sin\omega t)d\omega t$$

$$= \frac{1}{2r\omega}(\cos\theta - \cos\gamma)(Vv_1 + kV - V^2\sin\theta) \quad (10a)$$

and $\dfrac{1}{2r\omega}(\cos\beta - \cos a)(Vv_2 + kV - V^2\sin a) \quad (10b)$

Summarizing the above we have :—

Mean power loss per period in the valves.

$$\begin{aligned} W_r = \frac{1}{\pi r}\Big[& \frac{V^2}{2}(a - \theta - \sin a\cos a + \sin\theta\cos\theta) \\ & + V(k + 2v_1)(\cos a - \cos\theta) \\ & - 4Vv_c\Big(\frac{\sin a - \sin\theta}{a-\theta} - \cos a\Big) \\ & + (kv_1 + kv_c + v_1^2 + 2v_1v_c + \tfrac{4}{3}v_c^2)(a-\theta) \\ & + \tfrac{1}{4}\{(V\sin\theta - k - v_1)^2(\theta - \gamma) \\ & + (V\sin a - k - v_2)^2(\beta - a)\}\Big] \quad . \quad . \quad (11) \end{aligned}$$

Mean power rectified.

$$\begin{aligned} W_{TR} = \frac{1}{\pi r}\Big[& Vv_1(\cos\theta - \cos a) \\ & + 2Vv_c\Big(\frac{\sin a - \sin\theta}{a-\theta} - \cos a\Big) \\ & - (kv_1 + kv_c + v_1^2 + 2v_1v_c + \tfrac{4}{3}v_c^2)(a-\theta) \\ & + \tfrac{1}{2}\{(\cos\theta - \cos\gamma)(Vv_1 + kV - V^2\sin\theta) \\ & + (\cos\beta - \cos a)(Vv_2 + kV - V^2\sin a)\} \\ & - \tfrac{1}{4}\{(V\sin\theta - k - v_1)^2(\theta-\gamma) \\ & + (V\sin a - k - v_2)^2(\beta - a)\}\Big] \quad . \quad (12) \end{aligned}$$

If we neglect the terms involving the angles γ and β, which are small, then

$$\begin{aligned} W_{TR} = \frac{1}{\pi r}\Big[& Vv_1(\cos\theta - \cos a) \\ & + 2Vv_c\Big(\frac{\sin a - \sin\theta}{a-\theta} - \cos a\Big) \\ & - (kv_1 + kv_c + v_1^2 + 2v_1v_c + \tfrac{4}{3}v_c^2)(a-\theta)\Big] \quad (13) \end{aligned}$$

and

$$\begin{aligned} W_r = \frac{1}{\pi r}\Big[& \frac{V^2}{2}(a - \theta - \sin a\cos a + \sin\theta\cos\theta) \\ & + V(k+2v_1)(\cos a - \cos\theta) - 4Vv_c\Big(\frac{\sin a - \sin\theta}{a-\theta} - \cos a\Big) \\ & + \{kv_1 + kv_c + v_1^2 + 2v_1v_c + \tfrac{4}{3}v_c^2\}(a-\theta)\Big] \quad . \quad . \quad (14) \end{aligned}$$

Also, if we equate the quantity delivered to the load circuit to that supplied through the rectifying valve, we have, assuming no leakage current through the smoothing condenser,

$$I_0 \times \frac{\pi}{\omega} = \frac{1}{r\omega}\int_{\theta}^{a}\Big\{V\sin\omega t - \Big(k + v_1 + 2v_c\frac{\omega t - \theta}{a-\theta}\Big)\Big\}d\omega t$$

$$r = \frac{V(\cos\theta - \cos a) - (k + v_1 + v_c)(a-\theta)}{I_0\pi} \quad . \quad . \quad (15)$$

and the value of the smoothing condenser, if no filter circuit is employed, is approximately

$$C = \frac{I_0}{\omega}\{\pi - (a - \theta)\}\frac{1}{2v_c} \quad . \quad . \quad . \quad (16)$$

For the case of negligibly small ripple, Equations (3), (4), (14) and (13) reduce to

$$\sin\theta = \sin a = \frac{1}{V}\Big\{V_0\frac{(R+r)}{R} + k\Big\} . \quad . \quad (17)$$

$$\begin{aligned} W_r = \frac{1}{\pi r}\Big\{ & \frac{V^2}{2}(\pi - 2\theta + 2\sin\theta\cos\theta) \\ & + V(k + 2V_0)(-2\cos\theta) + (kV_0 + V_0^2)(\pi - 2\theta)\Big\} \quad . \quad (18) \end{aligned}$$

$$W_{TR} = \frac{1}{\pi r}\{VV_0(2\cos\theta) - (kV_0 + V_0^2)(\pi - 2\theta)\} \quad (19)$$

The design of the rectifying-valve electrodes and the smoothing condenser has usually been based on the following available data :—

(a) The mean supply voltage and power to the transmitter.
(b) The order of permissible voltage ripple.
(c) The maximum anode-filament valve P.D. with anode positive.

The value adopted for (c) determines the efficiency of rectification. For transmitter supply voltages of 10 000 to 12 000 utilizing silica rectifying valves with molybdenum anodes, the valves have been so designed that the maximum current is well below that for filament saturation for a maximum P.D. of 3 000 volts with anode positive. The value of k is of the order of 300 volts for valves with molybdenum anodes designed for an operating power loss up to 5 kW per valve.

As an example let us take the case of a valve transmitter requiring 15 kW of rectified power at a mean anode voltage of 10 000, the smoothing condenser ripple to be of the order of $\pm$ 4 per cent and the maximum conducting P.D. for the valve 3 000 volts.

Equations (15) and (16) enable the resistance r of the rectifying valve and the smoothing condenser capacity C to be calculated with a sufficiently close accuracy, if we assume $\sin\theta = (v_1 + k)/V$ and $\sin a = (v_2 + k)/V$ as approximations. This gives $r = 494$ ohms, $C = 1\cdot 56\,\mu$F.

Adopting this value for r, the power loss may be calculated from Equation (11), having first re-calculated the angles θ and a from Equations (3) and (4), and the angles β and γ from Equations (8) and (9). This gives

$\theta = 54° 42'$, $\alpha = 118° 4'$, $\beta = 125°$, $\gamma = 49° 30'$ and the power loss in the rectifying valves $= 3\cdot6$ kW (or $1\cdot8$ kW per valve).

The efficiency of rectification $= 15/18\cdot6 = 81$ per cent.

The valve filament has to be such that it will give a space current of $(3\,000 - 300)/494 = 5\cdot46$ amperes with the filament well below saturation.

The curves of Fig. 3 show the results of calculations for various anode voltages, assuming a constant maximum permissible conducting P.D. for the valve. They illustrate the increased efficiency to be obtained from rectifying at as high a rectified voltage as practicable, but in this connection due regard has to be paid to the maximum permissible voltage which the valve will withstand as an insulator, i.e. when the anode is negative to the filament. It has been usual to specify an acceptance-test P.D. of 40 000 volts with the valve as insulator and the anode not heated, but experience has shown that for average valves it is inadvisable to go beyond 14 000 volts (corresponding to 31 000 volts maximum P.D.) if the valves are to be worked at full power dissipation for long periods.

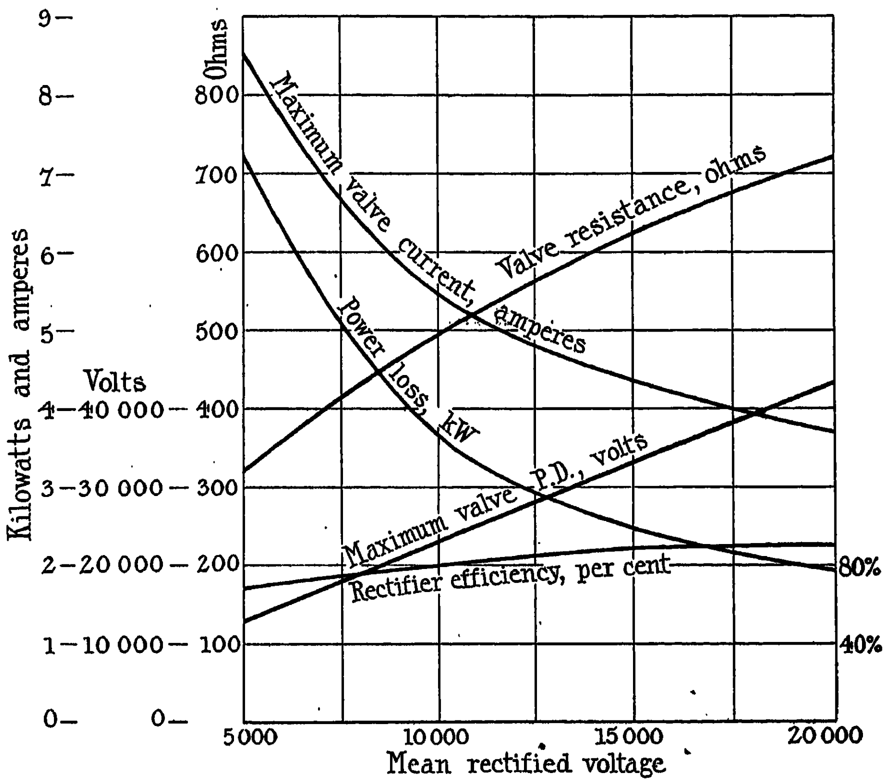

FIG. 3.—Calculated curves for constant rectified power of 15 kW.

Furthermore, as the valve transmitters have to be designed for a very large range of wave-lengths it is difficult at some wave-lengths to avoid the operation of the transmitter at aerial circuit adjustments corresponding to full power supply at lower voltages. For this reason the anodes of the valves are designed for full power supply at a rectified potential of 10 000 volts. Similar calculations may be made for other values of maximum positive anode-filament P.D.; reducing this P.D. corresponds to increased rectifying efficiency.

The filaments are usually designed for 50 per cent greater filament emission than the calculated value. Usually the length of the filament is settled upon as a first approximation, and the filament diameter can then be calculated. The filament length fixes the anode length. To estimate the anode diameter it usually suffices to calculate the diameter of the valve anode whose mean resistance from the space current equation (1) is equal to the required value.

From this equation $\dfrac{dv}{di} = \dfrac{d_a v^{-\frac{1}{2}}}{k}$

where $k' = 2\cdot93 \times 10^{-5} \times l \times 1\cdot5$

and mean value

$$= r = \frac{d_a}{V'}\int_0^{V'} \frac{v^{-\frac{1}{2}}dv}{k'} = \frac{2d_a}{k'\sqrt{V'}}$$

where V' = maximum anode-filament P.D., hence the valve anode diameter should not be greater than

$$k'\sqrt{V'} \times \tfrac{1}{2}r$$

The filament diameter for the filament emission required was calculated to be $0\cdot065$ cm for an effective

length (loop) of 28 cm.* For an anode of length 14 cm, $k' = 615 \times 10^{-6}$, $V'^{\frac{1}{2}} = \sqrt{3\,000} = 54 \cdot 8$, $d_a = 494/2 \times 615 \times 10^{-6} \times 54 \cdot 8 = 8 \cdot 3$ cm as maximum value. A molybdenum anode of these dimensions is sufficiently large for the required anode dissipation. A series of calculations for various lengths of filament enables the most economical anode to be determined.

The change of power each quarter-period

$$= 23 \cdot 1\sqrt{2} \times 27 \cdot 6\sqrt{2} = 1\,275 \text{ watts.}$$

The change of energy $= 1\,275/(4f)$ joules $= 76 \cdot 5/f$ calories for frequency f. The total length of the tungsten filament, allowing for end corrections, is

TABLE 1.

Type	Anode (Molybdenum)		Static bombard-ment	Filament			Rectified power; 2-wave rectification			Maximum conducting P.D.	Test voltage between electrodes
	Length	Diam.		V	I	Power	V_0	I_0	Power		
	cm	cm	kW	volts	amps.	kW	volts	amps.	kW	volts	volts
NU21 (silica) ..	9·5	8·0	3·0	18·5	16·9	0·31	11 000	1·0	11	3 000	40 000
NU22 (silica) ..	14·5	8·0	4·5	25·9	21·7	0·56	12 000	1·5	18	3 000	40 000
NU23 (silica) ..	30·0	12·0	20 to 25	33·0	51·0	1·68	14 000	3·6	50	4 000	50 000

The loop form of filament with cylindrical anode has been invariably used and, to secure uniformity of electron current in the two sides of the loop at any instant for alternating-current supply, a small double-wound inductance with mid-point tapping, known as an equalizing coil, has been placed across each filament. The electron current is taken from this mid-point, the two halves of the inductance being wound bifilarly so that each has the same inductance. The coils can be placed immediatley adjacent to each valve filament, and separate filament regulation is permissible.

An approximate computation of the effect of the filament supply frequency may be made by assuming that the filament temperature follows the energy change per quarter period. Let us take as an example the above filament requiring 27·6 amperes at 23·1 volts at a temperature of 2 480° K.

35·8 cm, its mass = 2·26 g, and its specific heat = 0·034. The mean temperature-change

$$= \frac{76 \cdot 5}{0 \cdot 034 \times 2 \cdot 26 \times f} = \frac{995 \text{ deg. C.}}{f} = 4 \text{ deg. C. for } f = 250$$

Hence for $f = 250$ there is a temperature variation not greater than $\pm$ 2·0 deg. C. every half-period.

The effect of unequal currents through individual valves of a rectifying system is reduced as much as practicable by rheostat control, and for quick visual indication it has been found convenient to place in each line small metal-filament lamps with resistance shunts so that each lamp glows brightly at full power.

Data relating to the electrodes for standard designs of rectifying valves are given in Table 1.

Two-wave rectifier unit.—Fig. 4 shows a typical unit for supply power up to 30 kW with smoothing condenser and switching arrangements whereby the anodes of the transmitter may be readily supplied with either

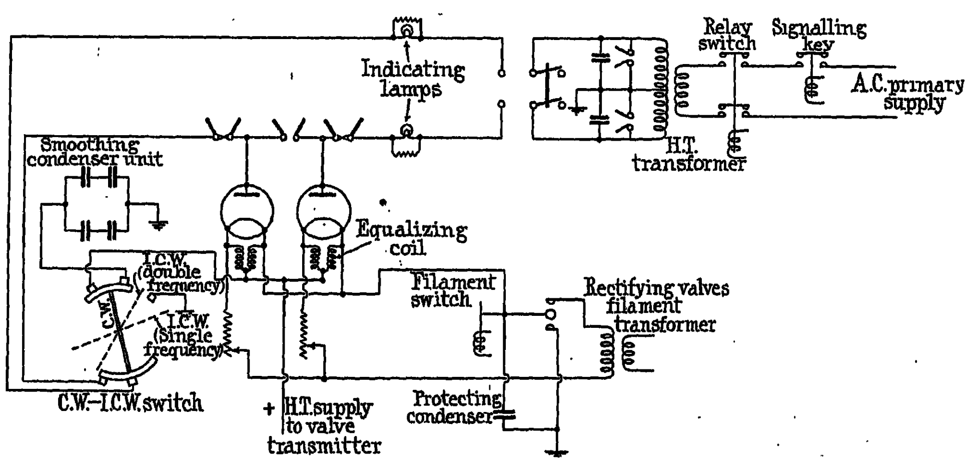

FIG. 4.

* For filament calculations see G. STEAD: *Journal I.E.E.*, 1920, vol. 58, p. 107.

a steady potential for C.W. transmissions or varying potential for I.C.W. transmissions.

Separate rheostat control is provided for each valve filament, which, in addition, is fitted with an equalizing coil. The filament supply switch is connected so that

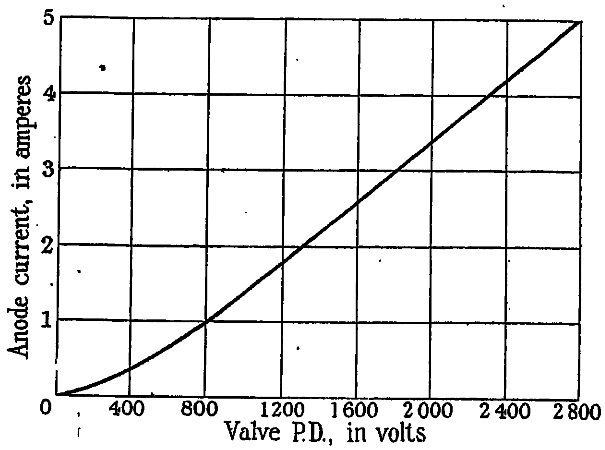

FIG. 5.—Anode current and valve P.D. Rectifying valve type NU 22.

the smoothing condenser is short-circuited to earth when the valve filaments are switched off. The smoothing condenser may consist either of condensers arranged in series-parallel as shown, or, for cases where the ripple of the supply voltage to the transmitter must be

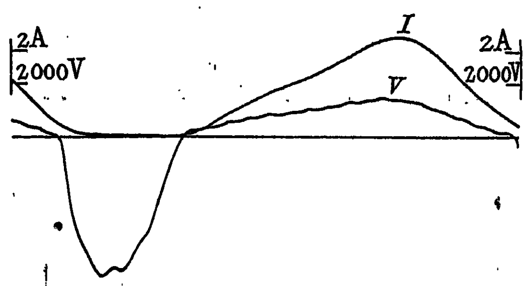

FIG. 6.—Valve current and valve P.D. for rectifying valve type NU 22. $f = 50$.

negligibly small, a filter circuit of chokes and condensers may be employed.

Horn-break fuses are provided in each line to protect the valves and transformer from short-circuiting of

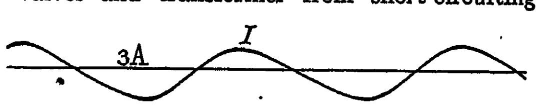

FIG. 7.—Two-wave rectification. Resultant rectified current; $f = 50$.

the smoothing condenser; these are combined with spark-gaps across the transformer. It has been found necessary also to insert across each line of the transformer secondary two small condensers of the order of one to five jars' capacity with the mid-point earthed as shown, to avoid high potential-rises which may otherwise occur and cause breakdown due to high-frequency induction in the h.t. supply lines. It is naturally very important that the high-frequency circuits should be as far away as possible from these lines, but the danger of stray induction due to the cramped conditions under which the sets are fitted cannot be entirely avoided.

A three-way switch has usually been fitted to enable a ready change to be made from C.W. to I.C.W. at

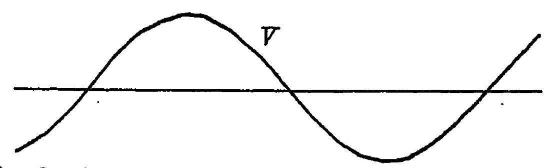

FIG. 8.—Open-circuit voltage (R.M.S.) = 5 750; $f = 50$.

either the frequency or twice the frequency of the alternator. For I.C.W. at twice the alternator frequency the smoothing condenser is disconnected from the valve filaments and earthed. For I.C.W. at the alternator frequency one line of the h.t. supply is also broken. Retaining the rectifying valves for the I.C.W. transmissions enables the change from C.W. to I.C.W. to be made with simple circuit adjustments, but in certain

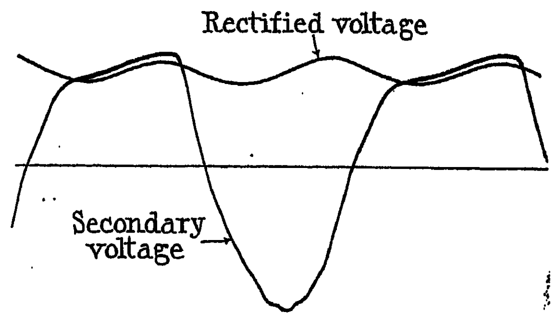

FIG. 9.—Two-wave rectification. Rectified voltage = 5 400; smoothing condenser 1 μF; rectified current = 0·23 ampere; $f = 50$.

cases I.C.W. is obtained by direct connection of the transmitter to one of the h.t. lines, which has the disadvantage that the transmitting valve is directly subjected to the alternating potential.

Experimental results.—The oscillograms of Figs. 6 to 11 inclusive have been obtained for valves of type NU 22 which approximates to the design outlined on pages 318 to 320. Those taken for a 50-period supply enable a voltage/current characteristic of the valve to be deduced, and from these and similar curves at in-

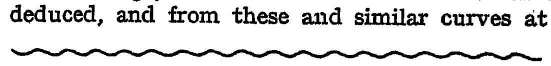

FIG. 10.—Curve of voltage ripple; smoothing condenser 1 μF; $V_0 = 9\,000$ volts; $I_0 = 1{\cdot}0$ ampere; $f = 300$.

creased voltages it is found that the valve is well below saturation for currents of the order of 5 to 6 amperes. The mean characteristic obtained from oscillograms is given in Fig. 5.

In connection with the voltage wave-form obtained

wire with multi-layer turns, and in most cases aerial circuit tuning by means of a large, coarse tapping coil and a smaller, fine tapping coil has been employed, very fine adjustments being obtained by a continuously adjustable small copper tube or strip coil. For the longer wave-lengths the anode tapping for best operation of the valve is usually intermediate between tappings on the coarse coil, and to enable best tappings to be obtained the coil section has been shunted by a coil of inductance considerably greater than that of the section. The anode tapping connection is then made to a continuously adjustable contact on this coil, which may for convenience be located in the valve panels, the best adjustment during operation being obtained by a switch operated from the panel front.

E.M.F. ωMI_1, and the anode voltage V_a is approximately at 90° to I_1, neglecting the mutual grid induced E.M.F. in the oscillatory circuit coupling coil and the P.D. across the anode condenser.

A difficulty experienced with the early sets when continuously changing wave-lengths, was the danger of operators transmitting with the grid variable condenser adjusted to such a position of increased capacity over the correct value that excessive grid currents were set up. These excessive currents caused breakdown either of the coil or condenser insulation or overheating of the grid-leak resistance, since increase of grid oscillatory current gives a corresponding increase of grid-leak current.

This danger has been minimized by the simple expedi-

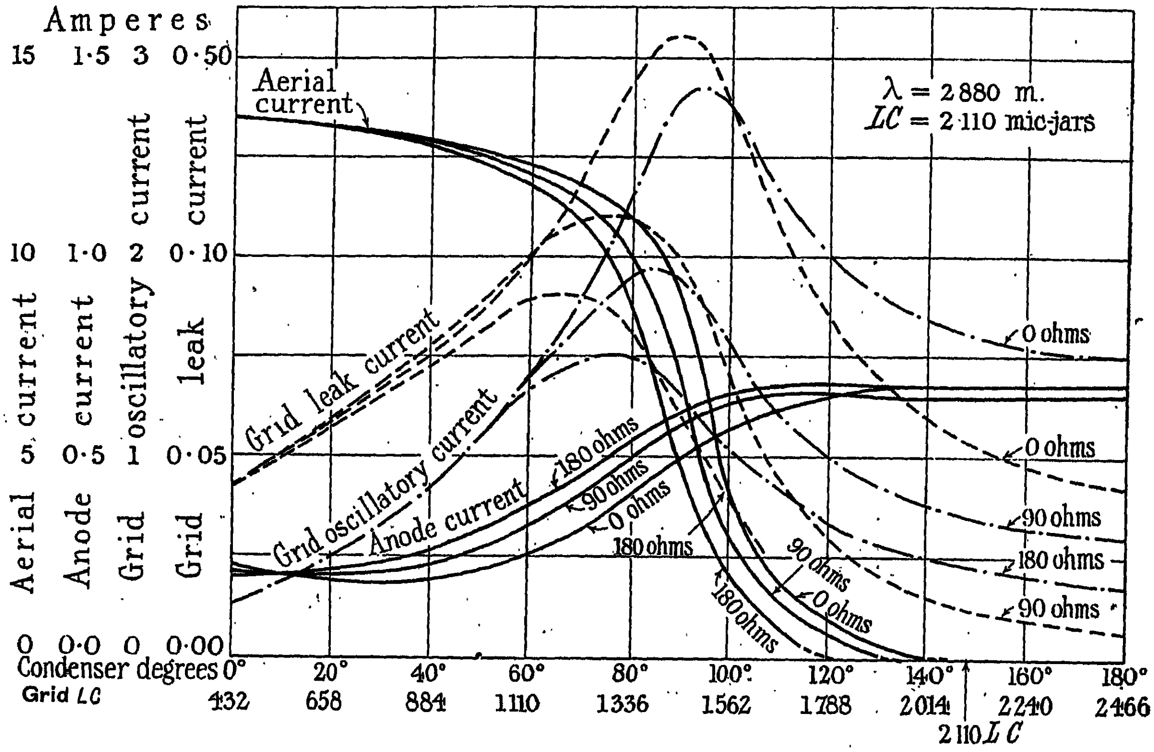

FIG. 19

Grid coupling coil circuits: inductive coupling.—The coils have been mainly of disc construction or partially disc and cylinder, the grid coil being usually shunted by a variable condenser. For ship sets giving aerial powers of the order of 2 kW the adjustments which have usually been provided are those for varying (i) turns of grid circuit coil, (ii) mutual coupling to aerial circuit coil, (iii) capacity of variable condenser, or (iv) turns of aerial circuit coil.

The vector diagram of Fig. 18 for the case of the circuit of Fig. 17 illustrates the conditions for proper direction of the grid coupling coil, neglecting the effect of the grid leak and valve circuit and of the anode condenser circuit. The grid current i_g leads over the grid induced E.M.F. by an angle which approximates to 90°. The oscillatory current I_1 is at 90° to the induced

ent of placing a resistance in the grid oscillatory circuit. Provided its value is not too high, the aerial, anode-supply and grid-circuit currents are practically unaltered with the condenser in the correct position; on the other hand, the maximum value of the grid current i_g is considerably reduced. When carbon lamps are used, or a lamp shunted by a resistance, a visual indication of incorrect dangerous adjustment is afforded. The experimentally determined curves of Fig. 19 illustrate the effect; the curves corresponding to the use of resistance coincide with the corresponding curves for no resistance, when the grid condenser adjustment corresponds to minimum anode current. For incorrect adjustments corresponding to increased capacity, when the value of LC for the grid oscillatory circuit approaches that for the oscillatory circuit, the resis-

tance reduces the maximum values considerably with automatic protection of the grid circuit.

In the vector diagram shown in Fig. 18 the effect of the grid leak and of the valve resistance from grid to filament has been neglected. This apparent valve

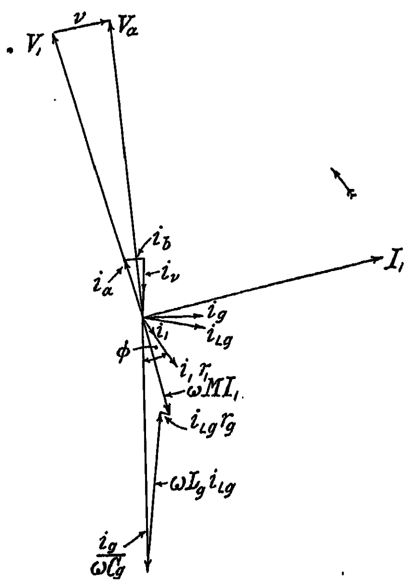

FIG. 20.

resistance will vary in value with the variation of grid potential; it will be a minimum when the grid-filament voltage is a maximum and positive. It is of interest to note in general the effect of a grid-filament resistance of value r_1. Referring to Fig. 17, the impedance of the grid leak and valve grid-filament circuit in parallel with the condenser C_g is :—

$$\frac{r_1(1 + r_L^2\omega^2c_L^2) + r_L}{1 + r_L^2\omega^2c_L^2} - j\frac{r_L^2\omega c_L}{1 + r_L^2\omega^2c_L^2}$$

and the phase angle ϕ of the current and grid-filament

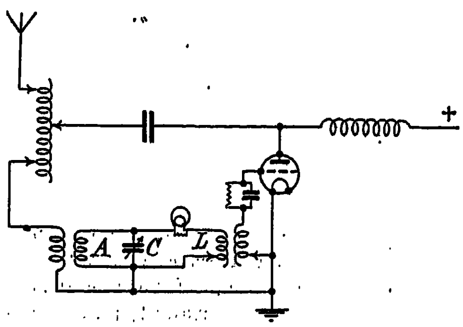

FIG. 21.

voltage, with respect to the voltage across the condenser C_g, is

$$\text{Arc tan }\phi = \frac{r_L^2\omega c_L}{r_1(1 + r_L^2\omega^2c_L^2) + r_L}$$

(neglecting the grid-filament capacity, which is usually negligibly small).

The effect of this phase angle ϕ is given in the vector diagram (Fig. 20). The current i_{Lg} is the vector sum of the currents i_g and i_1, and the induced E.M.F. ωMI_1 is at right angles to the oscillatory current I_1. For normal anode tapping, the anode tapping voltage V_1 is approximately at 90° to I_1, and so also is the anode condenser current i_a. The anode condenser P.D. v, when added to V_1, gives the valve anode voltage V_a. The valve current is i_v and the anode choke current i_b.

For the case of a large value of the angle ϕ corresponding to a small value of r_1 the effect may be a considerable variation from phase opposition for the anode and

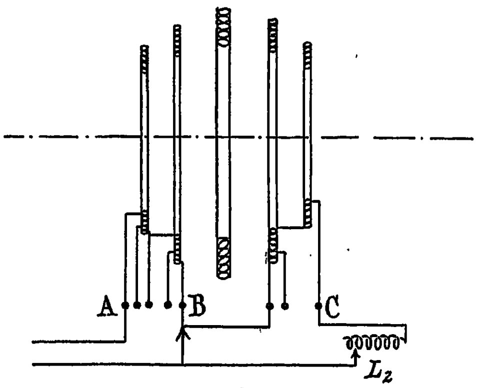

FIG. 22.

grid oscillatory potentials V_a and i_1r_1, respectively, resulting in a loss of efficiency. This condition may occur when a considerable number of valves are being arranged in parallel, especially for the case of a common grid-leak

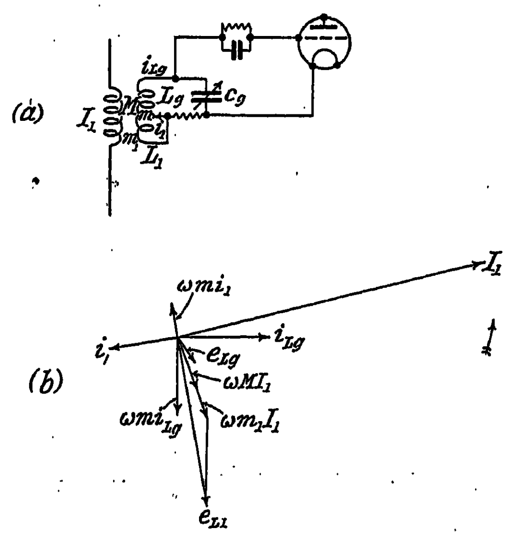

FIG. 23.

resistance and capacity; in this case separate grid leaks are usually better for efficient working. To a certain degree this de-phasing may be avoided by re-adjustment of the grid tuning condenser C_g if a resistance r_g is present, in which case the increase of the current i_{Lg} with increase of the condenser C_g gives an increased resistance P.D. $i_{Lg}r_g$ and so brings ωMI_1 more

nearly in phase with i_1r_1. This has the effect that V_a approximates more closely to phase opposition with i_1r_1. There is, however, a limiting condition beyond which this effect cannot be utilized.

As regards the actual value of the grid-filament resistance, this is such that the grid-filament current in practice is closely proportional to v_g^2 for positive values of v_g, i.e. the resistance is proportional to $1/v_g$. Provided that the grid-filament current i_1 when the grid is positive is not too large in comparison with i_g, the grid-filament oscillatory potential will closely follow a sinusoidal

case of a large number of valves in parallel, with resulting low impedance.

The cramped space available for grid coils caused a change to be made from cylindrical to disc coils. The grid coil had to be designed with tappings for a wide range of wave-lengths, and it was necessary to short-circuit the remaining turns when less than the total number were in use, in order to reduce the maximum coil potential and so avoid sparking; with the use of added resistance in the grid condenser circuit the danger of burning out the remaining turns was avoided.

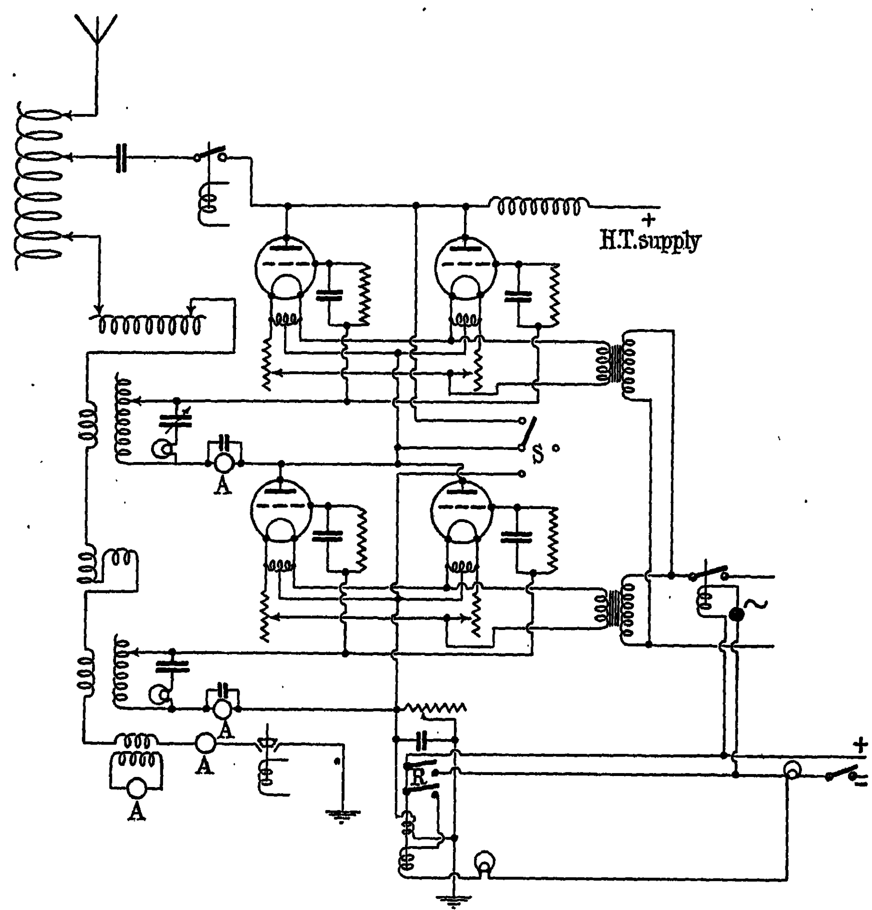

FIG. 24.

wave-form. For cases where this grid current is excessive, due to incorrect adjustments of the grid circuit, the effect may be to reduce the amplitude of the positive loop of grid potential.

For the case of a very low anode tapping, the ratio inductance/resistance for the inductance between anode tapping and earth may decrease considerably; this may cause a phase displacement of current i_a relative to the anode tapping voltage V_1, with resulting loss of efficiency. Usually, however, the best anode tapping for maximum oscillatory current is reached with a higher tapping than that at which this de-phasing occurs, due to the limitation imposed by impedance of the transmitting valves, but de-phasing may occur in the

For ship transmitters giving increased aerial powers of from 7 to 10 kW it has been essential for minimum adjustments over a wide range of wave-lengths to work with coils with no space adjustment, and it was found that if single coils were extended to meet the case, excess voltages and currents were induced in the remaining turns when short-circuited; also on certain wave-lengths the oscillatory current was unstable.

This effect is liable to occur on the shorter wave-lengths, as may be seen from the vector diagram shown in Fig. 23 (*b*) for the circuit indicated in Fig. 23 (*a*). For the current vectors I_1 and i_{Lg} the induced E.M.F. in L_1 will be the vector sum of the E.M.F.'s $\omega m i_{Lg}$ and $\omega m_1 I_1$, i.e. e_{L1}, the current i_1 will be at 90° to the E.M.F.

e_{L1}. The induced E.M.F. e_{Lg} in L_g will be the resultant of ωMI_1 and ωmi_1 and this value may become very small, with resulting instability of the aerial oscillatory current.

The use of multiple-disc coils together with an external inductance L_2 has overcome the difficulty. The former are placed symmetrically on each side of the aerial coupling coil as shown in Fig. 22, and the remaining turns are closed through the external inductance L_2 of suitable value. This reduces the mutual induced E.M.F. ωmi_{Lg} in the inductance L_1 due to reduction of mutual coupling. Further, the current i_1 is reduced in value by the additional inductance L_2 which constitutes a compromise between open-circuit and short-circuit conditions, with corresponding reduction of the mutual E.M.F. ωmi_1. In this way instability of operation on the shorter wave-lengths has been avoided and coils of this arrangement have been designed for a range of wave-lengths from 450 to 5 000 m. The use of discs of different diameters enables the connections to be made readily with no danger of sparking to adjacent turns at higher potentials.

The curves of Fig. 19 show that the variable grid condenser makes only partial use of the resonating properties of the grid circuit, as the phase angle is not far removed from 90° for the grid potential oscillations. Fig. 21 indicates how the correct phase conditions are obtained by the use of a grid oscillatory circuit which is in resonance with the aerial. The induced E.M.F. in coil A from the oscillatory circuit constitutes a supply to the circuit CL which is in parallel resonance with the oscillatory circuit, while the grid circuit is inductively coupled to the inductance L of this circuit. It is possible to operate such a circuit over a wide range of wave-lengths by adjusting the LC values of this circuit alone. This circuit can also be calibrated as a wavemeter, using a low-voltage lamp as indicator. Further, the resonating circuit can be readily modulated for radio telephony by grid potential control.

As regards the grid leaks used with these transmitters, experience has shown that for valves in parallel a separate grid leak for each valve is preferable. With the use of a grid leak common to a number of valves there is danger of short-wave oscillatory currents circulating in the valve inter-electrode capacities and the wires joining the grids to the grid leak. In certain cases the internal leads for grid and anode of the valve have been known to become red-hot due to circulating currents of very short wave-length, although this effect may be avoided by the insertion of resistance in the grid lead, as shown, for example, in the multiphase circuit of Fig. 16.

Series arrangements.—Increased efficiency results from operating the valves, both transmitting and rectifying, at maximum anode voltage. This voltage is limited to the value, in practice, above which there is a danger of blue glow occurring in the valves.

During the period 1918–19 in the naval service the maximum anode supply voltage for average glass transmitting valves in parallel, for an anode dissipation of 500 to 800 watts per valve, was of the order of 7 000 to 8 000 volts.

In order to obtain increased power at these lower voltages it was necessary to employ a large number of valves in parallel with rectifiers designed for low internal resistance and high filament emission. Whilst the experimental design of larger valves suitable for higher voltages was being pushed forward it was obvious that considerable time would elapse before such valves would be available in quantities, and another factor for consideration was the existing h.t. transformer plant which in many cases gave normally secondary voltages to earth of from 15 000 to 20 000 volts.

Experimental trials of valves in series were made during 1919 as shown in Fig. 13, the filament system of the upper valve being at a high-frequency potential to earth. With this arrangement it was found possible to operate at a supply voltage approximating to twice the safe value for a single valve, with the valve anodes at normal full-power dissipation. If we consider the case of valves in parallel, it is necessary, as the number in parallel is increased, to lower the anode tapping point in consequence of the reduction of valve effective impedance. With decrease of the inductance between anode tapping and earth to a small value, and depending on the aerial resistance, there may be a decrease of efficiency for the best aerial current position. Referring to Fig. 17, this is due to the anode condenser current i_a becoming displaced from a phase angle approximating to 90° to the oscillatory current I_1 and so resulting in an increase of the value of i_a, and therefore of the valve current i_v (with increased valve heating) relative to the current I_1. For such a condition it is advantageous to operate with valves in series employing a higher anode voltage and higher anode tapping. The normal advantage of the series system as regards efficiency is obtained, however, when the anode supply voltage is greater than that which can be applied with safety to a single valve. A further advantage is the reduction in the rectified current for a given rectified power, with resulting increase of rectifier efficiency.

The arrangement has proved to be very stable in operation, and no direct short-circuit to earth is caused in the event of failure of one valve, as is the case with valves in parallel. For the case of valves with open grids the insulated grids of the upper valves prevent excessive valve current if, for any reason, failure of the aerial oscillatory current occurs.

A typical circuit diagram for such a set is given in Fig. 24. The filaments for the upper bank of valves are supplied from a transformer with oil insulation which can be designed readily for high-frequency voltages between primary and secondary windings and have small capacity between windings. The grid coupling coil for the upper bank of valves has to be insulated from its aerial circuit coupling-coil for the high-frequency voltage across the lower bank. Separate filament rheostatic control enables equal division of the voltage across the valves to be obtained.

A number of sets of this type were designed early in 1920 for use with transformer plant already installed, and one set employing six silica valves (three valves in each bank with two banks in series) has been in use at Horsea for routine and experimental work since May 1920.

Coupled circuits.—The small space available in ships for the transmitter has necessitated the employment largely of plain aerial circuits for normal full-power transmissions. Provision has been made, however, for the introduction of a steadying circuit for drying-out if for any reason the aerial insulation is liable to short-circuit by salt water or spray. For wave-lengths below 600 m there is usually no difficulty in starting up under wet conditions. A coupled circuit is usually employed,

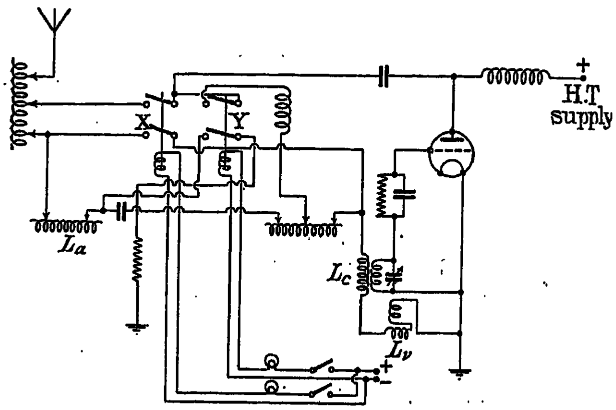

FIG. 25.

however, on these shorter wave-lengths to obtain the necessary constancy of wave-length for the highly selective valve transmissions.

In many cases use has been made of a resistance-coupled circuit. Alternatively, the more usual electro-magnetic coupling has been employed. To enable the change from plain to coupled circuit on the same wave-length to be readily made when required, switching

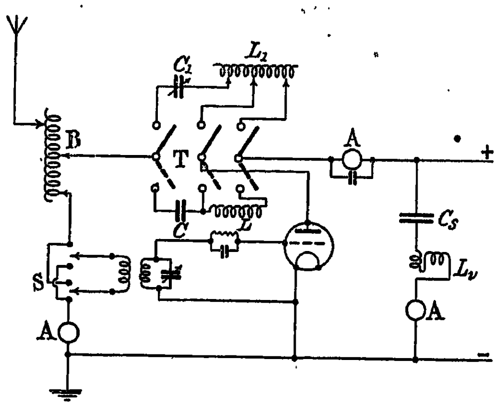

FIG. 26.

arrangements may be employed as shown in detail in Fig. 25. With the contacts of switch X closed, the normal oscillatory circuit is in use, and with the contacts of switch Y closed, the aerial circuit is resistance-coupled to a local circuit which is so adjusted that the wave-length transmitted is practically the same in the two cases. This is effected by arranging for the introduction into the aerial circuit of the inductance L_a of value equal to the sum of L_c and L_v transferred to the local circuit when the switch Y is closed.

The resistance employed for drying-out is that value for maximum product of local current and resistance with aerial earthed. The effectiveness of the drying increases rapidly with decrease of wave-length.

An alternative circuit which has been employed in certain cases for C.W. transmissions is shown in Fig. 26, in which the anode circuit C_1L_1 together with the smoothing condenser C_s and inductance L_v is tuned to the value of the aerial LC. The anode condenser C_1 is of small value and has a high-frequency P.D. which approximates to twice the value of the P.D. between anode tapping point B and earth; as a result, the valve anode potential oscillations are in phase opposition to the anode tapping P.D., and the grid coupling coil has to be reversed in direction by means of the switch S if, as in Fig. 26, the circuit is changed from the plain aerial circuit CL for normal transmissions to the tuned anode circuit C_1L_1 for drying-out by means of the change-over switch T. Exact tuning of this circuit can be readily provided for by placing in the earth lead of the smoothing condenser C_s a fine-adjustment inductance L_v of small value. The step-up current ratio can be of the order of 5 : 1 or 7 : 1 so that the size of the anode inductance and condenser is relatively small; the space occupied for a given power

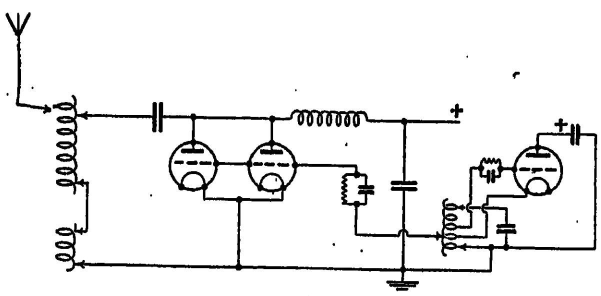

FIG. 27.

is considerably less than for the coupled circuits of Fig. 25.

Separate grid excitation.—Circuits employing separate grid excitation have been developed for use with medium-power and high-power valve transmitters. It has been usual to connect the grids of the main transmitting valves directly to the local oscillatory circuit, as shown in Fig. 27. For best operation at varying power it is desirable to arrange for proportionality between the grid exciting current and the main-supply anode voltage, having once adjusted the grid voltage to give best efficiency for a given anode voltage. A rectified a.c. supply for C.W. transmission can be arranged by supplying the exciter from a small transformer the primary of which is connected in parallel with the main transformer.

Comparative experiments have usually given a higher efficiency for this circuit than for the retroactive circuit, assuming proper adjustment of the grid exciting voltage. The fact that the grid is initially excited also renders the circuit more stable in operation, especially for the case of a low anode tapping, and the circuit has been found slightly more effective than the retroactive circuit for starting-up aerial oscillatory current when the aerial insulation is partially short-circuited by

moisture. The superiority of this circuit as regards constancy of wave-length is shown by the experimentally determined curves of Fig. 28, which also illustrate the rapid fall in oscillatory current with change of aerial tuning. For the case of ships' aerials, variations in wave-length of the order of 0·4 to 0·5 per cent have been observed with retroactive coupling during rough weather conditions for wave-lengths of the order of 2 000 m. From the curves it will be seen that these variations correspond to a reduction of aerial current by 30 per cent of its best value for the separately excited grid circuit, but for reception the change of intensity of received note arising from this is preferable

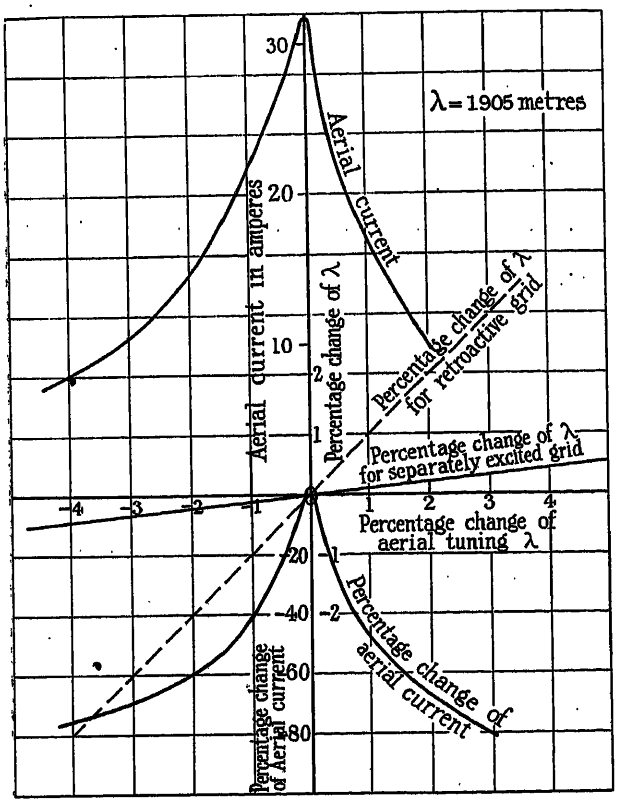

FIG. 28.—Change of λ for separately excited grid.

to the alternative of change of note with retroactive coupling.

The power supplied to the local oscillator circuit must be such that it will readily supply the power required to set up the necessary grid oscillatory voltage without instability of the local oscillatory current for any supply voltage to the main transmitter. The local circuit must also be so screened from, or at such a distance from, the main oscillatory circuit that there is no mutual inductive coupling. In addition, the tapping of the local circuit inductance at which the grid tapping point for the main valve is made must be such that there is no tendency for the main transmitter to set up oscillatory current by virtue of the valve capacity from anode to grid and the inductance from grid to filament of the local circuit, otherwise variations of wave-length will occur with change of the aerial capacity or inductance. This adjustment can be determined by trial for a given wave-length, or, alternatively, an additional resistance of small value may be used in the lead from grid to grid leak to minimize this effect. The best results have been obtained in practice by so arranging the grid tapping and adjusting the local circuit current that the inductance in use for suitable grid oscillatory voltage is from one-quarter to one-fifth of the local circuit inductance.

As the only adjustments required for the local circuit of Fig. 27 are those of the oscillatory circuit inductance or capacity, the whole circuit can be readily adjusted to any required wave-length. The space required for the arrangement is not very much greater than that for the ordinary retroactive circuit.

Overload protection of valves.—The supply circuits to the rectifier units have been protected from possible breakdown of circuit insulation by the use of horn-break fuses, and a simple form of overload relay with two coil windings has been fitted in the valve-current circuit for the transmitting valves and designed to operate if, for any reason, the anode current is excessive. The relay contacts short-circuit the bobbin for the main filament switch and so switch off all the valve filaments; at the same time, or slightly earlier, the d.c. supply circuit is completed through the other relay coil in series with a danger lamp. Thus the series lamp in the operating cabinet for the main filament switch bobbin lights up brightly to warn the operator, and at the same time the danger lamp on the set lights up. To reset the relay, all that is necessary is for the operator to break and then remake his d.c. control switch in the cabinet. Adjustment of the relay for any required operating current is provided by an adjustable resistance in parallel with the operating bobbin, which also has a condenser in parallel for the a.c. component of the unidirectional valve current. A relay of this type is shown at R, Fig. 24, arranged to operate in the case of excess current to the transmitting valves.

Alternatively, the relay contacts may be arranged to break either the primary a.c. supply for the transformer or the motor-alternator supply if desired, but in practice no difficulty has occurred when using the convenient arrangement of filament control, as the rectifying valves easily withstand the h.t. line voltage when the valve filaments are cold.

Reduction of harmonic interference.—The main interference caused is directly due to the valve transmitter itself, although interference is to some extent caused by the aerial circuit having distributed capacity and inductance. The valve interference is due to the non-sinusoidal wave-form of the current pulses which circulate in the oscillatory circuit via the anode condenser; more especially is this the case when the valves are operated at high efficiency with their grids at a considerable mean negative potential.

The principal methods which have been employed experimentally are (*a*) the introduction of special circuits in the anode tapping circuit to act as harmonic filters, (*b*) the use of special circuits (either acceptor or rejector in type) in the aerial circuit, and (*c*) the use of intermediate circuits coupled to the aerial.

In the case of methods (*b*) and (*c*), condensers and

inductances are required sufficient to carry for (*b*) the aerial oscillatory current and, for (*c*), currents which may be equal to or greater than the aerial current. These inductances are naturally expensive and occupy considerable space.

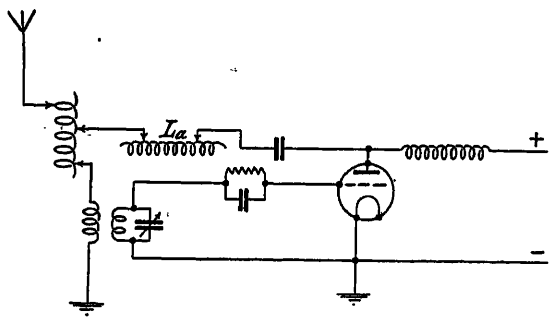

FIG. 29.

Experiments were made during 1920 with method (*a*), using a series inductance L_a between the anode condenser and anode tapping point to form a circuit from the valve anode tuned to the aerial LC as in Fig. 29,

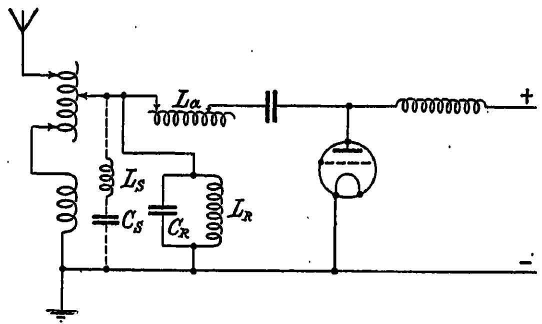

FIG. 30.

so that minimum impedance is offered to the fundamental component of the anode condenser current. These experiments indicated, however, that whilst considerable reduction of the aggregate harmonic power was possible,

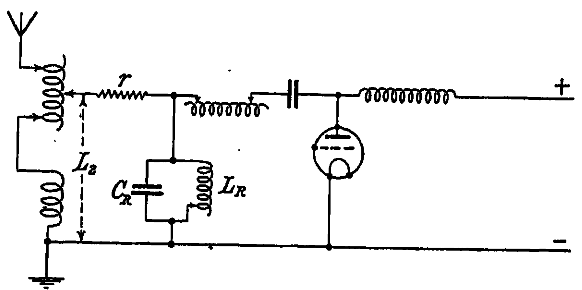

FIG. 31.

a certain harmonic, possibly irregular (depending on the value of the series inductance), was reinforced. If a rejector circuit L_RC_R was added, as in Fig. 30, a particular harmonic was reinforced, depending usually on the LC product of the rejector capacity and the aerial inductance from anode tapping to earth. Similarly it was found that if shunt circuits, such as L_SC_S indicated by dotted connections, were added tuned to particular harmonics, another harmonic was reinforced for the same reason.

The insertion of a resistance r between the anode tapping point and the filter circuits of a value such that the capacity of the rejector or shunt circuit when combined with the aerial inductance formed with the resistance r an aperiodic circuit, i.e. $r^2 > 4L_2/C_R$, was

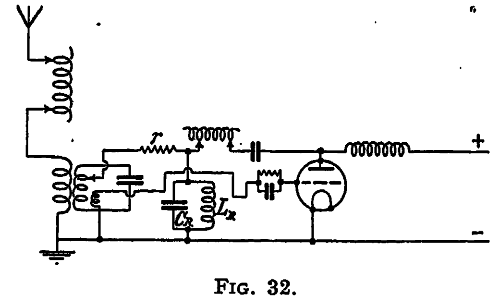

FIG. 32.

found to avoid the above harmonic reinforcement, and the arrangement found most satisfactory is given in Fig. 31. There is now a power loss in the resistance, but the pulsating current is small relative to the aerial current and it is possible to choose the rejector circuit capacity such that the value for r constitutes a loss of

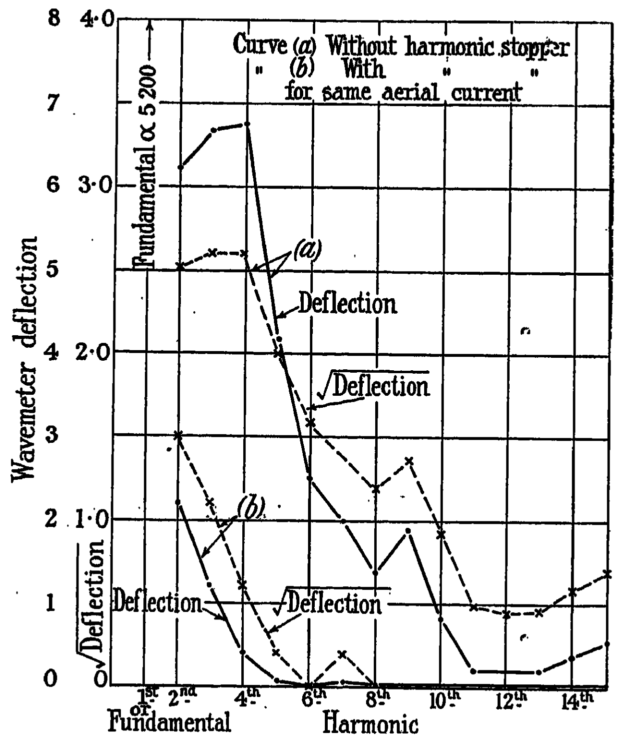

FIG. 33.—Comparative results.

the order of 5 per cent or less of the total oscillatory power. Provided that the circuit L_RC_R is highly efficient, its power absorption will be small.

The largest reduction has been obtained for harmonics above the 5th, and the reduction obtained has been small for the 2nd and 3rd especially. Fig. 33 indicates typical results obtained for the circuit of Fig. 31 by

direct measurement of the harmonics by the use of a wave-meter. For the 2nd and 3rd harmonics a greater reduction has been obtained using the ordinary coupled circuit, and the best results have been obtained by combining the filter circuit of Fig. 31 with either an intermediate coupled circuit (inductively coupled as in Fig. 32 or, alternatively, employing capacity coupling), or with a double-acting type of circuit in which the even harmonics are reduced by being set up in phase

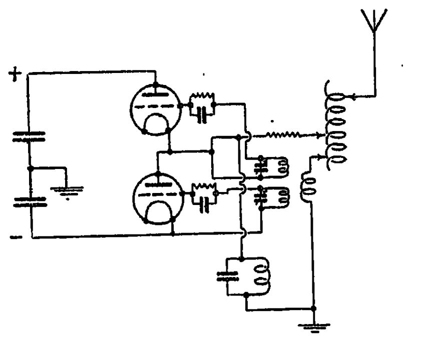

FIG. 34.

opposition for the two halves of each high-frequency period, as in Fig. 34. In addition, the valves must be operated at the minimum negative potential consistent with good efficiency.

Signalling arrangements.—For sets handling powers of the order of 20 to 30 kW and operated at hand speeds, primary-supply circuit control has been employed. For higher powers either h.t. keys in the transformer

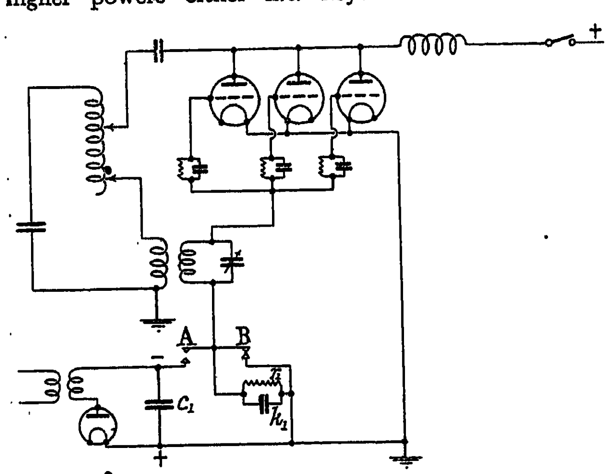

FIG. 35.

lines or anode supply, or grid potential control, have been employed. For the case of valves with separate grid leaks, it has been usual to employ a key in the common grid-filament lead operating across a resistance r_1 and condenser k_1, as in Fig. 35, a suitable negative potential being obtained from the condenser C_1 which is charged from a small rectifier unit as shown; this has been applied to control aerial powers of the order of 30 to 40 kW at speeds up to 150 words per minute, the aerial current being reduced to zero, or nearly so, depending on the value of the negative potential introduced across the resistance.

The resistance r_1 and condenser k_1 have such values that initial shutting down of the oscillatory current occurs when the contact B of the key is opened, and with suitable adjustment of the negative potential across condenser C_1 it is possible to work with very little sparking at the contacts A and B.

Other methods utilizing a 3-electrode valve as grid leak and signalling by the introduction of a negative potential from grid to filament of this valve have also been employed.* As listening-through is practically universal for all naval valve sets, methods of signalling by marking and spacing waves are not usually employed except in experimental cases. In the case of signalling by grid potential control, the rectifying valves have to withstand the full no-load potential of the a.c. supply; on the other hand, with primary circuit signalling there are intermittent electrostatic forces on the electrode system and care has to be taken that no mechanical resonance effects are set up, especially on the filament.

Design of transmitting valve electrodes.—The following method has been used for estimating the main dimensions of the electrode system when the grid is run at a considerable mean negative potential.

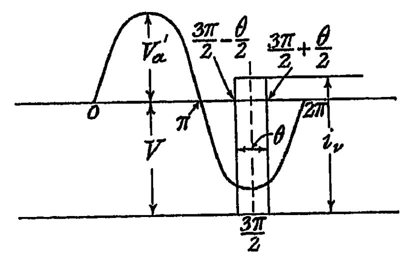

FIG. 36.

Consider the case of the circuit of Fig. 17 and assume that the anode oscillatory potential is sinusoidal, as indicated in Fig. 36.

Let V_a' = amplitude of anode oscillatory potential;
V = supply d.c. voltage;
W = d.c. power supply ($I = W/V$);
V_g' = maximum grid positive potential.

The valve has to carry maximum current for the anode-filament P.D. of $V - V_a'$.

The quantity through the valve per period of time T is IT.

This quantity passes through the valve for a fraction of the period considerably less than $\frac{1}{2}T$. As regards the wave-form of the valve current, since the anode potential is decreasing with increase of grid potential the resultant tendency is to maintain fairly constant anode current for the major portion of the time when the grid potential is positive. In addition, as already pointed out, the tendency of the grid-filament current is to limit the amplitude of the positive loop

* The use of a valve as grid leak for signalling has also been developed by the Royal Aircraft Establishment, Farnborough, without the use of a negative potential, the oscillatory current being set up by the use of a key joining grid to filament of the grid-leak valve. Also see paper by Lieut.-Col. A. G. T. Cusins: *Journal I.E.E.*, 1922, vol. 60, p. 246.

of potential. For these reasons a rectangular waveform of valve current for the angle θ corresponding to the time for which current flows is a fair approximation. The value of the angle θ will depend on the grid circuit and for the case of the circuits in use of the inductive coupling or separate excitation type it is usually of the order of $\frac{1}{2}\pi$ to $\frac{2}{3}\pi$.

The valve current $i_v = 2\pi I/\theta$.

The valve energy loss per period

$$= \frac{T}{2\pi} \cdot \frac{2\pi I}{\theta} \int_{(3\pi/2) - \frac{1}{2}\theta}^{(3\pi/2) + \frac{1}{2}\theta} (V + V_a' \sin \alpha) d\alpha$$

$$= IVT \left(1 - \frac{V_a'}{V} \cdot \frac{2 \sin \frac{1}{2}\theta}{\theta}\right)$$

The efficiency $\quad = \dfrac{V_a'}{V} \cdot \dfrac{2 \sin \frac{1}{2}\theta}{\theta}$

The energy given to the oscillatory circuit

$$= IVT\left(\frac{V_a'}{V} \times \frac{2 \sin \frac{1}{2}\theta}{\theta}\right)$$

As an example, assume the following :—

Supply power = 30 kW at 12 000 volts; $\theta = \frac{1}{2}\pi$ and $V - V_a' = 0 \cdot 2$ volt.

The efficiency $= 0 \cdot 8 \times \dfrac{2/\sqrt{2}}{\frac{1}{2}\pi} = 71$ per cent.

The supply current $I = 30/12 = 2 \cdot 5$ amperes.

The valve current $i_v = 2 \cdot 5 \times \dfrac{2\pi}{\frac{1}{2}\pi} = 10$ amperes.

The valve filament must be designed for this emission, also, in addition, to carry the superimposed electron current without excessive filament heating, and supply the grid-filament current during the positive grid oscillatory period.

It is usual to design the filament for 50 per cent greater emission current than the above value at a temperature between 2 450° and 2 500° K., i.e. the required electron current = 15 amperes.

The maximum grid oscillatory voltage should be less than the anode-filament voltage for maximum valve current; its value will be assumed to be about 1 500 volts, and a moderately close grid will be assumed of $m = 200$.

The valve grid diameter d' must be such that

$$i_v = 2 \cdot 93 \times 10^{-5} \times \frac{l_f}{\beta^2 d'} \left(\frac{V - V_a' + mV_g'}{m + 1}\right)^{3/2} *$$

(where l_f = effective length of filament)

$$= 2 \cdot 93 \times 10^{-5} \times \frac{l_f}{d'} (V_g')^{3/2} \text{ as an approximation.}$$

Also, for the anode diameter d_a relative to the filament,

$$i_v = 2 \cdot 93 \times 10^{-5} \times (V - V_a')^{3/2} l_f / d_a$$

Hence $\quad \dfrac{d_a}{d'} = \left(\dfrac{2\,400}{1\,500}\right)^{3/2} = 2 \cdot 03$

* B. S. Gossling: *Journal I.E.E.*, 1920, vol. 58, p. 676.

If for a loop filament (where l_f = effective axial length of loop), the value of d' is, for mechanical reasons, 5 cm.

Then the anode diameter should be not greater than $5 \times 2 \cdot 03$ (say 10 cm). For this diameter

$$l_f = \frac{i_v \times 10^5 \times 10}{2 \cdot 93 \times (2\,400)^{3/2}} = 29 \text{ cm}$$

The anode will have an area of $10 \times \pi \times 29 = 910$ cm. The anode power dissipation is $30 \times 0 \cdot 29 = 8 \cdot 7$ kW and this area of anode (if of molybdenum) is ample for the power dissipation required during static bombardment. The case of the valve being operated at full power at reduced supply voltage and efficiency will also be covered, e.g. if the valve is operated at 10 000 volts, and efficiency say 60 per cent, the anode dissipation is 12 kW.

If such a valve is bombarded during exhaustion to, say, about 70 to 100 per cent greater power than the maximum dissipation power, i.e. say 20 to 24 kW, this will provide a reasonable factor of safety for normal use at anode potentials up to 12 000 volts. In this connection it is desirable to specify a reasonable time of bombardment at full power, as in certain cases valves which are bombarded for a short time sometimes fail after continued use at full power, probably due to continued heating of the cooler parts of the valve.

Valve rating.—Reference to the above indicates that the geometry of the valve has a higher degree of importance than the anode power rating. This has been already pointed out by other writers.* For the valve manufacturer it is essential to specify a given anode power for static bombardment of the valve, and acceptance tests, but this may not necessarily represent the safe anode power dissipation for oscillatory conditions in which other limits are :—

(1) Maximum permissible oscillatory voltage between (*a*) anode and filament, (*b*) anode and grid, and (*c*) grid and filament.

(2) Maximum possible current through the valve at the specified minimum anode-filament voltage, without filament saturation. This depends on the geometry of the electrodes as well as on the filament.

For these reasons it is usual to specify the valve as capable of handling so much supply power at a given efficiency and to specify to the valve manufacturer a bombardment power giving a reasonable factor of safety; for example, for the case of a valve the anode of which is to be bombarded to 30 kW during exhaustion, if we allow 60 per cent as the minimum operating efficiency, the oscillatory rating of the valve for a factor of safety of 2 would correspond to a supply power of 37·5 kW and an aerial power of 22·5 kW. Efficiencies of the order of 60 to 70 per cent are readily obtained in practice, but higher efficiencies obtained by increasing the grid negative potential may result in a considerable increase of harmonics.

Size of valve units for a given output.—With increase of the power output from a transmitter there has been progressive increase in the size of the valve unit to

* See, for instance, E. H. Shaughnessy: Address to the Wireless Section, *Journal I.E.E.*, 1924, vol. 62, p. 51.

avoid complexities of circuit connections which would otherwise be necessitated by the employment of a large number of valves in parallel.

The larger unit also results in the saving of space with improved operation efficiency. It has been usual to employ not more than three valves in parallel for aerial powers up to 60 kW, these valves being capable of handling a supply power of 90 kW, and, for still higher powers, arrangements of six valves in series-parallel (three valves in each bank with two banks in series) are being employed. The use of the larger unit for these various groupings avoids excessive complexity of valve connections, and, in the event of failure of a valve, there is usually a sufficient reserve of power to tide over the emergency.

To meet these requirements the silica valve* was developed during 1919–1920 in three main sizes, namely for supply powers of 5 kW, 9 kW and 20 kW. More recently, single valves have been designed for supply powers of 30 kW and 60 kW at an anode supply of 12 000 volts. For supply powers up to 30 kW the valve seals and envelopes have been cooled by air ventilation, but for these or higher powers water cooling may be employed. Table 2 gives some of the main electrode dimensions of standard types of valves.

The paper is published with the permission of H.M. Admiralty. The author desires to express his thanks to the Captain, H.M. Signal School, for assistance in the preparation of the paper. He is greatly indebted to Mr. H. Morris-Airey, C.B.E., M.Sc., the Chief Technical Adviser, H.M. Signal School. He also desires to acknowledge the ready co-operation and assistance of members of the Signal School staff in the experimental work, particularly of Mr. E. J. Grainger, M.Sc., Mr. C. Matthews, Mr. H. R. Cantelo, B.Sc., and Mr. J. E. Sheldrick, B.Sc.

* Described by H. Morris-Airey in a paper read before the Wireless Section, 7th March, 1923.

Discussion before the Wireless Section, 3 December, 1924.

Professor C. L. Fortescue: Having been intimately connected with the early work forming the basis of the developments described in this paper, it is interesting to me to look back and to see how the many difficulties have been overcome. It has been mainly a matter of increasing the size of the valves used, combined with careful detail improvements. The increased power has enabled the difficulties arising from what the author naïvely describes as "severely wet conditions" to be overcome without risk of damage to the valves, which was perhaps the most serious obstacle encountered in the early days. With regard to the method of calculating the performance of the rectifier, this can be done from the 3/2-power law for unsaturated filaments by a method which seems quite as accurate as that adopted by the author. The general results are the same as for the case of the saturated filament, but the efficiency is higher in a properly designed valve, as was well known in 1918. With regard to Fig. 19, the protection offered by the addition of 180 ohms in the grid circuit seems to be scarcely as much as the author suggests. It appears, in fact, to make the conditions somewhat worse and renders protective devices still more necessary. The six-phase method of working shown in Fig. 16 gives good results when properly adjusted, and the amplitude of the resulting oscillation is as constant as that given by most sets employing two-way rectifying units and a single-phase supply. The author's method of calculating the performance of the oscillating valve from the curves of Fig. 36 is only very approximate. Many working conditions differ widely from this and results calculated in this way may be quite misleading unless based directly on closely similar experimental observations. Finally, the author's claim that the rating of the valve is less important than the electrode design is one which requires careful consideration. In practice the efficiency must be limited by the harmonics generated and, unless the valve can safely dissipate the losses, failure is inevitable. With regard to the electrodes, however, considerable variation can be compensated for by circuit adjustment, and consequently some latitude can be allowed to manufacturers.

Mr. L. Grinstead: In connection with the data concerning rectifying valves I should like to draw atten-

tion to the three items which the author gives as determining the design of the valve. Whilst items (*a*) and (*b*) are perfectly clear, the definition of (*c*) is rather vague. The author states "the maximum anode-filament valve P.D. with anode positive." Can he give any reason why the particular figure of 3 000 has been chosen, and what limits there are in practice within which one can depart from that value? Could that figure be greatly varied in the case of a valve worked over the saturation bend? The circuit arrangement shown in Fig. 24 is an interesting type of circuit design used in the Signal School which employs valves in series, and it is remarkable to me that it has been possible to obtain a filament transformer dealing with a fair amount of power which can be placed in the circuit, since this has to withstand not only half the high-tension voltage to earth, but also practically half the radio-frequency potential. The author gives some interesting information about separate grid excitation. Can he give some idea of the size of the valve which feeds the grid circuit of the main valves supplying the aerial? Is there any definite relationship between the rating of this to the main valves, and how much latitude is there in this respect? I am inclined to agree with Prof. Fortescue that the actual design of the valves, provided it is scientific, can be varied over very wide ranges. The question of the grid design, of course, does enter to some extent into the two conditions given in limit No. (2). During oscillation the anode voltage is actually a minimum, when the anode current is a maximum, and if the grid is too "close" it will be impossible to pass the necessary current to maintain the output. At the end of the paper the author gives some interesting data in regard to the large silica valves which are now made. At present the largest commercial valve is of the order of 30 kW input, and it would be interesting to know the probable limiting size.

Mr. R. V. Hansford: My very mild criticism is that I do not think the author has made sufficient distinction between experimental work and practice; that is, the paper gives a record of experiments made with circuits and apparatus, but we are not sure which have been adopted and become the standard practice of the Admiralty. The paper would have been even more interesting if the author had drawn further on his practical experience and given us some idea of the *relative* advantages of the various circuits. As examples I should like to refer to the two important questions of grid excitation and harmonic interference. Experience in the Post Office indicates that the method of separate grid excitation is much better than self-excitation for medium-power and high-power transmitters. It brings with it the great advantage of constancy of frequency to which the author refers, but also the disadvantages that variation in the aerial not only reduces the aerial current but may produce undue voltage strains on the valves themselves on account of the variation in the impedance of the associated circuits if a sufficient factor of safety is not provided. (Incidentally the text does not seem to be quite in accord with Fig. 28. Does a variation of 0·4 per cent of aerial capacity really reduce the aerial current to 30 per cent of its normal value?) Is it now the normal Admiralty practice to design a set of medium power with separate excitation on the grid? On board ship a difficulty, of course, is the small space available, but this would not apply to the case of a land station. With regard to harmonic interference, I should be interested to know whether harmonic stoppers are now normally fitted (1) on ships, and (2) on land stations. In the section of the paper which deals with harmonic interference, the author has a sentence which reminds me of a patent specification in the sense that it seems

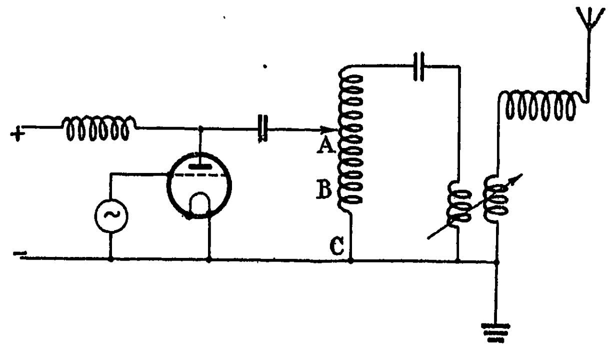

Fig. A.

to have been put in to be sure that everything is covered; it is as follows:—"The best results have been obtained by combining the filter circuit of Fig. 31 with either an intermediate coupled circuit (inductively coupled as in Fig. 32 or, alternatively, employing capacity coupling), or with a double-acting type of circuit in which the even harmonics are reduced by being set up in phase opposition for the two halves of each high-frequency period, as in Fig. 34." I should like to know which of the many possible combinations included in this comprehensive statement the author really does consider to be the

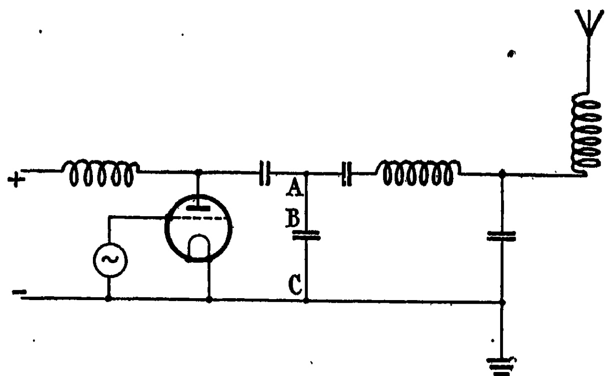

Fig. B.

best, because, of course, within the brackets he has given two alternative methods which are vastly different as regards efficiency in the reduction of harmonics. It seems to me that all the circuits given in the paper show a tendency to use inductive reactance where capacitative reactance would be preferable. Most of the circuits given in the paper are included in the general skeleton diagram of Fig. A with an inductive anode tap. Now we can equally well use a capacitative anode tap as shown in Fig. B. The impedance of path ABC in

Fig. A to the fundamental is the same as the impedance of the path ABC in Fig. B. The impedance of path ABC in Fig. A to the nth harmonic is, however, n^2 times that of path ABC of Fig. B and it is fairly clear (by inspection) what can be proved mathematically if it be assumed that the wave-form of the feed current is constant, viz. that a circuit with a capacitative anode tap is about n^2 times better in respect of harmonic emission than one with an inductive anode tap. The same argument applies to the coupling to the aerial circuit, so that the complete circuit of Fig. B. is roughly n^4 times better, as regards harmonic interference, than that of Fig. A. I suggest that these differences which the author has coupled together in a parenthesis are more important than the use of harmonic stoppers. I think also that if the grid coupling were capacitative, the difficulties of phasing referred to in the paper would probably be reduced, but I assume that questions of space and range of wave-length required would prohibit the general use of capacitative reactances for Naval circuits. The author says that it is usual to employ not more than three valves in parallel for aerial powers up to 60 kW, and for still higher powers a series-parallel arrangement. I should like to ask whether the Signal School does actually provide a regular wireless service in which three valves give 60 kW in the aerial. It is a splendid performance if that is the case, but of course it is one thing to do this for a short period of test and quite another thing to provide a regular service, with the necessary factor of safety not only on the anode dissipation but on the voltages which the valves will withstand. The series arrangement of valves was no doubt a desirable expedient under war conditions when it was necessary to use a particular voltage supply for a particular type of valve which would not withstand more than a certain voltage; but I presume that the author would not recommend a series-parallel arrangement for a new design under present circumstances. He says that such an arrangement avoids an excessive complexity of valve connections. I should have thought, on the contrary, that to place banks of valves in series would have added to the complexity, and I can see no compensating advantages.

Mr. B. S. Gossling: I am inclined to join issue with Prof. Fortescue in his criticism of the author's approximate calculations. It is certainly true that in the case of the rectifier valves the calculation could have been worked out as Prof. Fortescue has suggested, but I am not at all sure that the author's method may not have been equally good even in that case, and I think that his method of handling the three-electrode case mentioned towards the end of the paper is very satisfactory. There are so many variables to keep in mind—one has only to look at Table 2—and the author's method of getting clearly in mind what are the essentials of the problem and trying to combine those essentials into a relatively simple formula is likely to be a great help to those engaged in this work. When treating of the characteristics of the valve in relation to its efficiency as an oscillator, the author might have taken the full equation of the characteristic curves and have tried to find a mathematical approximation to them which would give him something that could be worked out, but the result is not likely to be so manageable as the simple formulæ given at the end of the paper. Although they contain assumptions the author does at least state where these occur. It is good to combine as much as possible of the essentials into a few simple formulæ so that one can get an approximate solution in a reasonable time and know where the pitfalls are. To take a case in point, the author makes assumptions about the average conditions under which a valve oscillates and then he says finally that it is usual to design the filament with a 50 per cent margin in emission. This statement interested me because I have actually measured the peak value attained by the valve emission using ordinary operating adjustments of the valve. The author deals with an ideal square-headed curve, while in my case the peak value does prove to be 50 per cent above his average value. I am in no disagreement with the grounds of the author's assumptions—I have these experimental reasons for believing them to be sound—but I should be glad if he would give some indication of the methods by which he has actually measured the minimum of the filament/anode voltage under operating conditions, and the method by which he has measured the maximum grid voltage. These points are absolutely fundamental to the design of the valve, and some indication of simple experimental methods of making those measurements when a set is being tuned up would be very interesting. For instance, it is quite clear that the operator can choose various sets of circuit adjustments which give him the same overall efficiency. Very small changes in the circuit adjustment may make a great deal of difference to the value of the valve current, and it is the value of the valve current that determines the life of the valve. It would be quite possible, if the circuit adjustments are made without paying attention to the variation of the anode voltage and the variation of the grid voltage, to arrive at a circuit adjustment which gives a desired efficiency but takes 50 or 100 per cent greater peak emission and consequently shortens the life of the valve. A simple circuit arrangement enabling these factors (which do not appear on the supply current instrument or the oscillatory current instrument) to be kept in view would be very useful. An obvious point when considering the competition between the valve, the alternator and the arc as alternative generating methods, is the average life of the transmitting valve together with the cost of replacement. Even at present it is true to say that, provided the valve is not of a specially expensive sort and that power is not obtainable at the very cheapest rate, valves can be made to last so long that the cost of replacing a valve by a new one is only of the same order as the cost of the power required for heating its filament during its life and is therefore a very small fraction of the total power bill for the installation during the same period. The author gives the running temperatures of the filaments as 2 450° and 2 500° absolute and as he refers to Mr. Stead's work I take it that these temperatures are temperatures corresponding to the curves given in Mr. Stead's paper. But it is a fact—the correction was actually made by Mr. Stead himself—that the true temperature is 100 degrees higher than that stated. This does not really affect the results obtained in the

paper mentioned, because the temperature is only used as a common abscissa to all the different curves which it gives. The present author has said a great deal about the design of valve sets and of valves without giving any definite figures on the subject of life; these would constitute a very valuable addition to the paper. Again, I wish to join issue with Prof. Fortescue on the rating of the valves. It is essential that there should be not only a dissipation rating of the valves but also an approximate input rating. Cases have arisen where it has been possible to exhaust a valve for a dissipation rating which would not actually be achieved by the user without either sacrificing a great deal in efficiency or raising his supply voltage above a convenient value. I am of opinion that the design of the electrodes with a view to the input rating is important. As regards the limit of voltage which a valve will withstand, I do not think that sufficient stress has been laid on the phenomenon of the extraction of electrons from a cold metal surface by a sufficiently strong electric field. This is a point to which designers of valves will have to give more and more attention.

Dr. W. H. Eccles: The paper contains, among much other matter, a larger collection of useful suggestions for design than any paper I can remember on the subject. It also contains many novelties; for example the author has arrived at the conclusion that the more economical way of working generating plant is to use the unsaturated part of the current curve. Four or five years ago the use of the saturation part of the characteristic curve was thought to be necessary for economy. On the whole I think that the author's work represents what might be called empiricism at its best. It is a mode of attack which I should like always to be able to follow and which I shall always recommend to every engineer. May I add that we all feel that the Admiralty is fully justified, judging by the papers we have had from the Signal School, in its policy of keeping up a large development department. The publication of the fruits of their labours is, we think, also justified and marks a departure from the Admiralty's pre-war policy, a departure which we should do well to approve.

Major A. G. Lee: In Fig. 28 the author gives the effects of changes of aerial tuning. Mr. Hansford has pointed out that when one obtains constant frequency by means of a separately excited grid one pays the penalty in a change of aerial current. This change of aerial current leads one into difficulties with the current or voltage limitations of the valves, unless one can ensure that the aerial constants shall not change beyond certain limits. We have found as a result of measurements of two different types of aerials—the flat-top Marconi aerial and another with a cage or "sausage" lead-up—that the "sausage" type varies in resonant frequency more than the other. It may, however, be improved upon very considerably. Another point of great interest in the paper is the methods of harmonic stopping. Mr. Hansford has already exhibited the diagram showing the method employed by the Post Office. Our general experience is that that circuit very efficiently eliminates the harmonics. If one does employ a condenser coupling in order to get a reduction in harmonics between the primary and secondary circuits one has to be careful that those circuits have no other form of coupling, because harmonics can get across from primary to secondary by stray couplings to quite a large extent. Another point of interest in connection with the measurements in Fig. 33 is how far from the station these measurements were made, because there is a possibility that harmonics can be radiated by the primary circuit as well as by the secondary. They do not travel very far from the primary circuit, of course, and probably these measurements were made fairly close to the station. Another kind of disturbance from valve sets is what is known as "key-clicks," which constitute a serious source of disturbance by a powerful valve transmitter. They spread from 100 to 200 m around the fundamental wave-length, and this means that it is quite impossible to locate another nearby receiving station within these limits of wave-length. This defect is probably also common to alternator stations. The marking and spacing method of signalling which maintains nearly constant amplitude on both frequencies, however, is not responsible for this particular defect; but the method is not liked in the Navy because of the necessity of listening-through. The details given in Table 2 are of great interest. Efforts are being made to increase the power of transmitting valves, and it is very satisfactory to know that the Navy has a valve with an output of 21 kW. The final choice of valve—silica, metal or glass—will depend on two factors: (1) the largest single unit that can be produced in either of the types, and (2) the economics of the case. Probably the second consideration will decide which type will survive.

Mr. H. Faulkner: The author states that the maximum value of anode filament valve P.D. with anode positive largely determines the efficiency of rectification. It seems rather strange, therefore, that in the example of design an arbitrary value should be taken for this voltage rather than attempting to reduce its value to the minimum possible. Later in the paper the author discusses the possibility of resonance of the circuit comprising the anode condenser high-frequency choke, etc., in the case of an I.C.W. transmitter. It is thought that, even without any conditions of resonance, in the absence of the smoothing condenser which normally provides the necessary bypass across the supply circuit the circuit would be a very dangerous one unless a suitable condenser were provided at some convenient position in the circuit or, alternatively, the inductance of the high-frequency choke were made large in comparison with the inductance of the secondary winding of the transformer. With regard to the stranded-wire tuning coils mentioned in the paper, I should be interested to know what acceptance tests are applied to the stranded-wire cable. My experience is that the normal commercial article leaves much to be desired with regard to insulation between the strands, and it is necessary to impose severe tests from this point of view. Imperfect stranding has a very bad effect on the high-frequency resistance of coils for radio frequencies, as Mr. Shaughnessy pointed out in his recent address * as Chairman of this Section. The author claims that the arrangement of valves in series results in increased efficiency of working over that obtained by using valves in parallel at, say, half

* *Journal I.E.E.*, 1925, vol. 63, p. 60.

the anode voltage. I cannot agree in principle: as in the case of rectifying valves, the principal factor governing the efficiency is the space-charge voltage necessary to give maximum anode current. In the case of valves connected in series it is clear that the permissible total anode voltage is increased, but at the same time the space-charge voltage is increased in proportion and it is difficult to see what is the advantage. It seems to me that the phase relationship between anode current and anode voltage can be adjusted by an adjustment of the proportions of the blocking condenser and the high-frequency choke. The Post Office experience as regards economy of change-over from spark to valve is similar to that of the Admiralty. At the conversion of the Stonehaven station practically every component of the spark set was utilized, with the exception, of course, of the disc dischargers and, I think, the "jigger," and the only additions required were the valves themselves and a few small auxiliary items.

Major H. P. T. Lefroy: When considering the design of radio transmitting apparatus, it is well to keep in mind the fact that a station only transmits in order that it may be received; hence transmission efficiency can only be considered in connection with reception efficiency. The latter is usually defined by a ratio, namely (strength of desired signals)/(strength of undesired signals), and factors that decrease the denominator of this ratio are as important for true efficiency as are those that increase its numerator. It is clear that improvement in the power efficiency of the transmitter will tend to increase the above numerator; but such improvement may tend also to increase the strength of the harmonics radiated, and such harmonics are undesired signals to stations with which the transmitter is not communicating, and thus tend to reduce the efficiency of radio communication as a whole. For radiotelegraphic reception, signal tone-filtering devices are very effective in reducing the above denominator; they normally exclude all but a narrow band of acoustic frequencies, so that, if the wave-length of the transmitter varies, the heterodyne note of the desired signals in the receiver may vary beyond the limits of this band and may thus be more or less filtered out, thus reducing the above numerator; such reduction will also occur, when using such a filter, if the ripple note of the high-tension supply to the transmitter modulates the received signals perceptibly. From the above, it follows that the true efficiency of any radiotelegraphic transmitting apparatus can only be ensured when the following four conditions are fulfilled: (1) Power efficiency; (2) constancy of wave-length; (3) purity of tone; and (4) absence of radiated harmonics.

Mr. G. Shearing (*in reply*): With reference to the remarks of Prof. Fortescue, I have deduced equations for the rectifier losses for a given voltage ripple based directly on the 3/2-power law, but I did not find them so easy to manipulate as those based on the assumptions given in the paper.

With regard to the grid circuit protection, the adoption of the resistance is solely to protect the grid circuit. Excessive grid currents which may cause breakdown of this circuit can be obtained for incorrect adjustment of the grid circuit when the anode current is below the safe value. This is illustrated in the curves of Fig. 19, in which the maximum value of the grid oscillatory current, for the case of no resistance, is of the order of 700 per cent of the value for correct condenser adjustment, and is dangerous for the grid circuit which is designed for small space requirements, whereas the corresponding value of the anode current of 0·5 ampere was perfectly safe for the valve itself. Again, the maximum anode current shown, of the order of 0·7 ampere, was a safe value. Resistances of this type, comprising a carbon lamp shunted by a resistance, the total value being of the order of 100 ohms, were applied during 1919–20 to the earlier transmitters and resulted in a reduction of breakdown of the grid coupling coils. An overload relay of the type shown in Fig. 24 and described on page 323 is fitted usually to protect the valves against excessive anode current; it is particularly to be noted that the anode, grid and aerial currents are practically the same for correct grid circuit adjustment for each value of the resistance.

FIG. C.—Anode current wave-form. Mean value = 0·52 ampere; d.c. supply power = 4·36 kW.

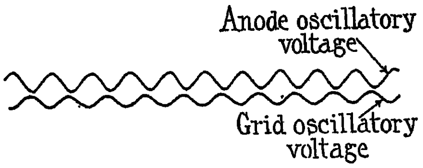

FIG. D.

Anode voltage = 4 250 (R.M.S.).
Grid voltage = 2 750 (R.M.S.).
D.C. supply voltage = 8 400.
Minimum anode-filament voltage = 2 230.
f = 400.

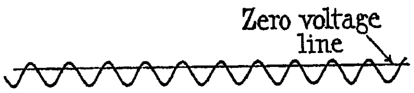

FIG. E.—Grid oscillatory voltage = 2 750 (R.M.S.).

The multiphase circuit of Fig. 16 can be made to give excellent results as regards ripple, comparable with that for two-wave rectifying units, provided that care is taken to ensure that each valve carries the same current in turn. With this circuit each valve filament has to be capable of supplying the total electron current for the case of a sine wave-form of supply voltage.

Whilst I agree that the method given of calculating the performance of the valve for an oscillatory circuit from the curves of Fig. 36 is only approximate, it is based on experimental observations, and the oscillograms of Figs. C, D and E taken for a type NT23 valve on a low-frequency oscillatory circuit show that the valve current wave in this case approximates to a flat-top form. At the same time it is true, as pointed out by Mr. Gossling, that the allowance of 50 per cent greater emission does cover the case of a peaky wave-form, but

our aim has been to avoid such wave-forms with a view to the reduction of harmonics, and the rectangular wave-form is a fair average assumption.

As regards circuit tuning, instructions based on laboratory measurements obtained for circuit adjustments on typical aerial systems are given to the operators.

For modern high-power valves with molybdenum or with water-cooled anodes, the maximum possible value for the oscillatory anode power dissipation is almost invariably less than the maximum permissible static power anode dissipation, due to the limitations imposed by valve geometry, inter-electrode voltages, and possibly filament emission as outlined on page 326. For this reason I prefer to assign first importance to the valve geometry. If the valve-operating voltage can be raised with safety to values greater than those at present employed, then it may prove possible for the valve oscillatory and static safe anode dissipations to approach more closely to each other. Improvement in this direction may be obtained by finally exhausting these valves under the oscillatory voltage conditions of practical use, and I am very interested in the remark of Mr. Gossling concerning the phenomenon of the extraction of electrons from a cold metal surface under a strong magnetic field.

Our experience so far has been that the filament life for transmitting valves is less than for rectifying valves. In our development work of the high-power valve since 1919 we had no earlier experience to draw on, and the tendency has been for us to increase the filament power and dimensions corresponding to lower temperatures since the first experimental designs. The filament life for transmitting valve types NT23 and NT24 varies from 400 to 1 000 working hours, whereas corresponding values for the NU21 and NU22 valves are 1 000 to 1 500 hours. The temperatures stated in the paper correspond to those given in Mr. Stead's paper, and the values he gives have been used consistently since 1919–20 for ready comparison in our experimental work.

As regards the reason for the adoption of the value of 3 000 volts for the maximum anode filament P.D., this depends on a number of conditions, and it is not necessarily practicable to reduce the value to the minimum possible considering the valve only, as suggested by Mr. Faulkner.

The main conditions may be briefly summarized as follows :—

(1) The minimum time during which it is desirable for the current-pulses to flow from each half of the transformer winding, since reduction of this time corresponds to increase of electrical and mechanical stress on the transformer and alternator windings and to an increase of harmonics in the secondary terminal voltage.
(2) The maximum amount of filament power it is desired to employ for the valve filaments.
(3) The minimum practicable diameter of the anode, relative to the filament for the voltage the valve has to withstand as an insulator.

As regards the design indicated in the paper it may be noted that for the rectified voltage of 10 000 the maximum instantaneous transformer kVA is $5 \cdot 46 \times 13\,000$, or 70, whereas the mean power output of the transformer is of the order of 18 kVA; this ratio must either not be excessive or, alternatively, it must be carefully specified to the makers of the transformer and the alternator plant for design purposes.

In reply to Mr. Grinstead, to operate the valve above the saturation bend corresponds to an increase of voltage across the valve for a given rectified power with reduced efficiency and increased valve heating, and the valve can be operated in this manner, at reduced power output, up to the permissible anode dissipation, by reducing the filament supply power. As regards the design of the grid, the value of m upon which grid closeness depends can be varied over a very wide range without affecting the performance of the valve when used on oscillatory circuits employing a considerable grid negative potential. Considerable variation of the valve design as regards electrodes, whether transmitting or rectifying, can be made subject to the valve being able to pass the required electron current at the specified voltage conditions. This is referred to (as regards the rectifying valve) on page 314.

It is not possible to differentiate between experimental and standard practice of the Admiralty, as the requirements are very exacting and diverse and one is usually not able to adopt the most straightforward technical design. The separate grid excitation circuit has great advantages for land-station working where fixed wave-lengths are the rule and aerial-swing can be reduced to a minimum; but for Naval use, where the aerial swing is greater and insulation more exposed to heavy sprays and seas, the change of aerial effective capacity with wet insulation may seriously prevent the aerial oscillatory current from building up unless an intermediate coupled circuit, separately excited, is employed. The circuit is but slightly better than the retroactive circuit for restarting under wet conditions, as stated on page 322. The size of the separate exciter valve has usually been of the order of one-sixth to one-eighth the size of the main valve. The statement on page 323 concerning the change of aerial current should have read "reduction of aerial current by 30 per cent of its best value" and this correction has been made for the *Journal*.

As regards the use of harmonic stoppers, these are being fitted to certain land stations, and in this connection, comparing the circuits of Figs. 32 and 34, the circuit diagrammatically shown in Fig. 32 has given the better results in practice. With the circuit of Fig. 34 it is necessary to ensure that both valves are balanced as regards their respective anode currents. I agree with Mr. Hansford that the description of Figs. 32 and 34 is brief, as I deliberately cut out further description in preparing the paper, to reduce its length. Our experiments so far made with capacity-coupled circuits have not been so satisfactory as those of the Post Office, but I presume the Post Office tests were on much longer wave-lengths than ours. I hope that comparative results for harmonic reduction, of the circuits referred to by Major Lee and by Mr. Hansford, will be published later. For the case of sets to be

operated on wide ranges of wave-lengths of the order of 600 to 6 000 metres we have experienced the difficulty referred to by Major Lee of subsidiary oscillations being generated by the various possible combinations of capacity and inductance with the main aerial circuit. Further, the overall efficiency has usually been reduced as the fine adjustments necessary for good efficiency on the wave-length range are prohibitive on account of space limitations. Incidentally, I should like to point out that the harmonic stopper described in Fig. 31 of the paper has the advantage of the capacitative anode tapping described by Mr. Hansford, since the harmonics have a path via the harmonic stopper condenser C_R, Fig. 31, which may be n^2 times as good as the path via the anode tapping inductance.

As regards the harmonic measurements in Fig. 33, these were obtained from readings taken with the key pressed immediately adjacent to the transmitting source, and the results obtained were in fairly close agreement with comparative signal measurements made by receiving in a ship at varying distances up to about 400 miles from the transmitter. The disturbance described by Major Lee, known as "key clicks," has been observed by us in experimental comparison of high-power valve transmitters at Horsea arranged for listening-through with an arc transmitter employing marking and spacing wave; the effect appears to be much greater for a given aerial current when employing high-tension signalling keys in the secondary than when signalling on the primary side of the high-tension transformer (which of course may not be practicable for high powers).

The series arrangements of valves were got out for higher supply voltages than were practicable for a single valve. The normal operating voltage for single valves requiring an input power of the order of 10 kW is increasing up to 14 000–15 000 volts, but we have operated valves in series at rectified voltages of the order of 20 000 volts and the arrangement is certainly very stable in action, as pointed out in the paper. Also, the circuit described in Fig. 24 enables either row of valves to be brought immediately into use by operation of the switches when the set is not required to be operated at full power; again this may be done if for any reason a single valve fails. No difficulty has been experienced in the design and manufacture of suitable filament transformers insulated between windings for high-frequency voltages of 10 000 to 20 000.

My remark *re* excessive complexity of valve connections had no reference to the comparison of series and parallel arrangement of valves; it applied to the advantage of the adoption of a larger valve unit over a number of smaller valves in parallel, and I am correcting the context to make this clear. Again, I think it should be clearly understood that the normal advantage of series operation is for the case when the supply voltage is greater than that which can be applied with safety to a single valve. It is undoubtedly true that for the smaller quantity of electricity required for a given power through the rectifying valves at the higher rectified voltage corresponding to valves in series, there is a gain of rectifier efficiency, as shown by the curves of Fig. 3. A gain of transmitting efficiency is also observed when employing two transmitting valves in series at voltages of the order of 50 per cent greater than the safe operation voltage for two valves in parallel. With reference to the use of a by-pass condenser for the I.C.W. transmissions, the smaller power sets developed up to 1918 were used mainly on relatively short I.C.W. wave-lengths and no transformer breakdowns occurred, as the stray capacity of the transformer windings was sufficient to carry the very small high-frequency current under the non-resonating conditions without excessive potential difference when an anode choke of the order of 20 000 to 30 000 μH was employed. I am doubtful whether much of the transformer inductance enters into the problem owing to the relatively small high-frequency impedance of the transformer winding stray capacity. Extension to longer I.C.W. wave-lengths during 1918 was found to give rise to the resonating difficulty referred to on page 317, and the small condenser was a simple solution now adopted for all sets.

The difficulty described by Mr. Faulkner with regard to the insulation between strands has not been experienced to the same extent by us; the enamelling of the wire is carried out to a specification imposing very severe tests. It is probable, however, that excessive heating of the wire may be due to the mutual inductance of the stranded wires not being the same for each individual wire per coil turn. The following procedure is desirable in stranding the cable. The wires should be built into groups of three wires and each group of the three wires should be twisted right-hand. Then three of these groups should be twisted left-hand to form larger groupings. These larger groupings should then be twisted three right-hand, and so on. This tends to ensure constancy of mutual inductance for each individual wire. Further, it is desirable not to impregnate the strands of the wire apart from the cable covering.

I agree fully with Dr. Eccles as to the importance of the unsaturated part of the current curve of the valve for power generation.

It is usually possible to adhere to the requirements laid down by Major Lefroy for the design of a land station, but for ship transmitters the additional practical conditions to be fulfilled may render the satisfaction of these requirements either much more difficult or not entirely possible.

INSTITUTION NOTES.

Associate Membership Examination.

The Council have decided to accept in lieu of Part I of the Examination the Higher Grade National Certificate or Diploma in Electrical Engineering, provided that the candidate satisfies the Institution in the subject of "English Essay."

Associate Membership Examination Results: October, 1924.

SUPPLEMENTARY LIST.*

Passed.

Barrs, H. H. (New Zealand).
Dalton, G. A. (South Africa).
Harvey, A. F. S. (Buenos Aires).
Prickett, J. H. (South Africa).

Passed Part II only.

Loveday, G. K. (South Africa).

Heat Engine Trials.

The Heat Engine Trials Committee of the Institution of Civil Engineers will present for discussion at a meeting to be held at Great George-street, Westminster, on Wednesday, the 25th March, 1925, at 6 p.m., the standard form or code for tabulating the results of a steam generating-plant trial. All interested in the subject are invited to attend and to take part in the discussion. Mr. W. H. Patchell, Chairman of the Panel responsible for drafting the code, will introduce the subject and will refer in particular to certain questions which it appears desirable to debate. Among these will be included questions relating to the make-up of the heat-account table, and to certain proposals in connection with recording the analysis of oil fuels. Discussion on other items in the code will also be welcomed. Copies of Mr. Patchell's introductory notes and of the code itself can be obtained on application to the Secretary of the Institution of Civil Engineers, Great George-street, Westminster, S.W. 1.

Briefly it may be stated that the code contains the description of the steam generating plant and the conduct and the results of trial or trials tabulated as follows :—

I. General information and design data.
   Specified performance.
   General description: (*a*) Furnace (solid and pulverized fuels, oil and gas fuels and waste heat); (*b*) boiler; (*c*) superheater; (*d*) economizer; (*e*) steam reheater; (*f*) air heater; (*g*) draught plant.
II. Methods of measurement.
III. Mean observations derived from log sheets and preliminary deductions.
IV. Final deductions and heat accounts.
V. Energy received for auxiliaries from outside sources.
VI. Net overall efficiency.

* See page 153.

Informal Meetings.

The following Informal Meetings have been held :—

57TH INFORMAL MEETING (27TH OCTOBER, 1924).

Chairman: Mr. W. B. Woodhouse (President).

Subject of Discussion: "The Interconnection of Power Stations" (introduced by Mr. W. B. Woodhouse).

Speakers: Messrs. H. M. Sayers, A. F. Harmer, W. E. Rogers, A. Williams, J. H. Sandiford, A. G. Hilling, J. F. Shipley, J. W. Robertson, W. F. Andrews, N. Brooksbank, A. W. Berry, J. R. Bedford, R. D. Gifford, D.Sc., V. N. Halliday, T. R. Renfree, R. V. Hook and A. J. Watts.

58TH INFORMAL MEETING (10TH NOVEMBER, 1924).

Chairman: Mr. A. H. Allen.

Subject of Discussion: "Research in the Cable Industry" (introduced by Mr. P. Dunsheath, O.B.E., M.A., B.Sc.).

Speakers: Messrs. G. L. Addenbrooke, P. Rosling, H. C. Silver, W. Day, J. H. C. Brooking, T. N. Riley, A. Collins, A. Rosen, E. S. Ritter, R. D. Gifford, D.Sc., W. G. Newberry, A. G. Hilling, H. Savage, J. Coxon and A. H. Allen.

59TH INFORMAL MEETING (24TH NOVEMBER, 1924).

Chairman: Mr. J. W. Beauchamp.

Subject of Discussion: "The Electrostatic Wattmeter used for Measuring Dielectric Losses in Cables" [introduced by Mr. N. A. Allen, B.Sc.(Eng.)].

Speakers: Mr. G. L. Addenbrooke, Prof. J. T. Macgregor-Morris, Messrs. A. Collins, A. Rosen, A. J. Tracey, R. M. Longman and J. W. Beauchamp.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 January–25 February, 1925 :—

THREE-WIRE DIRECT-CURRENT DISTRIBUTION NETWORKS: SOME COMPARISONS IN COSTS AND OPERATION.*

By HERBERT WILLOTT TAYLOR, Associate Member.

[*Paper first received* 3rd *June and in final form* 5th *November*, 1924; *read before* THE INSTITUTION 8*th January, before the* IRISH CENTRE (DUBLIN) 8*th January, before the* SOUTH MIDLAND CENTRE 14*th January, before the* NORTH-WESTERN CENTRE 20*th January, before the* SCOTTISH CENTRE 10*th February, before the* NORTH MIDLAND CENTRE 10*th March, and before the* TEES-SIDE SUB-CENTRE 12*th March*, 1925.]

SUMMARY.

This paper discusses the application of the following types of cables and methods of laying to the various parts of a three-wire d.c. network.

Types of cables: Single-core, three-core, and triple-concentric.

Methods of laying: Conduit, direct, and solid.

It endeavours to show that, wherever it can be adopted, the most satisfactory network is that composed of single-core lead-covered cables, the feeders being drawn into conduits and the distributors and services laid direct.

The paper also describes the "looped-neutral" service, the object of which is to facilitate the location of faults on the smaller sizes of triple-concentric vulcanized-bitumen distributors, and to improve the continuity of supply under fault conditions.

(1) INTRODUCTION.

Permissible current loading.—Before proceeding to compare the various types of systems, it is necessary to form some idea of the relative carrying capacities of cables laid under different conditions. No useful purpose would be served by comparing the costs of, say, a 0·5 sq. in. × 0·25 sq. in. × 0·5 sq. in. feeder made up of single-core cables laid direct in the ground, with that of a solid-laid triple-concentric feeder of the same cross-sectional area. For this reason it is necessary to find the sizes of the various cables which will give approximately the same performance for any given method of laying.

There are so many modifying influences that affect the safe current-carrying capacity of a cable, such as the type of ground in which it is laid, the depth and manner of laying, the nature of the loads and the construction of the cable itself, that it is impossible to fix any definite values unless all the prevailing local conditions are known. Some of these points are enumerated below:—

The method of laying the cable has a modifying influence. Where a single-core cable is laid direct in the ground the problem is a fairly easy one. When one comes to consider multicore cables and, perhaps, the bunching of cables, it is more difficult to estimate the temperature-rise for any given current.

With cables laid solid the chief factor that prevents any trustworthy figures being given is the nature of the material used for filling in the troughing. In some cases the thermal resistivity of this material is nearly as high as that of the cable dielectric, while in others it is considerably lower, almost equalling the value for damp earth. Until the question of the filling material has been more fully investigated, no loading tables will be available. For purposes of comparison, however, it has been assumed that for a vulcanized-bitumen cable laid solid the maximum permissible loading will be considerably lower than for an armoured cable laid direct, and about the same as for a lead-covered cable drawn into a duct.

The chief variable quantity that renders a comparison difficult when considering drawn-in cables is the layer of air that surrounds a cable in a duct. It is this thin layer of air that offers the greatest resistance to the flow of heat emitted from the cable and, as it may or may not be in motion, its lagging effect is very problematical.

Again, the carrying capacity of a cable depends upon its heat emissivity, which is inherently bound up with its design. It is obvious that a single-core cable completely surrounded by earth at a uniform temperature will be able to dissipate the most heat.

In a triple-concentric cable neither of the two inner cores borders directly upon the surrounding soil. This means that all the heat generated in the inner core has to pass through both of the other cores before it leaves the cable. It will readily be realized from this fact that for a given current in all cores the inner core will be by far the hottest, and hotter than any core in a three-core cable of the same sectional area and carrying the same current. Although the outer core, having a very good cooling surface, will operate at a much lower temperature, no advantage can be taken of this, as the safe current density that can be applied is limited by the temperature of the hottest core, which means that a triple-concentric cable will have a lower rating than either a single-core or a three-core cable.

Much very useful information on this subject is contained in the Second Report on the Research of the Heating of Buried Cables, issued by the British Electrical and Allied Industries Research Association (see *Journal I.E.E.*, 1923, vol. 61, p. 517), and, from the information given in this Report, Table 1 has been compiled as representing average conditions. This table shows the maximum permissible currents that can be applied to single-core, three-core and triple-concentric cables as used on a three-wire d.c. network with the three methods of laying. It should be noted that on a three-wire system the neutral conductor carries little or no current, so that the ratings can be increased above the values that would apply if all cores were carrying the same current.

* This paper was originally submitted in the form of a thesis in lieu of the Associate Membership Examination.

(2) Feeders.

Type of Cable.

When a network is first laid down it is, as a rule, only possible to anticipate the districts at which the heaviest loads are likely to occur, the probable amount of load at each of these districts being too indefinite to warrant any variation in the size of the feeders. It is therefore usual to decide upon the number of nodal points that are necessary and to connect these to the station with feeders of equal size. From electrical considerations the more nodal points there are the more efficient will be the operation of the system, but economic facts have to be faced and a compromise reached. It is well to err on the side of fewer feeders at the beginning, because, when an undertaking is young and therefore struggling, any unnecessary capital outlay is to be avoided. Another fact that lends support to this precaution is that the natural and most economic nodal points for a town frequently move, owing to the erection of new buildings and the migration of people from one part of the town to another, this generally being from the centre outwards. New feeders can be laid when necessary, by which time the extra expense can better be borne and an indication given as to the most suitable place for a new nodal point to cope with any migration of load that is taking place.

The choice of the size of cable for a feeder is more an economic than an electrical problem. This is because the question of voltage-drop on such a cable is only of secondary importance, as there are no limiting factors imposed by the Electricity Commissioners as in the case of distributors. Any variation in the value of this drop can be counterbalanced by an equal variation of the busbar voltage, so maintaining a constant pressure at the nodal points. It is therefore confined to a consideration of the heating effect of the current and a compromise between the energy lost in the cable and the capital charges. The most economical size of cable is obtained when the cost of the energy wasted, plus the capital charges for the part of the plant necessary to supply this loss and for the cable itself, is a minimum. This is expressed in the following formula:—

$$\text{Total charge (in £)} = \frac{I^2 rTd}{1\cdot 2 \times 10^6} + \frac{I^2 r C_1 p_1}{0\cdot 5 \times 10^6} + C_2 p_2$$

where the symbols have the values given in the appendix.

This condition may be considered ideal as, in practice, other factors, such as anticipation of future load, compel larger cables to be laid down than may be determined by this formula for the immediate requirements. It is, however, a useful guide in deciding whether a system is working in the most economical manner, or whether there would be any financial advantage in laying an additional feeder.

Single-core cables.—From the point of view of operation it is undoubtedly the best policy to use single-core cables for feeders, as advantage can be taken of their high current-carrying capacity. It is for this reason that some undertakings have adopted such a system of feeders, even though the rest of the network is made up of three-core or triple-concentric cables.

The greatest advantage in the use of single-core cables is the small amount of inconvenience caused to consumers under fault conditions, this being particularly evident when followed up by a similar type of distribution system. This point is fully considered in the section dealing with distributors.

Three-core and triple-concentric cables.—Between the other two types of cables there is not much to choose, any advantage resting with the three-core cable, whose maximum current-carrying capacity is rather higher than that of the triple-concentric cable. Joints on three-core cables are also simpler, but this is not so important on feeders where there are comparatively few; on distributors, however, the fact assumes much greater importance. The use of three-core cables is limited

Table 1.*

Maximum Permissible Constant Current Loading.

Area of live conductors (neutral core half the size of outers)	Cables laid direct (lead-covered and armoured)			Cables drawn in (plain lead-covered) or Cables laid solid (vulcanized-bitumen)		
	3 single-core cables	3-core cable	Triple-concentric cable	3 single-core cables	3-core cable	Triple-concentric cable
sq. in.	amps.	amps.	amps.	amps.	amps.	amps.
0·1	298	263	249	202	185	162
0·15	367	331	313	261	238	208

0·5	748	669	641	604	545	482
0·6	845	—	724	696	—	552
0·75	949	—	812	800	—	634
1·0	1 158	—	997	1 012	—	800

* The values given are for sandy loam with 10 per cent moisture content, and clay with 20 per cent moisture content.

to sizes up to 0·5 sq. in., cable manufacturers being unwilling to guarantee larger sizes. This disadvantage is not shared by the triple-concentric cable.

Method of Laying.

Conduit.—In deciding the best method of laying feeders, the local conditions are always the governing factors, and these will not be similar in every case. The type of roadway met with in the centre of a town, in which area the bulk of the feeder system will generally be situated, is often of a very different nature from that in the outlying districts, and this fact might warrant additional initial expenditure with a view to future saving in the event of probable faults and possible extensions. For this reason it is often considered advisable to incur a little more trouble and expense in drawing the feeders into conduits in order to reap, at some future time, the advantages derived from such practice, amongst which are :—

(1) Rapid localization and repair of faults.
(2) Low cost of increasing the size of the feeder.
(3) Saving on capital charges due to the possibility of installing a cable sufficiently large to cope with loads of the immediate future, thus avoiding having buried in the ground a large quantity of idle copper which is not then required and from which no return will be forthcoming for many years.
(4) Less depreciation.

The first of these points, namely the rapid localization and repair of faults, is vitally important in a system whose feeders, during certain hours of the day, are loaded almost to their utmost capacity. The ease with which a faulty length of plain lead-covered feeder drawn into conduits can be located and replaced, as compared with the amount of time spent in taking up sets and breaking through a concrete roadway foundation to gain access to a direct- or solid-laid cable, perhaps in several places before the fault is located, may prove invaluable when the other feeders are in imminent danger of suffering permanent damage due to overloading. The question of the cost of repairs is more or less bound up with the speed with which they are carried out, as time undoubtedly means money, whether reckoned in wages or in loss of revenue.

The conduit system has the advantage that when feeders of too small a section may have been originally installed due either to errors in calculations or to the shifting of the more heavily-loaded districts, the mistake can be rectified at a minimum cost. Advantage can often be taken of this good quality of the conduit system by intentionally installing a smaller size of cable than will ultimately be required, but large enough for loads of the immediate future. It will readily be seen that if, say, a 0·25 sq. in. feeder will carry all the load that is likely to be required for 10 years, after which it might be advisable to install one of 0·5 sq. in. cross-section, there will be a considerable net saving in capital charges due to the fact that the extra cost of the 0·5 sq. in. feeder during those first 10 years when the major portion of the copper will be lying idle and bringing in no return, will not have to be met. Even this arrangement can be improved upon by drawing another feeder into spare ducts, laid at the same time as the others, the two cables then operating in parallel as one feeder. This obviates the loss that would be incurred by drawing out and scrapping the original feeder. The heavier initial cost occasioned by the increased number of ducts to be provided is only slight, particularly in the case of multicore cables. It is also conceivable that, due to the causes mentioned above, the size of the feeder might never require to be increased, the result being a permanent saving only rendered possible by letting the future take care of itself more or less.

The possible amount of depreciation is much less in the conduit system than in either of the others because, should the cable break down or require to be replaced due to obsolescence or other reasons, the only renewable part is the cable itself, whereas in the case of the direct- or solid-laid cable the whole cost of the mains is lost, all the original trench work and reinstatement of the roads has to be done again, and probably the protective material will have to be renewed. If the copper and lead of the recovered cable are sold, the only loss will be the insulation, the cost of manufacture and the labour of pulling in and jointing the cable.

There are a few points that must be carefully borne in mind when laying down a conduit line. The position of other existing pipes should be ascertained before the work commences, and trial holes have generally to be opened up along the proposed route to find a clear course. This information can often be obtained from the various authorities, but in old streets this is seldom the case, as a number of old pipes, particularly drains, will be discovered of which there are no records. The positions of these obstructions must be ascertained in order that the conduits may be laid so as to drain into the draw boxes and any dips or hollows in which water could collect and, by freezing, cause damage to the cable and conduits. Another reason for the avoidance of dips and twists in a conduit line is that, whilst it makes it more difficult for a cable to be drawn in, it renders it almost impossible to draw out a cable that has been allowed to settle and take up a definite shape for perhaps a number of years. Where there are no obstructions, a depth of 2 ft. to the top of the conduit is ample; but in the main thoroughfares of a large town a depth of from 3 to 4 ft. or even more is necessary to enable all obstructions to be avoided. Such roadways often appear to the electrical mains engineer to be a tangled mass of gas, water and drain pipes with sometimes Post Office cables, tramway feeders and hydraulic mains added to thwart his endeavours to obtain a straight conduit track. It is in such roadways that the direct-laid cable shows to particular advantage, as it can be run to avoid such obstructions.

If concrete is used as a protection for the conduits, with the intention of saving them from the crushing strain of very heavy traffic, it should be laid underneath and packed round the sides as well as on the top. If intended merely as a protection from picks, it need be placed only on the top and at the sides. In either case it should have a smooth finish to enable it to be recognized by any workman opening the ground later as being there for a purpose and not to be smashed up

as a casual obstruction. The concrete surrounding the conduits also preserves their alignment and renders them gas- and water-tight; thus minimizing the risk of explosion or electrolysis. In the opinion of the author, the use of concrete is unnecessary unless in exceptional circumstances.

Plain lead-covered cable and earthenware conduits should be used. Whilst braiding certainly protects the lead sheathing during drawing-in operations, and steel-wire armouring, in addition to this, takes the strain off the lead, these will rot away after a number of years in a wet duct and effectively jam the cable should any attempt be made to draw it out.

Cables laid direct.—A fact that becomes quickly apparent when considering the laying of a cable direct in the ground is the ease with which such work can be carried out. There is no need for the same amount of preliminary caution to be taken as for laying a conduit track along a main road. The fact that an obstruction is easily passed by this method is often a deciding factor in its favour.

The life of a lead-covered cable laid in good ground such as clay or sandy soil has not yet been determined, but the fact that such cables on being examined after 15 or 20 years' service show no signs of deterioration, would appear to indicate that their useful life is very considerable.

For feeder work full advantage can be taken of the high maximum permissible loading of the direct-laid cable. This might in some cases enable a smaller size of cable to be used than if it were to be laid solid or drawn into conduits.

Two factors have to be borne carefully in mind when laying cables direct, viz.

(1) Electrolytic action due to stray currents from other sources.
(2) The corrosive action of certain types of ground.

When the cable runs for a considerable distance parallel to a tramway track, a portion of the earth current may be induced to leave the track and return along the lead covering of the cable. This can be guarded against by laying the cable solid or drawing it into watertight conduits over that portion of the route on which electrolysis might be expected.

In ground largely composed of ash or slag there is a certain amount of free sulphur tetroxide which, when dissolved by any water that happens to penetrate through, forms a weak solution of sulphuric acid. This would rapidly corrode the armouring of a cable laid direct in such ground. The danger can be avoided by the methods mentioned above or by the importation of a quantity of clay, if such a supply is easily available, in which the cable is embedded and through which the acid cannot penetrate.

Cables laid solid.—The system commonly known as the "solid" system was introduced by Messrs. Callender's Cable and Construction Co., Ltd., and marked a great advance on the methods previously employed. Practically the only occasions on which this system is used to-day is when local chemical or electrolytic action would be probable on a cable laid direct. Even when such a course is adopted, plain lead-covered cable is preferable to the vulcanized-bitumen sheathed cable, for the following reasons:—

(1) The cost is lower.
(2) The continuity of the lead sheathing is maintained where the rest of the system, following modern practice, is composed of lead-covered cables.
(3) Similar cable may be used for drawing into conduits on other parts of the system, and so the amount of cable to be kept in stock is reduced.
(4) Freedom from damage to other adjacent roadway works in the case of a prolonged leakage to earth. This is particularly liable to occur on single-core vulcanized-bitumen cables laid solid.

This latter fact was recently very forcibly demonstrated to the author. Two substations were interconnected by three single vulcanized-bitumen cables laid solid in the same wooden troughing. The Post Office had trouble with one of their trunk feeders and, on drawing out the faulty length of cable, electrolysis was found to be the cause of the breakdown. Shortly afterwards another fault due to the same cause developed on a local feeder lying in a duct close to the trunk line. While this was being repaired a heavy fault on the supply undertaking's interconnector was reported, the heavy protective fuses at both stations having blown and about 4 ft. of the cables having burnt completely away at a place adjacent to where the trouble had occurred on the telephone cables. It was clearly a case of a slight fault being fed unnoticed for a considerable time, gradually increasing until it developed sufficiently to give some indication of its presence. Had lead-covered cables been used on this interconnector, and the lead securely bonded to earth at both stations, the fault would have immediately developed sufficiently to blow the station fuses and the supply undertaking would not have had to meet an account of over £250 for damage to Post Office cables.

Another point against the use of even single-core vulcanized-bitumen cables is that no advantage can be taken of the special arrangement—dealt with below under the heading "Distributors"—which enables the continuity of supply to be maintained in almost every breakdown, when single-core lead-covered cables are used throughout the system.

Modern practice is to use earthenware troughs because:—

(1) They are more easily laid down and better joints are possible between two troughs.
(2) They are unaffected by acids contained in the surrounding ground, resulting in long life.

It is well known that all wood contains certain vegetable acids, chiefly acetic acid. If a wooden trough is laid in damp ground it will quickly deteriorate and the acid will ultimately attack the cable. It is for this reason that wooden boxes should never be used for enclosing joints.

When laying the troughing, pockets should be carefully avoided because any water that manages to find its way into the troughing will accumulate at such places

and, in time, percolate through the bitumen and destroy the cable. To do this it sometimes means that a deeper trench has to be excavated than is the case when laying a cable direct, to enable the troughs to be laid underneath most of the other roadway obstructions. A depth of about 2 ft. 6 in. will generally be found sufficient for this purpose. The troughs should not be laid directly on a bed of clay when the ground above is of a porous nature, as surface water is liable to collect at such a level and perhaps find any weak spot in the troughing. In such cases it is better to deepen the trench slightly to allow the cable to be completely surrounded by clay. A foundation of some pervious substance such as loose stones or sand is beneficial, as water will quickly soak through and leave the cable comparatively dry, instead of remaining in the vicinity of the cable.

Before the bitumen is run in it is essential to see that the troughing is perfectly dry inside. Should any appreciable amount of moisture be allowed to remain, blow-holes will be formed in the bitumen, through which, in time, water will percolate to the cable. (This is a very trying feature of solid-laid cables.) The cable is then covered with hot bitumen which is allowed to set. The reason for having the first filling fairly hot is to make it sufficiently thin to ensure it filling up the small gap which is formed between the bottom of the cable and the trough, due to the cable resting on the saddles, and thus prevent the formation of any air spaces. It also serves the purpose of helping better to expel, before it sets, any moisture that might be left in the trough. The remainder of the trough can be filled up with bitumen at a temperature of about 250–300° F., and if the tiles are fixed before this sets they will be firmly held in position.

Pilot Cables.

As feeders are usually accompanied by pilot cables, the cost of these pilots might be considered in conjunction with those of the feeders themselves. The cost of installing a pilot with any particular type of feeder is not always the same, nor is the additional material to be provided similar in every case. This difference is, however, so small compared with the cost of the feeder itself that pilot cables have been omitted when arriving at the costs of the various types of feeders shown in Table 3.

Costs of Feeders.

From the figures given in Table 1 a set of curves, shown in Fig. 1, have been drawn from which the respective sizes of cables that have to be used for a given load and method of laying can at once be determined. For the purpose of comparing the cost of the different systems for feeders, the respective sizes necessary to cope with a maximum continuous load of 500 amperes are taken as being :—

It is not of course suggested that, where the size indicated in the above list is not a standard, a cable should be specially constructed to meet the specific requirements. As it is necessary, however, to have some definite basis of comparison, the costs of the sizes of feeders which would give the same results in practice are considered, and where these are not standard cables their costs have been calculated from those of the nearest standard sizes.

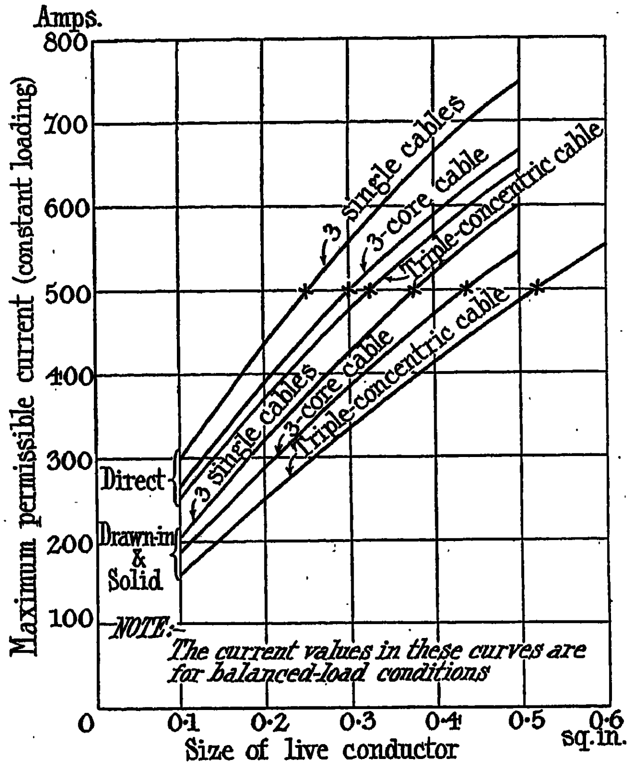

Fig. 1.

The costs of the various systems are shown for two types of roadway, namely :—

(1) Sets on a 6-in. concrete foundation.
(2) Waterbound macadam.

Table 2.

Depth of Track for Feeders.

Type of ground surface	Cables laid direct	Cables drawn in	Cables laid solid
	ft.	ft.	ft.
Sets + 6-in. concrete foundation . . .	2	4	3
Waterbound macadam	2	3	2

(1) 3 single-core cables (2) 3-core cable (3) Triple-concentric cable	Paper-insulated, lead-covered, steel-tape-armoured, laid direct	= 0·25 sq. in. × 0·125 sq. in. × 0·25 sq. in. = 0·3 sq. in. × 0·15 sq. in. × 0·3 sq. in. = 0·325 sq. in. × 0·1625 sq. in. × 0·325 sq. in.
(4) 3 single-core cables (5) 3-core cable (6) Triple-concentric cable	Plain lead-covered drawn-in and paper-insulated vulcanized-bitumen laid solid	= 0·375 sq. in. × 0·1875 sq. in. × 0·375 sq. in. = 0·44 sq. in. × 0·22 sq. in. × 0·44 sq. in. = 0·525 sq. in. × 0·2625 sq. in. × 0·525 sq. in.

The depth of track required for each of these types of roadway will not always be the same for all methods of laying. Table 2 shows the depths of tracks allowed for in estimating the results shown in Table 3.

The figures given in the latter table show that, wherever local conditions permit, three single-core feeders are the cheapest to lay down. When this fact is considered together with the technical advantages of this type of cable, there must be very exceptional reasons to cause any undertaking not hampered by restricted road space, to adopt a multicore cable for feeder work.

This table shows, exclusive of cable, the portion of the original expenditure that will have to be reincurred when it is necessary to increase the size of the feeder. It will also be seen that the harder the type of roadway, i.e. the more it costs to excavate and reinstate, the more substantial are the benefits derived from the conduit system.

(3) DISTRIBUTORS.

Single-core cables.—Owing to the ± 4 per cent voltage variation at consumers' terminals stipulated by the Electricity Commissioners, the choice of the type of cable to be used for distributors is very rarely affected by the maximum current-carrying capacity, the size required depending upon the voltage-drop when the cable will be carrying the maximum current with which it will have to cope.

TABLE 3.*

Cost of Feeders (500 amperes) per 100 yards.

Type of roadway	Lead-covered, steel-tape-armoured, laid direct			Plain lead-covered, drawn-in			Vulcanized-bitumen, laid solid

	£	£	£	£	£	£	£	£	£
Sets on a 6-in. concrete foundation	230	238	238	308	308	320	301	309	323
Waterbound macadam ..	146	153	153	218	218	230	212	220	233

It is also apparent from these figures that the cheapest way to lay cables is to lay them direct in the ground. There is little to choose between the conduit and solid systems, but both these are considerably more expensive to install than the direct system.

As already pointed out, the first cost in laying down a feeder is not the only consideration. When provision has to be made for future extensions and when the cost of repairing faults in cables laid under certain types of roadway that are both expensive to excavate and to reinstate is borne in mind, a considerable ultimate saving will be effected by incurring the increased initial cost of the conduit system, a fact clearly demonstrated by an examination of the figures shown in Table 4.

Apart from the cost of various types of distribution systems, the most important factor is that of continuity of supply in case of breakdown, and in this respect distributors composed of three single-core, lead-covered cables, used in conjunction with a similar type of feeder, form the best arrangement. This is because a fault can occur on one core without either of the others being affected, a rare occurrence on a multicore cable. Should one of the live cables break down, this cable alone need be cut out (provided that, by so doing, excessive load would not be thrown upon the neutral cable), the con-

* The costs shown in Tables 3 and 5 are based on the price of cables when the costs per ton of copper and lead were £60 12s. and £27 10s. respectively.

sumers connected to the other "side" being in no way affected.

A simple earthing device at the station reduces to a minimum the possibility of even this partial disconnection, and at the same time diminishes the cost of network boxes by allowing the more simple and reliable link box to be substituted for the majority of the fuse boxes (see Fig. 2). When an earth occurs on one of the "outers" it simply blows the light earthing fuse, and the neutral and other outer are respectively raised or lowered to 240 volts and 480 volts above or below

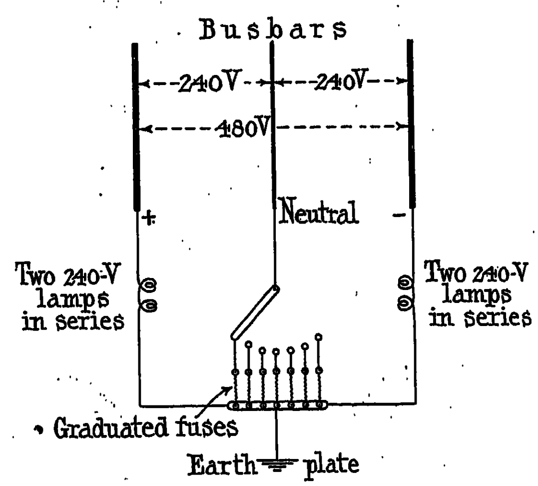

FIG. 2.—Method of earthing the neutral bar at the substation.

earth potential, as the case may be. The system will then continue to operate with one of the outers earthed instead of the neutral. Whilst this involves no danger to the electrical system, there is a greater risk of shock from the higher potential at which the unearthed pole is then operating. Such a fault must therefore be cleared as soon as possible.

system), in order to isolate completely the district in which the fault has occurred and allow the rest of the supply to continue undisturbed.

A point in connection with this system of earthing that should be carefully borne in mind is that the neutral cable under normal conditions may have an earth fault without the supply being in any way affected. Should an earth then occur on either the positive or negative cable there will be a short-circuit, varying in magnitude according to circumstances, between the two faults, and this will remain until one of the faults burns itself clear or is isolated by the operation of fuses. To guard against this possibility the neutral should, at periodical and convenient times, be raised to the potential of one of the outers through a light copper fuse, and any earth faults thus detected should then be immediately located and repaired.

Due to the fact that the potential is removed from the fault when the light earthing fuse at the station is blown, very little damage is usually done to the cable, provided that water has not penetrated through to the insulation. It is very often found in such instances that a new piece of cable is not necessary, as the fault can be repaired by simply stripping back a portion of the lead covering and, after taping the damaged part of the insulation, sealing it up in a cast-iron joint box or lead sleeve. This considerably reduces the cost of making the repair.

When the actual repair of a fault on one of the cables is considered this system shows up to further advantage, because:—

(1) The work can be left over, if desired, until such time when the least inconvenience will be caused to the consumers.

(2) When locating the fault, only the faulty side need be disconnected.

(3) The time taken to make a straight joint is very much less than with a multicore cable, and therefore the distributor can be put into commission again in a shorter time.

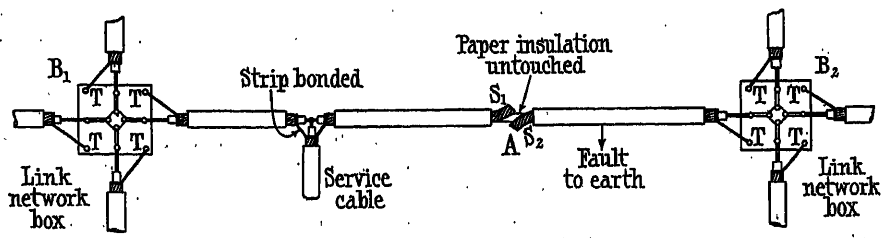

FIG. 3.—Testing-strip connections.

This arrangement offers no relief to the network when a fault takes place between cables, an occurrence which, though uncommon, must be provided for. For this reason it is not advisable to run the network without any fuses whatever, for should a short-circuit develop between two cables the fault must burn itself clear. During this time the cables leading up to the fault are liable to damage and the supply for the whole town is subjected to violent fluctuations of voltage. This difficulty is overcome by installing a few heavy fuse network boxes at certain points (their exact position being determined by the layout of the particular

By using a cable in which is incorporated a thin copper testing-strip, lightly insulated from the lead sheathing, it would be possible to locate a fault without actually cutting the core, which means that there would be no need to disconnect the faulty cable until the fault has been found and everything is ready for effecting the repair. In fact, if the cable is fed from both ends and it is found necessary to insert a new length of cable, this could often be done without interrupting the supply at all.

The method of connecting up this copper strip is shown diagrammatically in Fig. 3. It should be bonded across all straight joints and service joints on the cable

and brought to a terminal in each network box. Being lightly insulated from the lead covering, under normal circumstances it should test clear of earth and of the core. Its value in aiding fault-finding is based on the assumption that wherever a fault occurs from the core to earth the strip will be brought into contact with either the core or the lead covering, perhaps both. By testing to earth at the terminals T the faulty strip could be located; then by cutting this strip and testing both ways the fault may be found without interrupting the supply or cutting the cable, resulting in fewer straight joints.

A further advantage of the use of single-core cables is that the numerous tappings taken off distributors are more simple and easy to make and therefore more reliable. Also, when making such connections it is not necessary to make the cable dead. This fact, from the points of view both of the supply undertaking and the consumer, has beneficial results, because there is no loss of revenue during the time the connection is being made, and no inconvenience is caused to consumers.

This latter reason is of even more importance than the former and is often not fully appreciated by the officials of some undertakings. A comparatively trivial loss to the supply undertaking might be a matter of considerable concern, for instance, to small shopkeepers who use motors in their businesses. Interruptions should be cut down to a minimum as they only tend to cause dissatisfaction with electric supply. Many new consumers are obtained on the recommendation of old ones; their goodwill is therefore something to strive for and no effort should be considered too great, no detail too trivial, in the endeavour to establish it on a firm and lasting basis.

Three-core cables.—A network in which three-core cables are used for the distributors has not the same attractive features as those outlined in the system described above. The earthing of the neutral through a light fuse is unsuitable with such cables. The reason for this is that in a three-core cable, whilst it is possible to have a fault to earth on one live core without the others being affected, the time usually necessary for the trouble to spread and cause a short-circuit between cores is too brief for any material advantage to be gained by its adoption. It is thus usual for the neutral to have some form of permanent earth connection and for suitable protection to be provided to operate on a fault to earth or between cores.

The protection of a distribution system is necessarily a compromise between conflicting conditions. On account of their low cost and simplicity, fuses installed in network boxes or pillars at convenient junctions of distributors are relied upon to isolate a faulty section. The inherent weakness of the fuse is, however, plainly demonstrated on heavy faults, when, due to its lack of discrimination, large healthy areas are cut off together with the bad ones. For this reason, fusing points should not be multiplied unnecessarily. Besides being more expensive, the introduction of fuse boxes in the place of the link boxes decreases the reliability of the network.

As it is not necessary to cut any of the cores when a service connection is being made, the supply need not, in cases of urgent necessity, be interrupted during such time; but wherever possible it is better to make the distributor dead, as this allows the jointer to work in absolute safety and better workmanship is thereby obtained.

Trouble has recently been experienced on three-core distributors due to the straining of the cores when they are wedged apart to allow service connections to be made. When such connections are numerous, this strain may become serious. To overcome this difficulty, Messrs. Callender's Cable and Construction Co., Ltd., have produced a three-core cable the section of which is shown in Fig. 4. In the centre is a hemp core, around which are placed the three conductors which, in turn, are separated from one another by means of three more hemp cores. When a joint is being made these hemp cores are all cut away, thus leaving the conductors sufficiently spaced to allow the soldered connections to be effected without any straining whatever, and with much less risk should the cable be alive whilst the work is being done. Though a vulcanized-bitumen cable is shown in Fig. 4 the lead-sheathed type is more commonly used.

Triple-concentric cables.—The triple-concentric cable has such obvious disadvantages for low-tension d.c. distribution systems that it is remarkable that any

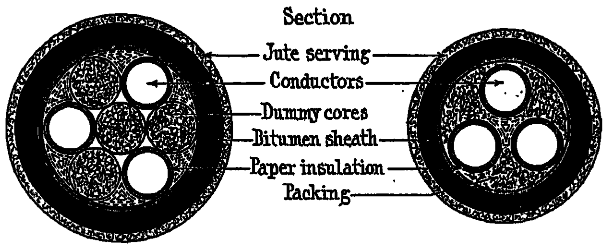

FIG. 4.—Three-core, paper-insulated, vulcanized-bitumen cable with dummy cores, and its diameter compared with that of a standard three-core cable.

undertaking ever adopted it for that part of a network where, owing to the smaller sizes of cables generally used, a three-core cable is possible. It has most of the disadvantages of the three-core cable enumerated above, as well as additional ones, against which it can only show a slight superiority in a reduction of cost and diameter. In addition, there are disadvantages arising out of the method of jointing. How the outer cores have to be stripped back to give access to the inner core is plainly shown in Fig. 6. To do this it is essential to make the cable dead if due consideration is to be given to the jointer's safety. Furthermore, when the connection is taken off the inner core, definite gaps are left in the continuity of the outer and middle cores and these have to be bridged by special fittings, resulting in two soldered connections on each of these cores. It will readily be appreciated that, however well these soldered connections are made, they can never be as reliable as the unbroken core of a three-core or single-core cable; moreover, joints have sometimes to be made under very adverse conditions which militate against good workmanship.

The inner and middle cores of a triple-concentric cable are usually connected to the positive and negative poles, the smaller outer core forming the neutral. This arrangement is maintained throughout the system so

that a joint cannot unwittingly be made with the wrong polarity.

With lead-covered armoured cables laid direct there would, however, seem to be something in favour of the outer core being made positive, the middle neutral, and the inner negative. In this case the lead sheathing, which is bonded throughout the network, provides a direct metallic connection between a faulty positive core and the station earth plate. Should a cable so connected be damaged, perhaps by the inadvertent blow of a pick, causing the lead sheathing to be pierced and come into contact with the live outer core, a fault is immediately apparent and can be repaired at once and at a low cost, which cost can be recovered from the authority responsible for the damage.

Supposing, however, that the outer core had formed the neutral, the man with the pick would not be aware of any trouble and no indication would be perceived at the station. After a lapse of perhaps months, when all recollections and evidences of the roadway having been disturbed have gone, a fault will be found to have developed due to water penetrating through the punctured sheathing. The fault is not now so easily traced and perhaps large expenditure is incurred which would not have been necessary had the circumstances been as in the case previously described. Moreover, due to lack of concrete evidence, blame cannot be fixed on any other authority, which means that the whole cost of the repair has to be borne by the supply undertaking. Making the outer core positive would also tend to prevent moisture from penetrating to the inner portions of the cable.

Method of Laying.

Drawing cables into ducts offers no considerable advantage for distribution work, so that the choice is limited to the direct and solid methods. In connection with these there are no new points that did not arise when reviewing their application to feeders. There is, however, one weakness in the solid system that is not of great moment on a feeder, but its presence is very much more likely to cause trouble on a distributor on which there will usually be numerous joint boxes. However well a joint is packed up below, pressure from above will cause it to sink slightly when the ground is filled in. The subsidence of the box is liable to crack the bitumen at the joint of the box and troughing and thus allow water to enter and ultimately cause a breakdown. How true this is can readily be appreciated by mains engineers, who generally find the majority of their faults taking place either at joint boxes or in close proximity to them.

Distributor cables, even more than feeder cables, should, wherever possible, be laid under the pavement. The advantages gained by so doing are many, the most apparent being :—.

(1) All service cables are shorter and therefore cheaper.
(2) Owing to the absence of heavy traffic over them they can be laid much less deeply, depths of 12 in. to 18 in. being as a rule sufficient, resulting in less expensive trench work.
(3) The ground around the cable is usually drier.
(4) Repairs are cheaper.
(5) More room is obtained, as gas, water and sewage mains are usually all in the roadway.

TABLE 5.

Cost of laying $0 \cdot 2$ *sq. in.* $\times$ $0 \cdot 1$ *sq. in.* $\times$ $0 \cdot 2$ *sq. in. distributors per* 100 *yards.*

Type of ground surface	Lead-covered, steel-tape-armoured, laid direct			Vulcanized-bitumen, laid solid		
	3 single-core cables	3-core cable	Triple-concentric cable	3 single-core cables	3-core cable	Triple-concentric cable
	£	£	£	£	£	£
Sets on a 6-in. concrete foundation ..	213	204	201	260	238	238
Waterbound macadam	128	120	117	170	149	148
Flagged pavement	120	111	108	161	140	139

Costs of Distributors.

Table 5 shows the comparative costs of laying distributors under different types of ground surface, while Table 6 gives the approximate depths of track that have been allowed for in each case.

TABLE 6.

Depth of Track for Distributors.

Type of ground surface	Cables laid direct	Cables laid solid
Sets on a 6-in. concrete foundation ..	2 ft. 0 in.	2 ft. 6 in–3 ft. 0 in.
Waterbound macadam	2 ft. 0 in.	2 ft. 0 in.
Flagged pavement ..	1 ft. 3 in.	1 ft. 3 in.

It will be seen from these figures that there is very little difference in the costs of three-core and triple-concentric distributors, whatever difference there is being due to the slightly higher cost of the three-core cable. There is thus no financial justification for the preference of the triple-concentric cable, with its inherent disadvantages.

The distributor made up of three single-core cables involves rather more expenditure than either of the other two, though this extra cost detracts very little from its manifold advantages, and, for the reasons already explained, the additional outlay is fully justified.

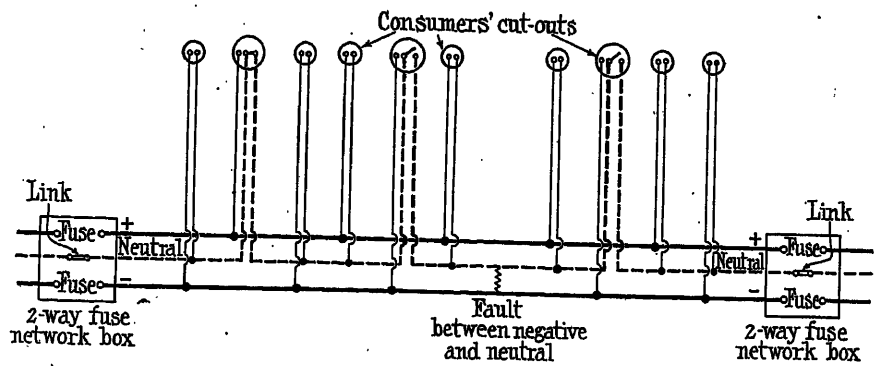

FIG. 5.—" Looped-neutral " services.

As previously stated, the chief factor in determining the size of a distributor is the maximum voltage-drop allowable so as to comply with the Electricity Commissioners' regulations of ± 4 per cent variation in voltage. It is not, therefore, generally possible to take much

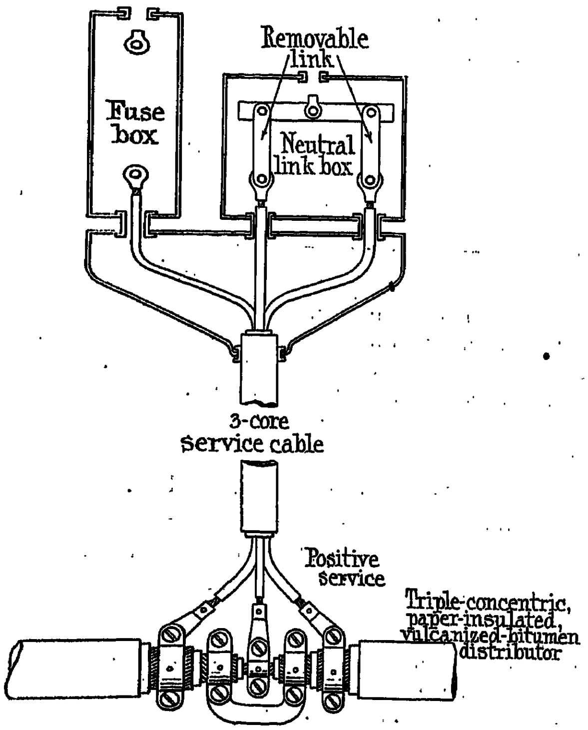

FIG. 6.—Connections for a "looped-neutral" service using a 3-core service cable.

advantage of the higher permissible current-carrying capacity of single-core cables, but it is well to remember that this good quality is a useful stand-by in cases of emergency when overloads may be temporarily thrown on to a particular distributor due to a breakdown at some other point of the network.

LOOPED NEUTRAL SERVICES.

While dealing with the subject of distributors it might not be out of place to put forward a suggestion which the author considers will greatly facilitate the location of faults on vulcanized-bitumen triple-concentric distributors up to about 0·2 sq. in. cross-section, and help to preserve the continuity of supply under fault conditions.

As faults on modern cables are usually due to external causes, the majority of faults on a triple-concentric distributor are between the middle and outer cores, i.e.

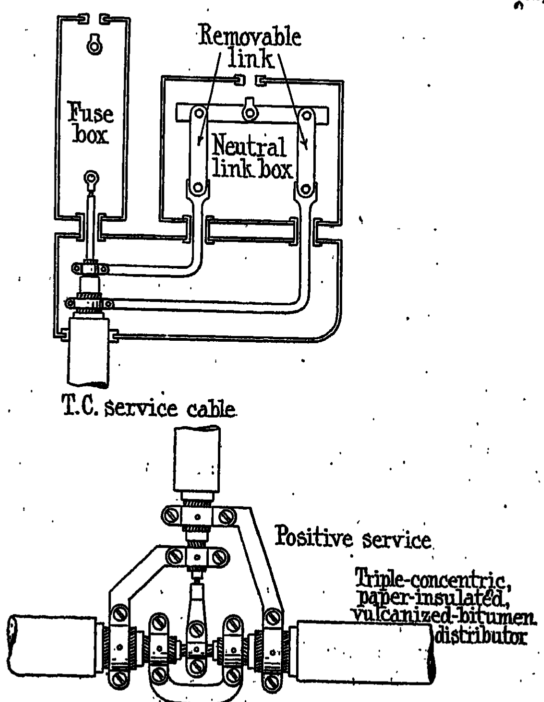

FIG. 7.—Connections for a "looped-neutral" service using a triple-concentric cable with the inner core alive.

between negative and neutral. This being the case, it is only necessary to cut the neutral core to enable a test to be taken that will show in which direction the fault lies.

If the neutral of the distributor is looped in at several of the services along its length, a convenient method of breaking its continuity is provided without any exca-

vating being necessary, thereby effecting a considerable saving in time and money (see Fig. 5). The fault having been traced to a position between two consumers in whose premises the neutral is disconnected, the supply can now be restored to all the consumers with the exception of those tapped off the faulty length. If the fault be between all three cores the positive and negative cores should be bridged at the network box and only one fuse replaced.

Where it is decided to adopt this system on an existing distributor that is not already supplying all the possible consumers, it can be installed whenever a suitable service is being laid, so that no scrapping of existing material is necessary.

The increased cost of such services depends upon their length and the size of the distributor, and amounts to from 25s. to £2 for short services. The saving in the event of *one* fault may cover the extra cost of many looped services.

Figs. 6 and 7 show the arrangement employing three-core and triple-concentric service cables.

(4) Services.

The type of cable and the method employed in laying the distributors is usually adopted for the services tapped from them. This preserves the symmetry of the network and generally simplifies the connections in the service joint boxes. For this reason, before any particular system for the distributors is decided upon the question of services should be considered.

As in the case of feeders and distributors, single-core lead-covered armoured cables possess the most advantages for services. One advantage of this type of cable is that the risk of fire is greatly reduced. A fault on such a cable inside a consumer's premises has only to blow the light station earth fuse to clear itself. With a concentric or twin cable, however, the heavy street fuses on the distributors have to blow before the fault is cleared, and in the meantime a fire may have been caused. For this reason concentric or twin service cables should be laid with more care inside the consumer's premises, anything inflammable being strictly avoided.

The service joints on single-core cables are simple to make, resulting in an increased reliability which more than counterbalances the necessity of having two or three service boxes for direct-laid armoured cables, in place of the single one used for multicore cables. The time taken by the jointer to fix the additional joint-box does not in practice affect the cost of the service, as a standard time, based on average circumstances, is usually allowed for the completion of ordinary services.

The armoured service is so much easier to lay, under all conditions, than is the vulcanized-bitumen solid-laid service that some undertakings actually connect armoured service cables to old vulcanized-bitumen distributors. This fact eloquently supports the armoured cable's claim to priority.

In the author's experience the weakest point in a vulcanized-bitumen service laid solid is where the cable passes through the outer wall of the building; here it may take a sharp upward bend to the cut-outs. If the wall is thick the difficulty of making a sound job of the troughing may contribute towards the frequent breakdowns that occur at this point on old services, but as bitumen is readily attacked by alkaline salts the lime in the wall is probably the cause of most of the trouble. At all such points the cable should be drawn through small earthenware pipes with suitable bends and filled with bitumen.

Where the service cable has to cross a hard road or any other ground that is expensive to excavate and reinstate, it is advisable to draw a lead-covered cable through small earthenware conduits, in order to lower the cost of repairing faults that might occur on that section. These conduits should be short—not more than 2 ft. in length—to enable the numerous pipes, etc., that are often encountered when crossing a road to be more easily avoided.

For large consumers who cannot afford to be shut down for any length of time in the case of a fault, it is very often expedient to loop a three-core or triple-concentric distributor into their premises so that they can always be given a supply, even though a fault may exist on either of the two sections of the distributor supplying them. This is not necessary on single-core lead-covered systems, due to the freedom from interruptions of supply experienced on such systems.

(5) Conclusion.

Sufficient has now been said of the various types of cables and methods of laying to enable a conclusion to be arrived at as to which is the most suitable system to be laid down, taking into consideration first costs, future extensions, load migration, maintenance and continuity of supply.

For feeders.

(1) Three single plain lead-covered cables drawn into earthenware conduits.

(2) Where future load has not to be provided for and where the feeder can be laid in good soft ground and free from the danger of electrolysis, three single armoured cables laid direct would be suitable.

(3) Where the authorities have not much road space available, a three-core lead-covered cable may be drawn into conduits, but this will forfeit the special advantages of single-core cables.

Where a multicore cable is desired larger than 0·5 sq. in. × 0·25 sq. in. × 0·5 sq. in., a triple-concentric cable is necessary.

For distributors.

(1) Three single lead-covered steel-tape-armoured cables laid direct with tile covering.

In a locality where there is a danger of electrolysis, plain lead-covered cables should be substituted for the armoured cables and laid solid in separate earthenware troughing with tile covering.

(2) Where the feeder system is three-core or triple-concentric, three-core distributors could be used, as most of the advantages of single-core distributors depend upon the whole system being made up of a similar type of cable. Triple-concentric distributors should be avoided.

For services.

A type of cable similar to that used for the distributors. If the distributor is laid solid it is often more convenient to lay armoured services direct in the ground.

The author wishes to express his thanks to Mr. J. S. McCallum of Messrs. Callender's Cable and Construction Co., Ltd., for the trouble he has taken in furnishing him with the prices of cables, etc., used in the foregoing calculations.

APPENDIX.

ECONOMY LAW FOR FEEDERS.

Running cost (in £) of energy lost in cable per annum

= watt-hours lost × running cost (in £) per watt-hour generated

= (R.M.S. current)^2 × No. of hours per annum × resistance of cable × running cost (in £) per watt-hour generated

$$= I^2 \times T \times \frac{2lr}{1\,000} \times \frac{\text{running cost (in pence) per unit}}{240 \times 1\,000}$$

$$= \frac{I^2 rlTd}{1 \cdot 2 \times 10^8} \text{ (in £)} \quad \ldots \ldots \quad (1)$$

Capital charges per annum on extra plant, etc., required to meet the demand of $\frac{2I^2rl \text{ watts}}{1\,000}$

$$= \frac{2I^2rl}{1\,000} \times \text{capital charges per watt of plant, buildings, etc.}$$

$$= \frac{2I^2rl}{1\,000 \times 1\,000} \times \begin{array}{c}\text{cost per kW}\\\text{of plant, etc.}\end{array} \times \begin{array}{c}\text{percentage allowable}\\\text{for capital charges}\end{array}$$

$$= \frac{2I^2rl}{10^6} \times C_1 \times \frac{p_1}{100} \text{ (in £)}$$

$$= \frac{I^2rlC_1p_1}{0 \cdot 5 \times 10^8} \text{ (in £)} \quad \ldots \ldots \quad (2)$$

Capital charges per annum on cost of cable and laying

= total cost of feeder × percentage allowable for capital charges

$$= \text{length of cable} \times \text{cost (in £) per yard} \times \frac{p_2}{100}$$

$$= \frac{lC_2p_2}{100} \text{ (in £)} \quad \ldots \ldots \quad (3)$$

where I = maximum current to be allowed for,
r = resistance per 1 000 yards of conductor,
l = route length of cable, in yards,
T = number of hours at which the maximum current I would have to flow to produce the same energy loss in the cable as would take place, during the year, with the usual fluctuating loads,
d = running cost per unit generated, in pence,
C_1 = cost per kW of plant, buildings, etc., in £,
C_2 = cost per yard of cable and laying, in £,
p_1 = percentage to be allowed for capital charges on C_1,
p_2 = percentage to be allowed for capital charges on C_2.

The whole formula now reads:—

$$\text{Total charges (in £)} = \frac{I^2rlTd}{1 \cdot 2 \times 10^8} + \frac{I^2rlC_1p_1}{0 \cdot 5 \times 10^8} + \frac{lC_2p_2}{100}$$

or, as $l/100$ is common in all expressions, the most economical size of cable is obtained when the value of the expression

$$\frac{I^2rTd}{1 \cdot 2 \times 10^6} + \frac{I^2rC_1p_1}{0 \cdot 5 \times 10^6} + C_2p_2$$

is a minimum.

When it is desired to use this formula to ascertain whether or not the installation of a new feeder would be an economical proposition, the following slight variations are necessary:—

Equation (1) should represent the saving in the cost of energy wasted that would be effected by the addition of a new feeder.

Equation (2) should represent the saving in capital charges due to the smaller amount of plant required to cope with the reduced losses.

When (1) plus (2) is greater than (3) a saving would be effected by laying a new feeder of the size allowed for in the formula.

When (1) plus (2) is less than (3) the capital charges on the cost of the new feeder would outweigh any saving due to a higher resultant efficiency.

DISCUSSION BEFORE THE INSTITUTION, 8 JANUARY, 1925.

Mr. W. E. Highfield: I agree generally with the author's recommendation that feeders should be lead-covered cables drawn into conduits. I should not go so far as the author does in adhering to three single cables, because I think the three-core cable has much to recommend it. In town areas, where the load can be fairly accurately estimated, three single cables are advantageous to use. In a growing area, such as is exemplified in the paper, one presupposes a considerable amount of suburban property, probably dwelling houses, with roads of macadam or asphalt. Under such conditions it is not only impossible to estimate the growth of the load but it is equally impossible to estimate the load centre. Consequently, when extensions are required, it is not necessarily a question of just strengthening the cable; it may mean running another cable along a new but adjacent route. I think that the author overstresses the value of the cable loadings. The loading is not always settled by the full-load ratings. With a booster on each feeder the

full-load ratings might be reached, but in practice the most that can be obtained is two voltages from two sets of busbars and this forms a determining point. The author alludes to the difficulty of pouring bitumen without air bubbles in it. Bitumen can be poured without air bubbles if a sprinkling of sharp sand $\frac{1}{16}$ in. thick is laid in the bottom of the trough. The hot mixture, as it is poured in, explodes any moisture into steam, and the sand provides, momentarily, a path for the escape of this steam. I have had samples of mixture, poured in this way, that were quite solid and able to withstand 120 000 volts (a.c.) on a thickness of $\frac{1}{2}$ in. For distribution I prefer lead-covered cable to the armoured type advocated by the author. Armoured cable is difficult to handle, and it is also difficult to remake the continuity of the armour once the latter has been cut. It is impossible to clamp straight on to the lead and possibly the best way is to slip a ferrule under the steel and clamp on to that. The system depends almost entirely on the type of box used, and that is not described in the paper.

Mr. H. A. Ratcliff: There are frequent references in the paper to the permissible loading of cables; but in the case of cables laid in town streets there are frequently so many factors involved that definite loading values are practically indeterminate. Fortunately, however, in the case of low-tension cables this is not of much consequence, since the loadings are limited by other considerations to values which are usually well within those based on the maximum permissible temperature of the cables. There is a possible exception in the case of vulcanized-bitumen cables, owing to the risk of decentralization of the conductor; but cables of this type are now rarely employed. In the case of either three-wire d.c. or four-wire a.c. distributors I strongly advocate the use of a neutral conductor of the same sectional area as the outers. In the case of feeders, however, as the neutral conductor only carries the resultant out-of-balance current, and, moreover, as there will usually be at least two feeders to any section of the network, a neutral conductor having half the sectional area of the outers is permissible. Experience has fully justified the use of the larger neutral conductor, since more complaints of low pressure arise from bad balancing than from actual pressure-drop in the distributors, and further, in the case of heavy network currents arising from short-circuits on the system there is less risk of damage to cables beyond the immediate vicinity of the fault when all the conductors are of the same sectional area. The reference to the shifting of the nodal points on a network is very interesting as the experience is by no means an uncommon one. The reason for it is not always very obvious, but it is probably largely due to certain industries becoming more or less localized, and the fluctuations in trade not occurring simultaneously in the different industries. Effects of this nature were much accentuated by the conditions prevailing during the war. The outward migration of the population usually results in an increase of the load in the central area, due to the conversion of houses into business premises or factories. The determination of the most suitable size for a feeder is, as the author states, largely an economic problem; but electrical problems also arise in connection with the maintenance of pressure at the feeding point and the provision of suitable regulating apparatus. It is always advisable, if possible, to avoid an undue multiplicity of busbars and boosting arrangements. For this reason expediency is usually the most important factor in feeder calculations, and as a rule it pays to provide a feeder of ample size for the probable requirements of the locality concerned. Unfortunately it is not always sufficiently appreciated that feeder losses are essentially peak-load losses, and hence relatively very expensive. The consequence is that in many cases the money spent on peak-load plant and the incidental complications might with advantage be put into the feeders. In connection with the economy calculations the factor T in the author's calculations appears to be rather cumbersome, and usually in calculations of this nature it is more convenient to introduce the load factor of the copper losses. For an average daily load curve, if F is the load factor of the load, it is usually sufficiently accurate to assume that the load factor of the copper losses is $F^{3/2}$. If provision is to be made for a subsequent increase in the size of a feeder, the better plan is to lay the initial feeder of half the ultimate size, and at a later stage to draw in another feeder of equal capacity. This provides a greater carrying capacity in case of emergency, there is less risk of total failure, and if necessary half the feeder can usually be disconnected for testing or repairs. The question of direct laying versus conduits is a very debatable one. The laying of conduits in city streets is frequently attended with many difficulties, and although conduits admittedly possess many advantages for feeders, telephone cables and pilot cables, they have very few real advantages in the case of distributors. Unless conduits are very well laid, lead-covered cables are very apt to fail at the duct joints, and a further possible disadvantage of conduits is that they provide facilities for the passage and accumulation of water and gases. Where it is possible to use them, steel tubes in some cases possess advantages and, furthermore, they provide an additional protection against troubles arising from electrolytic action. Wooden troughing cannot be too strongly condemned; it very soon ceases to support the cables in any way, and, when it commences to rot, the resulting organic acids have a detrimental effect on the cables. Experience has shown that true electrolytic action due to stray currents is of comparatively rare occurrence, and troubles of this nature are usually due to direct chemical action, frequently of a catalytic nature, and also occasionally to electrochemical actions arising from leakage from the cables concerned, as the result of mechanical damage. It is, therefore, essential that all cable sheathings should be effectively bonded and earthed at suitable points. As there is no reference to this requirement in the paper, the author's view on the subject would be interesting. His condemnation of wire-armoured cables in ducts is rather surprising. Wire-armoured cables possess some advantages when drawn into conduits and, moreover, the British Electrical and Allied Industries Research Association recognize an increased loading for cables so armoured. Where it is

possible and economically sound to use them, single-core cables are preferable to either three-core or triple-concentric cables, except in the smaller sizes, when the increased diameter and mechanical strength of a multi-conductor cable is a distinct advantage. Unfortunately the author's case for single-core cables is largely based on the assumption of unduly high current densities. Triple-concentric cables possess many disadvantages and only one real advantage, which arises from the possibility of making the positive conductor the outer, and the neutral conductor one of the inners. With this arrangement of conductors, earth faults on the negative and neutral conductors are impossible, osmotic troubles are entirely eliminated, and the comparatively rare earth faults on the positive conductor can be quickly located.

Mr. L. W. Perryman: The author speaks of a testing wire as a means of locating a fault; this is equally applicable, I think, to triple-concentric cable systems. I do not agree with his view that the triple-concentric cable is the worst of the three forms enumerated; I believe it to be the best as it is far more compact and there is but one cable to lay instead of three. In the case of single-core cables there are three to lay, requiring far more space, and it is important to note that, in towns especially, space is very limited, and for this reason armoured cables laid direct are certainly the most suitable type for getting round obstructions. The author points out that if he gets a fault on one of his outers, either positive or negative, he can, by opening his neutral at two points where he takes it into the consumer's premises, isolate the faulty section of his network and so maintain the normal supply to the rest of the system. That is so. On triple-concentric networks faults are cleared, either by the fuses blowing in the street boxes or being removed on either side of the fault; also some indication is given at the time on the earth-current ammeter at the station and thus gives a warning. Even if the fault develops, the currents going to earth are a minimum. With single cables laid in the ground a short distance apart, however, it is possible to have either the positive or negative main leaking to earth and for currents of considerable value to traverse the ground and produce electrolytic action on gas and water mains, and damage to Post Office wires, etc. In general I think that, except perhaps in special cases, the concentric system throughout is the simplest method for both feeders and distributors. The main advantage of single cables, from my point of view, is that new consumers can be connected without disturbing the old ones, as each of the mains can be jointed singly; the same can be done on triple-concentric cables, but it is not advisable and I believe that the practice is being discontinued.

Mr. E. Ambrose: The author states that the size of the three-core cable is limited to 0·5 sq. in. This is, however, quite a large section for a distributor, and I do not think that there are many instances where it would be necessary to use a larger cable. He also mentions the advisability of making trial holes before laying conduits, but that applies also to cables laid on the solid system and to some extent also to cables laid direct. If cables have to be laid in a road which is likely at some not very distant date to be widened, there is everything to be said for laying them in conduits, because when the road is ultimately widened it may be possible to put the cables under the footway. It is only necessary then to lay the new distributors under the footway and draw out the old ones from under the road. The author advises the draining of conduits and making arrangements for a fall into the manholes. It might even be possible to discharge them into the Corporation drains, but then some sort of non-return valve would be necessary. Very often in a new district that has not been thoroughly drained, the conduits will act as the drain, and so long as the water does not lodge anywhere I do not think that very much damage is done. Regarding his objection to the use of lead-covered and braided cables drawn into conduits, I think that, providing a conduit of not less than 3 in. internal diameter is used, there will be no difficulty in withdrawing the cable, even if the braiding does rot. I have experienced no trouble of that nature. The author speaks of cables laid on the solid system. The great disadvantage of this system is that the work cannot be done very well in wet weather. Another disadvantage is that if the cable is being laid on a hillside, all the compound may collect in the valleys. Again, extra care must be taken to see that moisture does not get into the troughing. It is very difficult to get bitumen to adhere to earthenware in such a manner as to ensure that no moisture is present. In speaking of distributors the author says on page 342 that three single-core, lead-covered cables form the best arrangement from the point of view of continuity, because a fault can occur on one core without either of the others being affected, a rare occurrence on a multicore cable. If he means a fault on, say, the negative of a multicore cable, assuming the negative to be the intermediate conductor on a triple-concentric, perhaps he is correct; but, as Mr. Perryman said, it is possible to get a fault on the outer or earth conductor without necessarily having a fault on the intermediate or inner conductor. I do not, however, agree with Mr. Perryman that the moment a fault occurs on the outer or neutral conductor it is indicated on the station earth ammeter, as unless there is some leakage on either the positive or negative there should not be any reading. It is the usual practice on a triple-concentric system to make the inner conductor positive, the next conductor negative, and finally the outer conductor the neutral. The author advocates a reversal of this procedure, and there is something to be said for this arrangement—the neutral conductor, which carries the least current, is situated where it will not do much heating. At the same time, however, any water that may enter the cable will be driven by osmotic action towards the centre of the cable. I do not like the author's method of earthing the neutral bar at the station or substation. I suppose the switch is closed first on one graduated fuse, and, when that blows, on the next, until they are all blown. When this occurs the neutral is probably 240 volts above earth potential. It would be much better to tie the neutral down to earth by a resistance and shunt the resistance with a circuit breaker and ammeter, so arranged that when the current rises above the value

which is to be allowed with a direct earth connection, the circuit breaker opens and connects the neutral to earth through a limiting resistance. This will at any rate prevent the risk of a 480-volt shock. The author refers throughout the paper to tape armouring, but this is most unpleasant to work. For armouring, it is better to use steel wire. Armouring gives trouble wherever a service has to be taken off, because of the bonding.

Mr. F. C. Raphael: I should like to refer, as previous speakers have done, to the comparison between three single-core cables and triple-concentric cables on the basis of current-carrying capacity according to the figures of the Electrical Research Association. It should not appear in our *Journal*, in the convenient form of a table and uncontradicted, that the cost of feeders or even of distributors is practically the same whether they are three single cables, three-core cables, or triple-concentric cables, because these costs in Table 3, which come out practically the same, are based on greatly different ratings. This is made clear if we refer to the curves in Fig. 1. The table relates to a 500-ampere cable, and it will be seen that the comparison of cost is made between 0·25 sq. in. for three single-core cables, 0·3 sq. in. for the three-core cable, and 0·325 sq. in. for the triple-concentric cable. That is in the case of cables laid direct to the ground. In the case of cables drawn in, the sectional area taken is about 0·38 sq. in. for three single cables, 0·44 sq. in. for a three-core cable, and 0·51 sq. in. for a triple-concentric cable. If they are compared on those bases their prices may be about equal, but there are very few instances in which cables are rated according to their current-carrying capacity in the case of an ordinary three-wire system. They have to be rated on a fall-of-potential basis, and consequently no comparison can be correct unless it is based on the same sections of the cable, in which case the triple-concentric cable is at a very considerable advantage. This advantage compensates for certain inconveniences met with in connecting up. Then again, the author says that the total annual charge is the cost of the energy lost plus the capital charges on the cable. This is obvious. Kelvin's law, however, goes further and states that theoretically a given cable is most economical when that part of the capital charges which depends on the section of the conductor (not laying charges and so on) is equal to the cost of the energy lost. From a modern point of view the cost of that energy lost must not be taken at so many units at the average cost per unit, but at the cost at peak load, which is a very different matter. I am fully in agreement with the author on the question of vulcanized-bitumen cables. The solid system generally is, I think, getting rather out of date, except in those cases where it may be necessary to have particular protection against corrosion of the sheathing. The objection to wood troughing has already been referred to by a previous speaker, but vulcanized-bitumen cables laid in the old-fashioned iron troughing are even worse. The troughing is made up of comparatively short lengths of iron troughing, laid just inside one another without any bonding except the weight of the sections. When water penetrates into the duct or the insulation of the cable perishes, the current leaks first to the duct and thence, as the bonding is bad and the resistance high in consequence, to the first gas or water pipe with which the duct is in contact, and at this place an arc is set up. Within the past 18 months I have met with at least four cases of pipes of other services being damaged by that cause. Referring to the use of three single-core cables for distributors the author says that, should one of the live cables break down, the consumers connected to the other side will in no way be affected. Is that really his experience? Would not a breakdown of one of the outers cause a rise in pressure on the other outer? The graded-fuse method is quite impracticable; if the fuse blows, one of the outers will be at 480 volts above earth potential and the other outer at zero potential, and this dangerous condition will exist until the matter is put right. There is little to be said against the well-known system mentioned by a previous speaker of the circuit breaker and resistance in parallel, so that the resistance is inserted between the neutral and earth if a fault develops, but too much trust is placed in the earth ammeter. It may sometimes show faults in the neutral, but it cannot be relied upon to do so, and in any case the differences in the reading of the ammeter due to a fault in the neutral will not be so great as those due to a fault on one of the outers. It is by no means impossible, however, to make periodical tests which take into account the insulation of the neutral. I will go further and say that when the Electrical Advisers to the Board of Trade permitted neutrals to be earthed through ammeters they did not relieve the undertaker of the necessity of making the other periodical tests on the network which are laid down in the regulations. The special cable manufactured by Messrs. Callender's is interesting, but I do not know that it has been found very necessary in practice. I do not think that jointers experience any great difficulty in making joints on three-core cables when they are alive—in fact it is a matter of common knowledge that it is very often done. Much has been said as to the way in which concentric cable should be connected—whether the neutral should be the outer or the inner conductor of the cable. Personally, I prefer the neutral to be the outer concentric conductor for reasons which have already been stated. The proper place for the conductor at earth potential is obviously near the sheath. It is a protection, and it makes service connections much easier to carry out; if the neutral is made the middle conductor, both of the others have to be cut through for every service. I am not in favour of the looped-neutral method proposed by the author. I do not see that it will be of much assistance in finding faults, and if great care is not taken in removing the links many lamps will be burnt out. If the method is only intended to be used when the system is dead it is another matter, but in any case it does not seem to be quite a sound plan to bring the main cable in and out of the consumer's premises.

Mr. H. Brazil: I am entirely in agreement with the author when he stresses the importance of continuity of supply, and for this reason I am strongly in favour of single-core cables as against triple-concentric cables, not only because there is less likelihood of short-circuits,

but also because new consumers can be connected without cutting off old ones. In this connection I should like to describe a method which we employ to hasten the restoration of supply after a breakdown. In Fig. A three feeders, A, B and C are shown, connected by distributors in which are placed fuses F. Each feeder has an automatic circuit breaker set at 2 000 amperes, the fuses blowing at 500 amperes. The circuit breakers have no time-lag, and apart from the difficulty of fitting these to the existing breakers I do not favour them, because of the destructive effect on the mains and the possible formation of bitumen gas. Assume that a short-circuit comes on at X and that as a result all three feeder automatics come out, making the whole section dead. If we try to restore one of these feeders

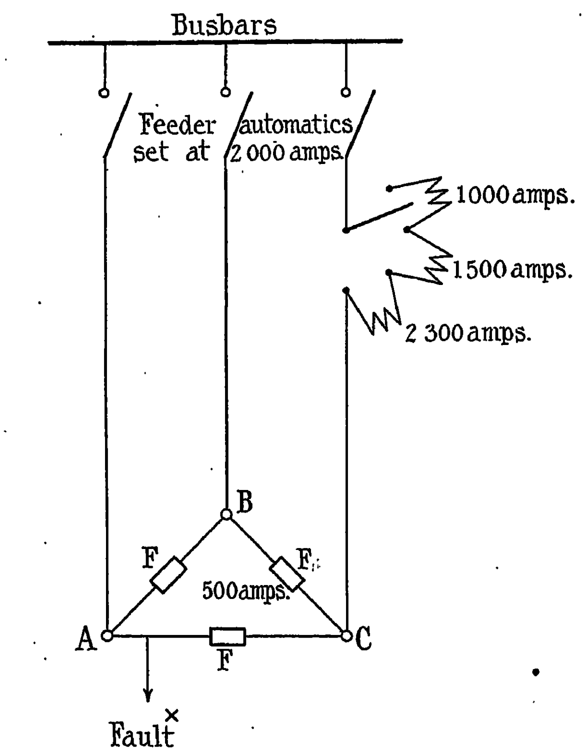

Fig. A.

by closing the circuit breaker, as there is a certain time-lag on the fuses the breaker may come out before the fuses blow, and it will not then be possible for the good feeder area to isolate itself. If, however, a feeder is made alive through the resistance shown, the current on the first or the second step will be sufficient to blow the fuses without causing the circuit breaker to open. When all the resistance is cut out, if the ammeter shows that the feeder is taking its normal load it can then be plugged back on to the bank. If the next feeder tried happens to be the one on whose area the fault is, there are no fuses to blow, and the current will go on rising, until on the third step it will be sufficient to trip the circuit breaker. The operator then knows that this is the faulty area and leaves it dead. The remaining feeders can then be put in in the same way, the faulty feeder area broken up, and sections of it switched on through the resistance in a similar manner. While on the question of quick restoration of supply, I should like to visualize what might be done in the future. Most feeders have three-core pilots run with them, and when one remembers what wonderful things can be done with two wires, in the way of starting up, synchronizing and shutting down rotary converters from a distance, it would appear to be quite simple for three wires to open and close switches controlling distributors situated in the feeder chambers. One can picture the mains engineer of the future sitting in an office with rows of push-buttons in front of him, and ringing the changes until he has, without the help of any jointers, isolated the fault to one section of the distributor.

Mr. J. S. Highfield: The author has invented an ingenious method of testing for faults by taking the two ends of a neutral conductor into a house or premises for the purpose of testing, but I feel that he may find he is in quite an illegal position if he enters a consumer's premises for the purpose of making tests on his own mains.

Mr. J. C. Wigham: I fully agree with previous speakers that in most cases one cannot lay down feeders or distributors, especially the latter, with reference to their heating. It is the voltage-drop that governs the size. This entirely alters the estimates of costs of the different systems given by the author. Further, it alters the costs more than is apparent at first sight, for while, by Table 1, a 0·25 sq. in. single cable carries only 10 per cent more than a three-core cable, yet a three-core cable to carry the same current as the 0·25 sq. in. single cable is 0·3 sq. in.—a 20 per cent increase—and an estimate based on cables of the same section would therefore differ very greatly from that based on heating. There is a point in connection with the use of three single cables instead of three-core cables. To put a three-wire service into a consumer's premises will necessitate three wiped lead joints. This will cost approximately three times as much and take three times as long as jointing a three-core cable. The looped-neutral service is suggested in the paper as a means of facilitating the detection of faults on cables while maintaining continuity of supply. Presumably the author means testing the main while alive, but the neutral wire must not be broken if the outers are alive. What, then, is the use of the proposal?

Mr. P. M. Baker: As I interpret his paper, the author bases the whole of his estimate of cable costs on the assumption that their loading (feeders in particular) is limited by considerations of temperature-rise. This premise is not, so far as my experience goes, justified. The loading of every feeder with which I have had to work has been limited by voltage-drop considerations and is considerably below the permissible temperature-rise for the material. Indeed, it seems to be clear that only on short feeders would it be economical to force the loading up to the temperature-rise limit in a three-wire system, especially one deriving its power from fuel. The effect of the temperature coefficient on the resistance of the cable has not been lost sight of in coming to this conclusion, and Kelvin's law must fix the loading. If this main premise fails, the author's whole case for the use of three separate single-core cables also fails and

the table of cable costs becomes misleading. Further, the whole cost of the cable and its connections must be considered and the service boxes used on three single-core cables must surely be larger, more expensive and involve more labour in installing than boxes for three-core or triple-concentric cables. Careful consideration of costs seems to show that, at any rate in a district in which I am interested, three-core cables drawn into earthenware ducts are the most practical economical propositions both for feeders and distributors as, on cable alone, there is a 10–12 per cent saving over triple-concentric cables of similar section, and reinstating charges are high—frequently as much as 50 per cent of the whole cost of the laid cable. There seems to be little difference in the cost of labour in jointing or making connections to triple-concentric and three-core cables (although jointers seem to prefer triple-concentric), but I cannot say how these costs would compare with those for similar work on three single-core cables.

[The author's reply to this discussion will be found on page 363.]

IRISH CENTRE (DUBLIN), AT DUBLIN, 8 JANUARY, 1925.

Mr. C. P. Coote-Cummins: The permissible current loading given in Table 1, which, I understand, is based upon the result of very exhaustive research, will, I think, be very useful for reference as it is in a very convenient form. The formula given on page 338 is also useful, and is very fully and clearly worked out in the Appendix. I am glad that the author emphasizes the necessity for considering the question of the time in which repairs can be executed. Unless repairs can be carried out in a reasonable time the cost will always be excessive, and this point is too often overlooked. The author appears to favour the laying of plain lead-covered cable in ducts, and Table 4 is a strong argument in support of this, but although I appreciate all that he says I think that the table is apt to be a little misleading, because it should obviously be read in conjunction with Table 3, and in comparing the lead-covered cable laid in ducts with the steel-tape-armoured cable laid direct the former system should be debited with the cost of interest and sinking fund on the increased expenditure during the period which elapses before the extension is required. When this is taken into account the conclusion arrived at might easily be the reverse of that indicated in Table 4 alone.

Mr. A. H. Watson: A distribution network of the sort described in this paper is, I think, more or less a branch of the industry in itself, and one in which an engineer might well specialize. On page 338 the author states that the question of the voltage-drop on such a cable is of only secondary importance, as any variation in the value of this drop can be counterbalanced by an equal variation in the busbar voltage, so maintaining a constant pressure at the nodal points. I do not agree with this; I should consider it bad practice to try to compensate for drop in pressure by varying the busbar voltage, as the loadings on the various feeders might not all be equal, with the result that if the busbar pressure were increased to maintain normal voltage at the nodal point where a cable is fully loaded, the lighter loaded cables would suffer accordingly. The permissible loadings given in Table 1 come as rather a surprise to me as the densities are very much higher than we have been used to in the past. For example, I notice that three single-core cables having a sectional area of 0·1 sq. in. can be loaded up to 298 amperes, which is equivalent to 2 980 amperes per sq. in., and even a 1 in. cable can be run at a density of 1 158 amperes per sq. in. With regard to Fig. 2, I doubt very much whether graduated fuses will work satisfactorily in practice, as it has been found that the behaviour of fuses varies so much according to their condition at the time and the contact at the fixing point.

Mr. P. A. Spalding: In my remarks, I propose to ignore triple-concentric and vulcanized-bitumen cables because I feel sure that no supply engineer would prefer such cables to three-core and paper-insulated cables unless under very exceptional circumstances. On page 337 the author says: "It should be noted that on a three-wire system the neutral conductor carries little or no current." I think, however, that the general experience is that the neutral wire carries considerable current, especially during peak-load periods. If the author has any grounds for expressing such an opinion, why does he provide for neutrals varying in size from 0·125 sq. in. to 0·2625 sq. in. in his figures of cost in Table 3? Clearly he does this because his figures are for standard cables which usually provide a neutral having one half of the sectional area of the outer cores. My own opinion in regard to these cables is that the cross-section of the neutral core need never exceed 25 per cent of that of the outers of a d.c. three-wire system. Anything larger than this is only a needless waste of capital. With a maximum continuous loading of 500 amperes the system would be very badly balanced if the current in the neutral exceeded 100 amperes. For even a moderately balanced system, the current in the neutral, under the loading conditions above referred to, would scarcely be 60 amperes. Therefore, if a 0·25 sq. in. outer will carry a maximum load of 500 amperes, what is the sense of having a 0·125 sq. in. neutral to carry only 60 amperes? On page 338 the author states: "Any variation in the value of this drop can be counterbalanced by an equal variation of the busbar voltage, so maintaining a constant pressure at the nodal points." Here again I must disagree, because, more often than not, regulation of the busbar voltage does not by any means ensure constant pressure at all the various feeding points of the distributing system. On the same page he says: "The use of three-core cables is limited to sizes up to 0·5 sq. in., cable manufacturers being unwilling to guarantee larger sizes." Presumably he implies a 0·5 in.–0·25 in.–0·5 in. cable, and, if so, such a heavy neutral as 0·25 sq. in. would be quite unnecessary, especially as he has already expressed the opinion that the neutral of a cable carries little or no current. For a feeder of this size a 0·1 sq. in. neutral should be ample.

Nine years ago I installed on our system two three-core feeders laid direct, each carrying 0·6 sq. in.–0·06 sq. in.–0·6 sq. in. cables, which have so far given excellent results. The comparatively small neutrals in these feeders have proved quite sufficient. In connection with methods of laying cables, the necessity for considering conduit at all only arises in cases where important cable-runs have to be made along roadways laid with sets on concrete. In such cases, as the author points out, the cost of opening up the road and reinstating the surfaces is a very expensive matter, and to avoid the repetition of such expense a draw-in conduit system may be found necessary. In all other cases, however, and especially where cables can be laid along the footpaths, paper-insulated, lead-covered and armoured cables laid direct are undoubtedly the cheapest to install and maintain. When comparing single-core with multicore cables, the author has made out an apparently strong case for the former, but I consider that his references to the latter type of cable are by no means complete. I am very surprised to find that no reference whatever is made in the paper to the all-important matter of bonding the cable sheathing. In my opinion most of the breakdown troubles on cables—e.g. those due to failure of the protective coverings caused by electrolysis, resulting in premature deterioration of the insulation—have been caused by want of electrical continuity throughout in the lead and armoured sheathings of these cables. I fail to see any special advantage in using "a cable in which is incorporated a thin copper testing-strip lightly insulated from the lead sheathing" (see page 343). Such a cable would have to be specially manufactured and would therefore be costly. Efficient bonding, so easily obtainable with multicore armoured cable, would answer very much the same purpose. I quite admit that single-core armoured cables laid direct provide certain advantages over multicore cables laid direct—when used as feeders—but the drawbacks that I see in the use of single-core cables for distributors are (1) the difficulty of maintaining complete and efficient bonding throughout each run, and of the system as a whole, of the lead and armoured sheathings of these cables; (2) the danger of damage to the neutral cables owing to the relatively small sizes of these in the distributing system, and (3) the extra cost of making service connections, further reference to which I shall make later. With three-wire supplies it is of the utmost importance that the neutral shall be maintained intact and in good order throughout the system, and this condition is rendered far more secure where multicore cables are used because here the neutral core is absolutely immune from any mechanical risk of fracture. The only damage that can affect the neutral of a three-core cable is an internal "dead short-circuit" on the cable itself, but this is such an extremely remote contingency that it need never be seriously taken into account when considering the merits of the respective systems. On page 344, under the heading of "Three-Core Cables," the author states: "The earthing of the neutral through a light fuse is unsuitable with such cables," but I think that the more correct word to use would be "disallowed." Three-core paper-insulated, lead-covered and armoured cables, all laid direct, were installed at Dundalk more than 12 years ago, the cables —with few exceptions—being laid along the footpaths. Although up to the present time upwards of 500 connections have been tapped off these cables, not a single fault has yet developed. Small local faults have, of course, occurred, such as temporary short-circuits or leakages on the street lamp standards and pole bracket fittings, caused by bad weather; these troubles are to be expected under such exposed connections. The worst of these occurrences is a "dead earth" of one or other of the outers due to a fusion of the connections at the neck of a street lamp standard; until such defect can be cleared the effect is a "dead short-circuit" between the outer and neutral (external, of course, to the distributor itself), but the current in such cases is always limited to about 25 amperes by the resistance inserted across the contacts of a circuit breaker between the neutral busbar and the main earth connection at the generating station. Normally this resistance is bridged, but when the leakage current exceeds a certain limit the breaker opens and leaves the resistance in circuit. Thus the neutral can never become open-circuited. On the question of relative cost, at the top of page 342 the author says: "The figures given in the latter table [No. 3] show that three single-core feeders are the cheapest to lay down." Table 3, however, gives the cost of the feeders only, and if the costs of opening up the ground and reinstating as specified in Table 4 are added, the inclusive cost of laying multicore cables is actually less than the corresponding cost of laying three single-core cables. The figures in Table 5 also clearly prove this. I do not question the author's figures in these tables as I presume they are taken from actual practice, but a summation of the figures in Tables 3 and 4 gives the following results as representing the total inclusive cost of laying:—

Type of roadway	3 single-core cables	Multicore cables
	£	£
Sets on concrete	369	366
Waterbound macadam ..	200	197

On the score of inital cost, therefore, I see no advantage in using single-core cables. There are no "exceptional reasons," as the author puts it, why supply undertakings adopt multicore cables for feeder work; it is simply on the grounds of economy, combined with efficiency, that such cable is preferred for both feeders and distributors. At the top of page 345 the author states: "Distributor cables . . . should, wherever possible, be laid under the pavement." I quite agree. It is a pity, however, that he did not include figures of cost under this heading in Table 4. No special difficulties are experienced in making service connections to multicore distributors, and the actual coupling-up is quite easily effected during the dinner-hour, usually between 1 and 2 p.m., when the particular length of cable that is being tapped can be isolated (at the

disconnection boxes) without any inconvenience whatever to existing consumers. The advantage of the single-core cable in respect of facilitating service connections is therefore by no means as evident as the author would have one believe by his remarks at the top of page 344 and again on page 347. I entirely disagree with him in regard to the relative cost of carrying out service connections, and it can easily be demonstrated that, of the two systems, the cost of making services off multicore cable is considerably the cheaper. I should be interested to know whether the author has had any experience of plain lead-covered cables laid in fibre conduit such as is (or was) manufactured by the Key Engineering Co. If so, perhaps he would state whether the lead sheathing of the cables remains as sound in such conduit as it does in the other conduit systems to which he refers in the paper.

[The author's reply to this discussion will be found on page 363.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 14 JANUARY, 1925.

Mr. H. W. Blades: The author in his conclusions recommends the use of lead-covered cables drawn into watertight earthenware conduits. I should like to ask if he has any special recommendations as to making the conduits watertight. It is practically impossible to do this by surrounding the conduits with concrete. One of the chief things to guard against in any conduit system is the accumulation of gas, and the only cure is an efficient system of ventilation of draw-in pits, joint pits and the conduits. Before leaving the question of conduits I should like to ask the author if he has experienced any trouble due to the movement or creeping of drawn-in lead-covered cables, this movement being due to the expansion and contraction of the cables. In this district there have been considerable difficulties due to this, but these have been overcome and it would be interesting to know if the author has experienced any such trouble. The author states that when the feeder can be laid in good soft ground so as to be free from electrolysis, single armoured cables should be suitable. I agree that the factor of electrolytic action must be seriously considered before the decision is made to lay armoured cables direct in the ground. In large cities the feeder cables sometimes not only run parallel with the tramway track but often cut across several tramway routes. There is thus the danger of heavy earth currents being shunted by the armouring of these cables. In Birmingham for the past 20 years it has been the practice for all high-tension lead-covered steel-wire-armoured cables to be laid solid with bitumen in earthenware troughing. In no case can I remember having noticed any signs of electrolytic trouble, and judging from the state of these cables both inwardly and outwardly they are in splendid condition and should last more than another 20 years. With regard to the author's proposal on page 343 for raising the potential of the neutral wire by means of a light copper fuse, I suppose this means entirely disconnecting the neutral from earth and then flashing one of the outers through a light fuse. This is not good practice, and such flashing should only be done through graduated resistances. One of the best-known maxims for the successful maintenance of any three-wire mains system is to keep the neutral wire healthy, and this can only be done by clearing off all incipient faults on the neutral wire. I presume that the author's suggestion for the looped-neutral services will necessitate the laying of a service cable of the same cross-sectional area as the distributor, in order that the carrying capacity of the distributor is not reduced. The service cable shown in Figs. 6 and 7 appears to be of much smaller cross-sectional area than the distributor. This would also seriously affect the accuracy in loop tests for the localization of faults. In an industrial or shopping area it might be difficult to obtain access to the consumer's premises for the purpose of disconnecting the special neutral link, and in a residential area it would be very difficult to accommodate a service cable of the 0·2 sq. in. triple-concentric type. It would therefore be advisable for any disconnecting of the neutral wire to be done in suitable boxes in the street, which would always be accessible day or night.

Mr. N. A. Allen: In making a comparison between single-core, three-core, and triple-concentric cables, it is only fair to do so on a basis of their performance, but it is suggested that it would have been of more use had the more practical method been adopted of comparing on a basis of the B.E.S.A. copper sizes instead of the intermediate sizes chosen, which, as a matter of fact, would never be used. Thus in the first case shown under "Cables laid solid" the areas would be 0·4, 0·5 and 0·6 sq. in., instead of 0·375, 0·44 and 0·525 sq. in. given in the paper. These comparisons have been made on a load of 500 amperes for a 0·25 sq. in. section, but for transmission purposes such a current would give an excessive voltage-drop. Even if a 1·0 sq. in. cable were taken instead of the 0·25 sq. in. chosen, and the drop limited to 20 volts in order to conform with the Commissioners' Regulations for a 500-volt system, the useful length of transmission would be limited to about ½ mile. With reference to the testing-strip type of single-core cable, this is a well-known principle for three-core high-tension cables where one strip does the work for the whole system, but the introduction of a single strip for each core would involve considerable expense out of proportion to the advantages gained. The question of electrolysis due to cables crossing the line of tramway systems has been raised by several speakers and in this connection it is of interest to remember that in the United States, tramway earth currents are regarded as a necessary evil and steps (sometimes very elaborate) are invariably taken to guard against damage to cables through this cause. These consist of the introduction of copper bonds or connecting sheaths and drainage wires at suitable points, these having been predetermined in an "Electrolysis Survey." A point of interest in connection with the use of three single-core armoured

cables, which is recommended in the conclusion of the paper under certain circumstances, is in connection with the possibility, which sometimes occurs, of having to change over from a d.c. system to an a.c. system while using the same cables. In this case, of course, three single cables could not be used, owing to their high inductance, whereas the change could be made without difficulty on the other types of cable.

Mr. R. H. Rawll: There are two points in the paper which interest me from the point of view of the behaviour of consumers' wiring under fault conditions on d.c. three-wire networks. The author describes a system in which the neutral wire is earthed through a fuse at the station. If an earth occurs on one of the outers this fuse will blow and the other outer will be raised or lowered to the full outer pressure, above or below earth as the case may be. It is, of course, true that the Electricity Commissioners require this state of affairs to be remedied within 24 hours, owing to the greater risk of shock to earth. I cannot, however, agree that apart from this consideration "it involves no danger to the electrical system." This may be true if the undertaking's mains only are included in this category, but due regard must also be taken of the condition of consumers' wiring, particularly old installations in wood casing, where in my own experience fires have occurred through this cause. It may, of course, be argued that consumers are responsible for the maintenance of their installations in good condition. But in how many cases is it done? We must face these facts, and distribution systems should be so designed and operated that the liability of excessive pressure to earth with its attendant risks is reduced to an absolute minimum, and if such a contingency should occur it should be remedied with all possible speed. The author also explains that when an undetected earth fault occurs on the neutral cable, should an earth subsequently develop on either of the outer cables a short-circuit will take place between these two faults, and will remain until one of the faults burns itself clear or is isolated by the operation of fuses. Such faults should, of course, be confined to the street mains, but it may be of interest if I describe certain conditions in which a consumer's wiring may take part in such an undesirable short-circuit. Where a consumer takes a considerable quantity of energy from the mains it is often necessary to balance the load as near as possible on either side of the neutral. In such cases three wires are sometimes run from a central distributing point in the premises to the service position, as in Fig. B. No fuse, of course, is permitted in the neutral wire, because any interruption of the neutral without the simultaneous opening of the other two wires would occasion a risk of an excessive pressure across the terminals of those consuming devices, the normal operating voltage of which is half that of the full pressure between the outer cables. Now the insulation of this neutral wire may break down and give rise to an earth fault of such small magnitude as to be undetected. Should an earth develop on one of the outer cables in the street in the vicinity, however, a short-circuit will occur between these two faults, as the author has described, the full current of which, in this case, will pass through the consumer's neutral wire. Owing to the fact that there is no fuse in this wire, this will continue until one of the faults burns itself clear, or the fuses in the network or at the station, which are usually of high capacity, come into operation. It is clear that in either case the results on the consumer's property may easily be disastrous. This is obviously very bad practice, but the number of wiring contractors who are unaware of this fact is surprising. The only safe method is to provide a three-pole circuit breaker with a trip coil on *each* pole; but since this is usually out of the question for a variety of reasons, the system shown in Fig. C should be adopted in all cases. Here the balancing of the load takes place at the service position and, in the event of the faults under consideration taking place, one of the fuses connected to the neutral service cable will blow and thus not only prevent further damage to the consumer's property whilst the other fault continues, but, by reason of the notification to the supply undertaking of the blown fuse, will give an indication of the location of that most elusive of all faults—the neutral fault.

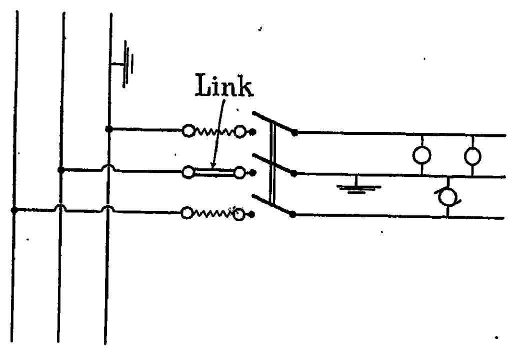

FIG. B.

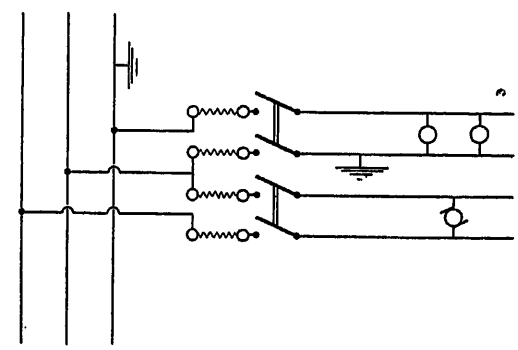

FIG. C.

Mr. A. E. Smith: The solid system of laying cables is recommended where the ground may contain corrosive substances, but the direct system if subsidence is likely to occur. Subsidence is continually taking place in certain mining districts in this vicinity, and the ground is frequently made up with ashes, which are notorious for causing corrosion. What system would the author recommend in such a case?

Mr. F. Forrest: A true comparison of the costs of

various types of distributor cable should combine the figures given in Tables 1 and 5, so as clearly to set out the fact that the cheaper lead-covered cables laid direct are also capable of carrying a higher current loading. I have combined in the Table A particulars with reference to three types of 0·2 sq. in. × 0·1 sq. in. × 0·2 sq. in. distributor cable laid under flagged pavement, using the figures given by the author.

It is evident from the table that the vulcanized-bitumen cable is an extremely expensive type, and where cost is a first consideration there seems to be no justification for its use. The author has not considered the use of plain lead-covered cable without any further armouring. Such cable, so long as it is laid in trenches on soil which has had the sharp stones sifted out of it, and afterwards covered with a protecting tile, should be perfectly satisfactory and still further cheapen the cost. In all cases the bonding of the lead should be very carefully done by means of wiped joints and the cables should be kept more than 3 ft. away from the nearest tramway rail, so as to avoid the possibility of electrolysis due to stray traction return currents. Pilot cables for use with low-tension feeders are really not justified. A more satisfactory means for indicating the feeder-point voltage can be obtained by carefully calibrating the feeder ammeter to read the feeder-point voltage after a careful test of the resistance of the feeder has been made. The looped-neutral system mentioned by the author seems to me to add danger without introducing any substantial benefit. It is quite conceivable that the neutral link box in a consumer's premises might be opened by an unauthorized person and the link removed; this might have disastrous consequences, and for this reason I cannot believe that it will ever be generally adopted.

Mr. H. S. Davidson: The author is strongly in favour of laying three single-core cables as distributing mains. I should be interested to know what type of box he uses when tapping services off such distributors, assuming his intention to be that the service cable should be a three-core cable, and that all the cables used are paper-insulated. Cast-iron boxes do not appear to be satisfactory and the only alternative is a lead "tee" box. This entails the making of seven plumbed joints and is a very tedious and costly method. Has the author considered this additional expense in preparing his paper?

Mr. W. E. Groves: In comparing three-core with single-core feeders it is not generally practicable to carry this comparison above a load rating of 1 000 amperes per sq. in., on account of prohibitive voltage-drop and boosting requirements; this current density represents a voltage-drop of approximately 40 volts on the outers of a feeder 800 yards in length. Full advantage therefore cannot be taken of the higher rating of single-core mains under 1 sq. in. in section. It is therefore, on the score of cost, advantageous to use three-core cables as far as manufacturing limits permit. The use of conduits should be avoided wherever possible, having due regard to street disturbances and the difficulty of accommodating a large number of cables on one route. It is also safer in the case of breakdown than bunching the cables in the ground if several feeders have to be laid close together. The making of trial holes is an obvious preliminary of conduit laying, but unfortunately does not always guarantee a clear course. Although concrete helps in this direction, stoneware conduits should never be regarded as being gas- or water-tight and it is necessary to provide for ventilation and drainage. They are not a safeguard against electrolysis, the evil effects of which are usually concentrated at the conduit joints. Flexibility for joints in conduit pits must be provided for where lead-covered cables are heavily loaded, otherwise expansion and contraction will crack the plumbs of the joints. Apart from their cost there is no sounder system of distributors than single-core paper-insulated vulcanized-bitumen cables run solid in stoneware troughing. They have an enormous advantage for rapid fault localization and repair. Their cost, however, puts them generally out of court for new networks, particularly where road widenings and disturbances are contemplated. In solid laying, care should be taken that troughs *are* filled under all conditions. Wooden troughs are inherently bad. Pilot cables on a three-wire system, apart from their cost, are most unsatisfactory on account of uncertain surface contacts of plug boards and fuses. Ammeters should be calibrated for voltage-drop; this, with a reasonable balance, is a sufficiently accurate measure. The outers of triple-concentric cables should be neutral and the insulation of the neutral should be maintained as on the outers. As in the case of feeders, comparison of costs of different types of distributors based on load ratings of cables is fallacious, very high current densities being generally inadmissible for reasonable "regulation," particularly with developments of heating and cooking supplies. Single-core armoured distributors appear attractive from the point of view of continuity of service, but it is surprising to learn that the service tees are not more costly than for three-core cables. Three-core cables need not be disconnected for jointing,

TABLE A.

Type of cable	Constant current loading	Price per 100 yards	Cost per yard per ampere
	amps.	£	d.
3 single lead-covered and armoured cables laid direct ..	438	120	0·66
3-core lead-covered and armoured cables laid direct ..	390	111	0·682
3 single vulcanized-bitumen cables laid solid	317	161	1·22

but it is risky to joint triple-concentric cables while they are alive. Fuses on distributors should be confined to interconnecting points of feeder networks. In Birmingham simple network boxes are used which permit of any distributor being isolated, solid-linked or fused as desired, the fittings being interchangeable. Tightening of three-core cables is more in evidence with shaped than with circular conductors. The extra cost of the larger-spaced cable would detract somewhat from the economical advantage of the standard cable. The use of conduits for distributors is obviously disadvantageous if frequent services are likely to be required.

[The author's reply to this discussion will be found on page 363.]

North-Western Centre, at Manchester, 20 January, 1925.

Mr. L. Romero: The author's main argument is that single-core cables are better than three-core cables for three-wire networks, solely because the results of faults on three-core cables are more serious than on single-core cables. I do not agree with that idea at all, as I think the author throughout the paper attaches too much importance to the fault question. In my view a modern network consisting of lead-covered armoured cables should have very few faults indeed whether the cable is single-core or three-core; and that view has been borne out by my experience. But certainly I would expect more faults on single-core than on three-core cables, first because far more faults occur on small cables than on large cables, owing to the difference in mechanical strength, and secondly because in the case of the single-core cable there is three times the length of cable to break down, and between two and three times the number of joints. In Salford the three-wire network originally consisted almost entirely of single cables, but about the end of the war, for reasons of economy, we began to use three-core armoured cables laid direct. Since then we have laid about 30 miles of three-core distributor cables and made some 2 000 joints on them. During all that time we have had exactly one fault on a small cable, the results of which were not at all serious. I have also had experience extending over a longer period with concentric cables on the a.c. system, and in this case also faults are of extremely rare occurrence. I estimate that the cost of a single-core network, including services, would be about 12 to 15 per cent higher than that of a three-core network. I feel sure that a similar freedom from faults on three-core networks is experienced in many other undertakings, and I hope that some other mains engineers will give us the benefit of their experience. There is one other disadvantage of putting down single-core armoured cable for a d.c. network which appeals very strongly to me, viz. that it makes it impossible to change over the network to alternating current. We have recently changed over portions of our d.c. network to single-phase three-wire, without re-laying a single yard of cable, and we have other schemes in hand. Of course these schemes would be impossible if the network consisted of single-core armoured cable. Table 1 seems to me very misleading in that the maximum current allowed for the larger cables is much too high. A 1 sq. in. single cable in a nest of conduits cannot be loaded safely above 750 amperes, which is the current allowed by the author for a 0·5 sq. in. cable. Above this limit crystallization of the lead, due to expansion and contraction of the cable, sets in. I agree with the author that single-core cables are to be preferred for feeders, because nothing smaller than 1 sq. in. cable is of much use for feeders on low-pressure d.c. networks, unless they are very small networks indeed. If one did use 0·5 or 0·25 sq. in. feeders, as the author seems to suggest, I am of opinion that three-core cables would be better. The author seems to think that pressure-drops in feeders are of no importance. I do not agree with him. In practice it is usually impossible to keep all the feeding points at the same pressure, due to differences in length and loading of the feeders. I find that a 0·5 sq. in. feeder, 1 000 yards long, loaded to 748 amperes—the figure given in Table 1 for 0·5 sq. in. single-core cable—would give a pressure-drop of nearly 20 per cent on a 440-volt system. Drops of this order must be considered excessive from the points of view of both pressure regulation and losses. I think that pilot cables should be dispensed with altogether if possible. I believe this could be done if instrument makers would only set themselves to design a voltmeter which would indicate the busbar voltage less the feeder drop. If they would do this, I believe that most undertakings would install these voltmeters and scrap their pilots. An instrument is required with three coils instead of one; one coil for the busbar voltage, one for the outer voltage-drop, and one for the neutral voltage-drop. An instrument of this type would give a direct reading of the voltage at the far end of the feeder, the pilots being dispensed with altogether. As an alternative I should like to suggest that feeder ammeters should have their scales marked in voltage-drop in the feeder on one side and in amperes on the other side. The switchboard attendant could then easily calculate the voltage at the feeding point. Both these suggestions seem so simple that quite possibly they have already been carried out, though I have no information on the point. The author's suggestion for cable with a testing strip to facilitate the location of faults seems to me totally unnecessary for the reasons already given. The author's scheme for looped-neutral services on vulcanized-bitumen triple-concentric distributors is ingenious, but in my opinion the money would be better spent in replacing the distributors with three-core lead-covered cables. If there are so many faults as to make it necessary to carry out all these expensive precautions, I think that the cables should be relaid altogether. Although I do not believe that it ever pays to run additional feeders, it has nevertheless to be done because the existing feeders become overloaded and because satisfactory pressure must be maintained. I do not take exception to the author's figures in Table 5 but I should like to ask him whether

he has included in the cost of the lead-covered steel-tape-armoured cables, laid direct, the extra cost for the transport and labour with three cables instead of one, and the extra cost for protective boards or tiles. In regard to the author's statement that trouble has been experienced due to the straining of the cores of three-core cables when opening them out for making service joints, I have not experienced any trouble of that sort and I do not think it is likely to occur on properly designed cables.

Mr. A. J. Lovell: Several points the author has not mentioned may appreciably alter the comparison of costs of different systems. In the case of cables laid direct, the ease with which holes may be bored with one of the hydraulic borers on the market, and cables drawn in across busy thoroughfares, and the resulting saving in excavation, heading, driving and reinstatement, would materially alter the estimates. For example, the first 320 yards so laid in Manchester showed a saving of £339, or about £1 a yard. The author does not mention the use of pass-through boxes on duct lines, by which levels may be altered to avoid pipes, and so avoid laying the total length at any great depth. This is an important point in large cities where pipes are numerous. I do not consider that the concreting of earthenware ducts laid at depths of 2 ft. 6 in. to 3 ft. in the roadway is necessary. Reinforced concrete slabs placed above are a convenient protection against picks, though such protection is not generally necessary. On page 340 the author mentions watertight conduits. In my experience I have never known of a length of duct line in wet soil which might reasonaby be called water-tight. Because of this percolation of water and the risk of acid entering with it, I favour the drawing-in of armoured, lead-covered, jute-served cable. The expansion and contraction, and consequent creeping of cables, calls for secure anchoring at every box, and frequent inspection, so that maintenance costs become a considerable item. Duct lines can only be profitably used in congested areas where frequent street excavations must be avoided. On page 340 the author says: "Modern practice is to use earthenware troughs . . . because better joints are possible between two troughs." Personally I consider that if there is any feature that condemns earthenware troughing it is the joints, unless the author is referring to the use of lock joints. Several have been devised, but none, I believe, has been sufficiently tested. Though wood troughing has many serious disadvantages there is much to be said for its mechanical strength when joints are made to butt and are surrounded with a cast-iron trough box with cover bolted down, as used in Manchester. I have known a subsidence to take place, and a length of troughing containing a joint to support the ground above without buckling over a span of 10 ft. This could not be said of an earthenware trough. Intimately connected with the type of trough is the question of depths. In Table 6 the depth under flagged pavement is given as 1 ft. 3 in. I doubt whether the local authority would permit this depth, apart from the difficulty of avoiding gas services and the risk of fencing pins at some later date piercing the troughing so near the surface. As no general rule can be laid down for mains work—no two jobs being alike—each must be dealt with on its own merits. More trouble is caused by vibration than by crushing at ordinary depths, and the nature of the road traffic should be one of the deciding factors. Generally speaking, cables laid solid should be deeper than those laid direct, owing to damage at troughing joints due to vibration. I do not agree that troughing and service boxes will sink when the ground is filled in. If settlement does take place it is due to bad workmanship. With regard to triple-concentric cables, theoretically, from the point of view of heating, the neutral cable should be the inner conductor, as it carries the least current, but often the practical requirements outweigh the theoretical advantages, and in this case the outer is usually made the smallest conductor for increased flexibility. I do not agree with the author that this is a disadvantage, as he points out on page 345, where he says that in the event of the cable being damaged by a pick no indication would be perceived at the station for some months. If no network insulation resistance test is ever taken at the station I can quite believe it, but I do not think that any mains engineer would rely merely on the earth ammeter readings. Frequent tests should be taken at the station, and the resulting figure in ohms will at once show up a neutral fault, when steps can be taken to locate it. That the outer conductor is the neutral is, in fact, a decided advantage, for a neutral fault can be located with much less risk of interruption of supply. On page 337 the author says that the neutral conductor on a three-wire network carries little or no current, and Table 1 shows that the sectional area of the neutral is half that of the outers. In these days of cookers, radiators, and domestic appliances, the diversity of the load, which is not under the control of the engineer who makes his balance sheets, may give rise at times to considerable out-of-balance current in sections of the neutral. I have known the current in the neutral on a normally balanced section to be 150 per cent in excess on a cold and changeable day, due to the varied use of radiators and lighting. Again, if the supply to one outer be interrupted the neutral will carry the whole current of the other outer. In large modern networks it is desirable to run neutrals of the same sectional area as the outers; the cost of the increased copper is partly offset by the reduced pressure-drop and the immunity from damage to the neutral caused by excessive overloading under short-circuit conditions. I agree with the author that the disadvantages of triple-concentric cable rule it out for use on modern networks. I do not, however, agree that it is necessary to make the cable dead for jointing, either on concentric or three-core cables; my experience of jointing is that if carried out by well-trained jointers the joints are as reliable as, if not more reliable than, the cable itself. The best type of cable to use is undoubtedly that which gives the surest continuity of supply. In Manchester there is a very large amount of three-core and four-core distributors. Over 10 000 joints are made annually, about 75 per cent being on three-core and four-core cable; and so far I have not known one fault to occur. Jointing of all kinds is done while the cables are alive, and with well-trained jointers and careful

supervision no difficulties are experienced. Thus there is no interruption to supply. This, I think, proves the case for a three-core network. I agree with the author in so far as where distributors larger than 0·5 sq. in. are necessary, a single-conductor continuous lead system is preferable, and full advantage can be taken of the reduced current density permissible in the larger cable.

Mr. H. M. Crellin: It is by no means agreed that the current densities shown in Table 1 are acceptable as safe figures. The densities given imply that the final temperature of the cables will be of the order of 150° to 160° F.—possibly more in some situations—and this, in my opinion, is too high. The effect of these high temperatures on the voltage-drop should not be overlooked when working out sizes of cable conductors. The drop at the temperatures I have mentioned will be 20 to 25 per cent more than that calculated on the copper resistance figures given in the B.E.S.A. tables for 60° F. Allowing for this, the voltage-drop for some of the sizes and densities indicated in Table 1 will be as much as 18 volts per 100-yard run. I do not know of any undertaking which could endure this drop on either feeders or distributors. On page 338 the author says: "The choice of the size of cable for a feeder is more an economic than an electrical problem." I think that in 99 per cent of the schemes I have had to work out the sizes have been entirely decided by the question of the voltage-drop. Speaking generally I should say that the advantage of single-core cables would be most marked in the case of feeders on large undertakings, where heavy currents have to be provided for, the advantage of large single-core cables being in the much greater lengths of cable that can be conveniently handled, compared with the comparatively much shorter lengths of three-core cable of the same sectional area per core. The author refers to the use of a "copper testing strip" on single-core cables. From the point of view of cost I doubt whether it would be considered a practical proposition in most cases, but if it is a practical proposition for single-core cables I should say it is far more so for three-core low-pressure cables. The extra cost, of course, is due to the cost of the copper test sheath and the comparatively thin insulation between it and the lead sheath. That extra is a far bigger item on a small single-core cable than on a large three-core cable. While the cost might be about 30 per cent on a single-core cable, it would be less than half that on a three-core cable. With reference to the statement attributing trouble on three-core distributors to the straining of the cores when they are wedged apart for jointing on services, a certain borough electrical engineer some 20 years ago always ordered three-core cables for low-tension work to be made having the same thickness of dielectric as on his 6 000-volt cables, stating that it paid to have the increased thickness on account of the greater facility for jointing services and greatly reduced risk of damaging the cores by straining them apart. On page 344 the author discusses the disadvantages of triple-concentric cables, referring in particular to the smaller sizes, and in this matter I am in full agreement with him. One of the greatest disadvantages of that type of cable is its mechanical weakness. To give the requisite area, the intermediate and outer conductors are composed of a comparatively large number of fine wires (or thin strips) over which are placed the (comparatively) heavy thicknesses of dielectric, the final result being a cable containing a large amount of insulating material and very little copper—a not at all desirable type compared with the equivalent three-core cable.

Mr. A. B. Mallinson: I am rather surprised to find that the author has given no indication as to the prices of copper and lead at the time at which he took out the costs. That, I think, is a very important factor. The price of lead, for instance, has risen nearly 50 per cent during the past year. The value for reference purposes of the tables given in the paper would be greatly increased if this information were added.

Mr. H. C. Lamb: On page 343 the author recommends that the potential of the neutral wire should be periodically raised to that of the outer, with the object of detecting faults. This was tried in Manchester some years ago, but had to be given up because it was followed by many faults on installations, and, in one or two cases, I believe, fires actually broke out as a result of these faults. On page 345 the author says that there is no particular advantage in laying distributors in ducts. In large towns, I think, there is often a considerable advantage, because (particularly in crowded streets, such as Market-street and Piccadilly in Manchester) the spaces under the footpaths are full, and distributors frequently have to be laid in the roadways. The author says that concrete is a very good protection against men with picks. I agree that it should be so, but our experience in Manchester has been that navvies break through it.

[The author's reply to this discussion will be found on page 363.]

Scottish Centre, at Glasgow, 10 February, 1925.

Mr. J. Henderson: There can be no doubt that the best system of laying for feeders is the draw-in system, more especially for a growing load. For a dense city area my preference is for three-core distributors, lead-covered and laid solid. To lay cables solid appears to be the best system in such a case, and direct laying could not be considered. With large and congested tramway systems electrolysis would be almost a certainty and trouble would ensue. The usual system nowadays is to adopt alternating current with four-core cables laid direct in outlying districts. For services the cheapest method consistent with reliability should be used and twin, lead-covered armoured cables appear to give the cheapest service. I certainly disagree with the author that it is necessary to make a triple-concentric cable dead to give a service, and I do not think it is ever done. The "looped neutral" idea looks very attractive, but it may lead to more trouble than it is

worth, and it looks probable that most of the faults might be located in the joint fittings. The author is scarcely consistent in his comparison of costs. He has allowed for the current-carrying capacity of the cables in his tabulations, but on page 346 he states that this can scarcely be taken advantage of due to the permissible voltage-drop. Likewise, mains engineers will be influenced in the steps taken to give further supply to an outlying district, not by the author's equations given in the Appendix but by the permissible voltage-drop and the complaints of consumers.

Mr. C. E. Shaw: I am not in agreement with the author's suggestion relative to triple-concentric cables, viz. that the outer conductor of the cable should be made positive instead of neutral, as is the usual practice. Practically all cable faults, and a large percentage of joint-box faults occur, in the first place, as neutral faults, which may exist for some time before the cable actually goes out of commission. A study of the earth recorder chart will often, but not always, reveal the presence of a neutral fault, and if prompt measures are taken it is possible to locate and repair the fault before it actually causes an interruption of supply. If the positive pole were to form the outer conductor, it is obvious that a fault would develop so quickly that the cable would be interrupted before the fault could be located.

Mr. A. McLennan: I agree with Mr. Henderson that it is quite unnecessary to make cables dead when jointing. This does not strengthen the argument in favour of three-core cables.

Mr. D. Berry: The problems in connection with cable laying and distribution vary considerably with different undertakings. Local conditions and size of supply system affect the point of view, and one hesitates before stating definitely that this or that system or method is the best. I propose to consider the paper mainly from the point of view of the application of the methods favoured by him to a distribution system in a large city such as Glasgow. He treats first of feeders and states that the voltage-drop is only of secondary importance. This may be so where multiple busbars are used in the generating stations, but in cases where one busbar voltage only is maintained the voltage-drop is of primary importance. With regard to the formula on page 338, I think that it will generally be found advisable to select the suitable size of feeder mainly on an empirical basis, and to err on the large side. The author indicates a preference for single-core cables but I do not share his enthusiasm for these against multicore or triple-concentric cables. He admits that space is a determining factor in a consideration of the type of cable to use, and in a large city where almost every inch in the streets and pavements is valuable the claims for triple-concentric feeders are strong. This is especially so when 1·0 sq. in. feeders are used, as three-core cables, as explained by the author, are inadmissible. For instance, a section pillar with three feeder ends—one feeder and one looping in—and 10 distributors would require 39 single cables. I think that the author claims too much for the draw-in system for feeder laying. There may be small zones in which, for special reasons, it is advisable to lay ducts, but as a rule the exact route of further feeders is uncertain, and if ducts are laid they may never be used. Fortunately, feeder faults in Glasgow have not been numerous, but in any case it is by no means certain that the average cost of locating, drawing-out and replacing a length between manholes will be less than that in faults on feeders laid solid. I agree with the author as to single bitumen cables, partly, among other reasons, for the one he gives, viz. the danger of damage resulting while the fault is in its incipient stage. His contention that the choice of the type of distributor cable is very rarely affected by the maximum carrying capacity does not hold if the distributors are short, as is generally the case in large cities, where voltage-drop is, as a rule, of secondary importance to current-carrying capacity. Three-core lead-covered cables laid direct or triple-concentric cables laid solid (depending on circumstances) will, I think, be found to be more satisfactory generally than single lead cables. Direct laying is the fashion, but while the long life of a direct laid cable has not yet been proved, its advantages in speed of laying and low cost are very tempting to the mains engineer. The author's objections to the danger of jointing with triple-concentric cables alive is probably based on experience with the use of link fittings as shown on Figs. 6 and 7. With shell-type fittings, triple-concentric joints are made with the cable alive every day, and I have known jointers more ready to work with triple-concentric cables alive than with the tightly formed three-core or four-core cable in vogue. The author's suggestion of a looped-in neutral for triple-concentric distributors will not always be so satisfactory as he suggests. Apart from the introduction of a possibly dangerous break in the neutral, the localization of a fault may not be clearly defined if intervening consumers' switches are closed, and it may be that one cannot obtain access to the premises with the looped-in neutral joint when it is desired.

Mr. H. M. Stronach: The author deals with single-core, three-core and triple-concentric cables for feeders, distributors and services on a maximum-current basis and arrives at what he considers to be the ideal combination, viz. single lead-covered cables throughout. Every city has its own special circumstances, but to ignore the length of feeders by running at different pressures to overcome voltage-drop, allowing for voltage-drop in distributors, and providing ducts for feeders, suggests one station, the load going for some length in one direction, the feeders being short and the distributors comparatively long. In a town with 50 000–60 000 kW of d.c. load supplied by a number of substations from 2 000 to 6 000 kW capacity, the duplication of rotary converters, busbars, etc., in each substation to allow two or more pressures to be supplied to feeders would make this impossible. With 1 sq. in. feeders running at a fixed pressure with a maximum load of 750 to 800 amperes, the effective length is 400 to 500 yards, and in these circumstances single cables laid in any manner are more expensive than triple-concentric cable. The question of space also arises. The question of ducts is a very serious one. The author mentions the shifting of load, and no more expensive job can be conceived than laying ducts and then finding that they either

cannot be used at all or can only be used by increasing the length of cable necessary. Distributors are generally comparatively short, and the load starts to drop immediately they leave the feeding point. Therefore if the pressure is maintained at the feeding point, voltage-drop can be ignored except in exceptional cases. The author condemns triple-concentric network. Glasgow has roughly 400 miles of such network, both lead-covered cables and vulcanized-bitumen cables laid solid. Probably half of it was laid 20 to 25 years ago, and there is no reason to condemn it. Lead-covered paper-insulated triple-concentric network laid 25 years ago is as good as, and even better than, any cable laid to-day. Vulcanized-bitumen cable can be found in the same condition, although personally I do not think that its life will be as long as that of lead-covered cable. Perhaps the link fittings shown in Figs. 6 and 7 account for the author's dislike of it. With modern shell fittings and about 60 to 70 per cent of all joints made alive, comparatively little trouble is experienced. A few years ago three-core distributors were adopted, but it was the cost of joints and not their failure that brought this about. The three-core standard cable shown in Fig. 4 was tried, but the difficulty in jointing mentioned was very serious, and I know of cases where the cores had to be cut to overcome this. The three-core cable with dummy was, I think, specially made for Glasgow to overcome this difficulty, but it is a lead-covered cable and not a vulcanized-bitumen cable. The success or otherwise of a lead-covered system rests entirely with the bonding. With three-wire network and three-wire services this means nine bonds against three with multicore cable. It is questionable whether the cost of three separate joint boxes with single-core cables and extra reinstatement, giving increased reliability, against that of one box for multicore cable, can be justified. The protection of service cables passing through walls is very important, and I agree that special precautions are necessary. The author says that the risk of fire and damage to other people's services is less with single cables than with triple-concentric or multicore cables, but my experience is decidedly the reverse. The looped neutral described in Figs. 7 and 8 might possibly be useful, but on 0·15 sq. in. and 0·25 sq. in. triple-concentric or multicore networks necessarily fused to carry full load, 75 per cent of faults are burn-outs and are not so easily bridged as suggested. I think that a strong case can be made out for triple-concentric lead-covered feeders laid solid, three-core lead-covered network laid solid in busy and heavily loaded streets, and lead-covered and armoured cable laid direct in outskirts, with three-core and twin lead-covered and armoured services laid direct, the earth test to be taken regularly, positive and negative alternately every week.

Mr. R. B. Mitchell: The question which has been raised as to the desirability of triple-concentric cables affects Glasgow very materially. As Mr. Stronach has said, there are hundreds of miles of this type of cable laid in this city. It has been used for 25 years with satisfaction, and in view of the large sizes and the congested state of the subsoil in the streets it is the only method possible. For low-tension work I do not consider ducts to be either necessary or desirable. The feeders from substations, for instance, have to take divergent routes, and in very few cases would any saving be made. The author has not mentioned the number of ducts that he would be inclined to lay in one trench. If he had a considerable number, say 12, then the question of temperature-rise on the cables laid in the centre of the nest is very serious. It may not be so bad for low-tension cable, with which the author deals exclusively, but with high-tension cables it would be a serious difficulty and I believe that in America it has already been noticed that the cables in the centre of a nest of ducts suffer very seriously from temperature increase, even with ordinary loads. On page 339 the author refers to a cable breakdown, and indicates a preference for the duct system because the cable may be most cheaply and easily repaired. Evidently he means the total breakdown of the whole length of cable, but this does not take place with present-day cable. It might have done so when insulating materials, the permanency of which was a rather doubtful quality, were used, but now a cable will break down probably at one point only and, if laid on the direct or solid system, can be repaired at that point without the rest of the cable being interfered with in any way. On page 338 the author refers to the liability of nodal points moving. We have had no experience of that in Glasgow. The load at any of the feeding points has always increased, and what had to be done to reduce the load on adjacent feeders was to lay another feeder to an intermediate point between the two feeders, so as to relieve both. When referring to the solid system, the author has always mentioned bitumen as being used as the trough filling. We have not used bitumen in Glasgow for many years, but have used instead a gasworks pitch reinforced with whin dust, which I think has proved itself equal in every respect to bitumen as a filling material and is also very much cheaper. This filling has been proved to be absolutely watertight, and also to have a very good heat-conducting capacity, which is a decided advantage with a filling material. Another very great advantage is that if ever the troughing breaks away or decays, this reinforced filling will retain its shape round the cable without the support of the trough. The author has referred to the fusing of networks. I agree that this is very desirable, but is it not also desirable to go as far as possible in that direction and isolate particular feeders on particular sections of network so that the minimum number of fuses will act on faults, or will be affected when faults occur at any one point?

Mr. R. M. Freer: I certainly agree with previous speakers regarding the looped neutral. On page 340 the author mentions the use of earthenware troughing to protect the cable from acids. I can vouch for the effectiveness of that method. We have in one particular spot a vulcanized-bitumen cable laid solid in earthenware troughing passing alongside acid boilers, where it is more the practice than otherwise to have spills. The cable has been working for 9 or 10 years and its insulation resistance is still high.

[The author's reply to this discussion will be found on page 363.]

THE AUTHOR'S REPLY TO THE DISCUSSIONS AT LONDON, DUBLIN, BIRMINGHAM, MANCHESTER AND GLASGOW.

Mr. H. W. Taylor (*in reply*): In attempting to compare the various type of systems used in three-wire direct-current networks, it should not be forgotten that the enormous differences in local conditions make it impossible to form any definite conclusions that will be applicable to every case. The most that can be hoped for is to arrive at some conclusions of common, though by no means universal, application. Even such conclusions when obtained as the result of individual observation are necessarily coloured by the conditions prevailing on the systems where the experience has been gained. This fact is clearly discernible in the discussion. Whilst reading the paper before the various Centres, I have been greatly impressed by the conflicting opinions of engineers in different localities. We are all, perhaps, inclined to become unduly prejudiced in favour of or against a system with which we are most conversant.

A point that I should like to emphasize here is that the paper was written from the point of view of an undertaking of medium size. It is therefore a little unfortunate, though perhaps unavoidable, that most of those who have taken part in the discussion are connected with some of the largest undertakings in the country, with the result that many of their remarks are due to their experience of the exceptional conditions prevailing in very large cities. To these I would suggest that, though many of the recommendations in the paper are not applicable to their cases, they may be to the more numerous smaller undertakings.

There are one or two points that have given rise to more general adverse criticism, with which I will deal before proceeding to reply to the remarks of individual speakers.

Basis of comparison of feeders.—The choice of current-carrying capacity as a basis of comparison of feeders is disapproved because the voltage-drops on feeders of different cross-sectional areas are not the same and that these drops, on long feeders loaded up to the rating shown in Table 1, are too high. Let me first of all make it quite clear that the results shown in Table 3 are only intended to be a basis of comparison, and that "wherever they can be adopted" the sizes indicated are permissible. Local conditions will always be the deciding factors in the choice of the size of a feeder. As it is impossible to introduce this factor in attempting to form a general conclusion, the most that can be given is a comparison, based on some property common to all, that will provide a starting point from which the true value of a feeder can be assessed when local conditions compel modifications to be made.

I do not altogether subscribe to the opinion of several speakers that voltage-drop provides a better basis for this purpose than does the one I selected. Equal voltage-drops entail the use of cables of the same size, thus introducing another variable quantity that may be called the "earning capacity" of the cable, which would have to be considered together with the respective costs before a true comparison could be made. For instance, a single-core cable loaded as it would be to a lower percentage of its maximum rating is a much greater asset to a network, from the points of view of long life and reserve in case of emergency, than a triple-concentric cable of the same section will be. This latter point may be of considerable importance in a medium-size network with comparatively few feeders, where the failure of one may throw considerable additional load on another. It was to preserve this true basis that I chose to compare those sizes of cables that would, under favourable circumstances, give the same results, instead of taking the nearest standard sizes, and I stated at the time that such non-standard sizes would not of course be used in practice.

This voltage-drop basis would also make it impossible to take advantage of the higher permissible loading of the single-core cable which sometimes, in the case of short feeders, is very useful in obviating the necessity of boosting arrangements for the long ones. I am thus of the opinion that, bearing in mind its imperfections and limitations when making comparisons, current-carrying capacity forms a convenient basis.

As regards the current loadings shown in Table 1 being too high, I would point out that these are the maximum permissible loadings that the cable will stand if called upon, and it is not suggested that cables should normally be loaded up to such values. This, however, does not impair their usefulness as a basis of comparison.

Looped-neutral services.—Some little confusion seems to prevail as to the advantages of this type of service and the conditions under which it is used. The great majority of faults on a triple-concentric distributor, being due to external causes, occur between the outer and middle cores, i.e. between the neutral and one live core, and the cable has to be isolated until the fault has been repaired. For locating faults on distributors, ordinary tests are often rendered unreliable owing to the disturbing influence of the numerous service connections. The cable has then to be exposed and tested after cutting the neutral, perhaps in several places, before the fault is located. To have a convenient method immediately accessible of breaking the neutral, means that a fault can be located more quickly and with less cost, particularly when the roadway is of a type that is expensive to excavate and reinstate. It should be noted that during these operations the cable, contrary to Mr. Wigham's presumption, is quite dead, so that no harmful results would be obtained by breaking the neutral at more than one point, though it is usual to have only one such break whilst testing. Having located the fault between two looped services the neutral links are withdrawn at these points. If the distributor is fed from both ends it then becomes possible to make the inner cores alive with their own polarity, thus giving the correct supply to all the consumers with the exception of those tapped off the faulty length of neutral. Care should be taken to withdraw the main fuses of these latter few consumers to prevent the possibility of any of them having a pressure of 480 volts across their installations owing to this length of neutral being

alive, usually from the middle core. Should the fault be a short-circuit between all three cores, by making both inner cores alive from, say, the positive side at one end, the supply is again restored to the same consumers as before, but the meters of those connected to the negative side will be reversed. This will not result in a serious loss to the supply undertaking as such conditions will not usually last for any appreciable time; but if the premises supplied are mainly shops and business premises, as will generally be the case where these services are adopted, such a temporary supply may prevent considerable loss and certainly much inconvenience being caused to these consumers. This type of service is of little practical value on a lead-covered cable, its usefulness being confined to the triple-concentric vulcanized-bitumen cable laid solid, the earth leakages on which, under the above conditions, are usually small.

With regard to Mr. J. S. Highfield's suggestion of illegality, I would point out that no testing is done on consumers' premises; but, notwithstanding this, I think that in the Provisional Orders of most undertakings, authority will be found for their " . . . responsible agents to enter upon the premises of the consumers at all times, for the purpose of inspecting, repairing or testing any cables or apparatus installed therein." Quite apart from this authority, my experience is that consumers, particularly shop-keepers, are only too anxious to afford any assistance within their power in order to expedite the restoration of their supply. None of the possible consequences feared by Mr. Forrest and others, have been experienced with the many services of this type that have been laid by the undertaking with which I am connected, since this paper was first written. The depreciatory remarks of several speakers on this question are, I think, due partly to them not having quite grasped the essential details and to being unfamiliar with its working in actual practice.

Mr. Ratcliff raises many interesting points in the course of his remarks. He advocates the use of a neutral conductor for a distributor of the same size as the outer, and I can appreciate that this may be justifiable in a large city where there may be a considerable heating load which renders a reasonable balance difficult to obtain. I doubt, however, whether this policy could be proved economically sound for general practice, as the results of any tests that I have taken indicate the usual size of neutral to be sufficient. If steel tubes are adopted in the place of earthenware conduits it will be necessary to use an armoured cable where there is any roadway vibration, as the latter will quickly wear away unprotected lead sheathing.

I certainly agree with several speakers that it is necessary to bond and earth the lead sheathing of a lead-covered cable. It was perhaps because this is such a common practice that I made but incidental reference to it in the paper. With regard to armouring, I have been unable as yet to form any definite conclusion from my own experience, but I think that some method of bonding it to the lead sheathing as shown in Fig. D is beneficial, in spite of the fact that on some networks, where no attempt is made to do this, no resultant trouble is experienced.

I have never seen a testing strip (as described in the paper) applied to a low-tension network, but having found it beneficial in the case of e.h.t. cables I made reference to it, in the hope that some useful points in connection with it might arise during the discussion. I agree with Mr. Perryman that a triple-concentric distributor has to be isolated immediately under fault conditions, but this being the case a testing strip on such a cable would be of no advantage, as its suggested use was to enable a fault to be located without the cable itself having to be disconnected. I am inclined to agree with Mr. Crellin and others that the cost of such a strip on low-tension networks would render it too expensive a luxury. I am surprised that in arriving at his conclusion of the superiority of the triple-concentric cable Mr. Perryman makes no reference to the three-core cable, which really is its chief rival.

Mr. Ambrose seems somehow to have become a little confused with regard to my statement that a three-core cable is only manufactured in sizes up to 0·5 square inch.

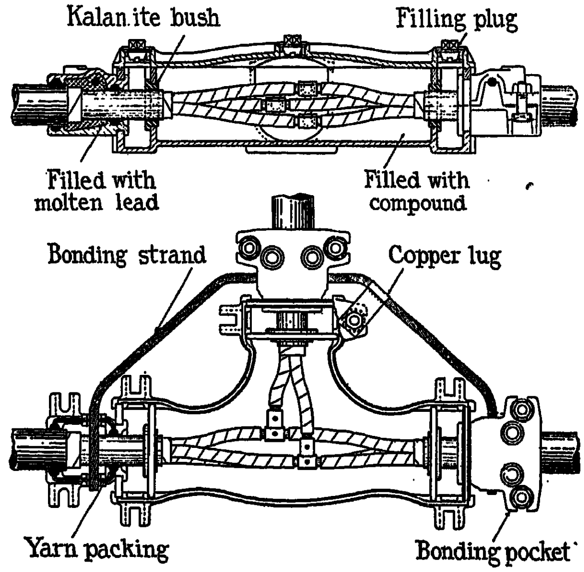

Fig. D.

This is mentioned in connection with feeder cables, not distributors, and I agree that a larger size of the latter will rarely, if ever, be required. I consider it advisable, wherever possible, to drain all manholes and network boxes, a Buchan's trap being sufficient to prevent the escape of sewer gases. I have not found a non-return valve necessary for other reasons. It is when it becomes necessary to draw a new cable into old existing ducts that very little clearance is sometimes obtained. I once had occasion to draw about two miles of e.h.t. cable with an overall diameter of 2¾ inches into an existing 3 in. duct. I have known several cases of braided cables jamming when an attempt was made to draw them out, with much more clearance than obtained in this instance.

With regard to the arrangement of the cores on a triple-concentric cable, I do not suggest that the neutral should ever be the inner, as is implied by Mr. Ambrose.

This would necessitate cutting through both live cores at both positive and negative services. On vulcanized-bitumen sheathed cables it is advisable to have the outer core the neutral, but I suggest that it would be better to have the middle core positive rather than negative, as such an arrangement would tend to keep moisture from entering the cable. It is only with lead-covered cables that, by making the outer core positive, the middle core neutral and the inner core negative the following beneficial results would ensue :—

(1) Accidental damage would be immediately apparent.
(2) Osmosis would tend to keep the cable drier.
(3) The maximum pressure between two cores would be 240 volts instead of 480 volts.
(4) A mechanically stronger outer core would be obtained, an advantage mentioned by Mr. Crellin.

I am familiar with the method of earthing the neutral described by Mr. Ambrose and referred to by Mr. Raphael, and it is the one to which I refer on page 344 in the section dealing with three-core cables. I do not, however, agree that to have a limiting resistance in the neutral earth circuit " will at any rate prevent the risk of a 480-volt shock," this being a disadvantage cited in connection with the system described in the paper which is really the same method without the resistance. Should an earth occur on, say, the negative conductor, there will be 240 volts across the resistance, and the positive conductor will be 480 volts above earth. The only effect of the resistance in allowing a leakage current to pass through the fault will be to increase the distribution losses by an amount depending on its ohmic value and, in the case of a multicore cable, to hasten the spreading of the fault to a short-circuit between cores. It does not reduce the liability of damage to consumers' installations under these conditions, and for this reason I agree with the principle of the fusing arrangements indicated by Mr. Rawll in Fig. C. It is for the same reason that I disapprove of the practice of some supply undertakings in terminating the neutral conductor of their two-wire services in a link box instead of a fuse box. A slight advantage obtained by the use of a series of fuses, the heaviest of which would correspond to the setting of the circuit breaker, is that an additional warning is given in the case of a fault which is sufficient to blow one of the lighter fuses but would not operate the circuit breaker. I recommend the use of tape-armoured cable for laying direct, as I consider that it provides better protection from the blow of a pick than does wire armouring, but the latter would appear to be more immune from the chemical action of certain types of ground.

With reference to Mr. Raphael's remarks regarding the cost of energy wasted in a feeder, I would point out that the second expression in the formula given in the paper is intended to take into account the fact that the maximum losses occur at periods of peak loads. Were this not the case no additional plant would be necessary to cope with them. As the running costs per unit at peak loads will be less than the average running costs, one would be erring on the right side by taking the latter, even if it did not represent a closer approximation to the correct figure. By reconstructing the first part of the appendix I hope that I have eliminated what may have been a slight cause for misconception.

I think that Mr. Wigham is inclined to be too favourable to the three-core distributor in his estimate of the time taken to make the service joints, as compared with that in the single-core distributor. In the first place it is only the larger consumers (whose load is sufficient to necessitate it being balanced across both sides of the system) that require a three-wire service, so that in the great majority of cases only two boxes are required for single-core cables. Furthermore, it is not correct to take the actual time to make the joints without considering the conditions under which they are made. For instance, in actual practice considerable time is saved by the jointer being able to prepare the distributor cables to suit the type of box used, whilst his men are excavating the ground, etc., preparatory to laying the service cables. The costs of laying complete services should be compared together with the time taken to carry out the whole work; this introduces the human element of the average jointer which, in my experience, enables him to return to the works at the end of the day at the same time whether he has laid a twin, concentric or single-core service. With a length of 8 yards a concentric service will cost about 10s. more than a twin cable, and the increased cost of single-core cables over twin cables will vary from 25s. to 35s., depending upon the type of boxes used.

Mr. Baker appears to be in a very comfortable position in that none of his cables are loaded up to more than one-quarter of their capacity.

Mr. Blades and others refer to the difficulty of making earthenware conduits thoroughly watertight. The following instance where this was obtained may be of interest. About two years ago a conduit line was laid through on old slag heap and it was considered advisable to take every precaution to ensure that the e.h.t. cables that were to be drawn into them would be free from the action of any acids contained in such ground. The joints of the conduits were accordingly completely surrounded with a mixture of cement and granite chippings, care being taken to see that the whole of the joint was enclosed. It was thought that the water would be more likely to take the easier path through the surrounding porous ground than to penetrate such a formidable object as protected the joints. That this reasoning was justified was shown by a recent test. A piece of clean, dry rag was pushed through two of the spare ducts and in both cases it came out only slightly "moist," in spite of the fact that the ground about the conduits was saturated by the almost continuous rainfall that had occurred from some time prior to the test. When the rags were tested they were found to be quite neutral, whilst the water contained in the ground showed unmistakably the presence of acids, which would indicate that even this trace of moisture had not come through the joints of the conduits.

I have only once had experience of trouble caused by the movement of drawn-in lead-covered cables. This was on a length of three-core 6 000-volt cable which supplied chiefly a large hand-operated electric

furnace. Practically all the wiped joints had to be re-plumbed. The trouble in this case was perhaps not so much due to expansion and contraction as to the effect of the very unbalanced load that occurred for some time after the furnace had been recharged, when there would be as much as 100 amperes out of balance, first on one core and then on another.

Mr. Blades is obviously right in assuming that the two neutral cores of a looped-neutral service are of the same size as the neutral of the distributor; the sketches shown in Figs. 6 and 7 are only intended to be diagrammatical. I do not recommend this type of service on distributors having a neutral larger than 0·1 sq. in.

I refer Mr. Allen to my previous remarks as to the reason why certain non-standard sizes of feeder cables are compared. The length of transmission possible will usually be calculated from the nodal point and will be independent of the feeder drop which his figures seem to include. I quite appreciate that single-core armoured cables would be of no use on an a.c. system, but I must remind Mr. Allen and Mr. Romero that the object of the paper is to discuss the application of various cables of a three-wire d.c. network, any advantages that some cable may have for other purposes being beyond its scope.

The case mentioned by Mr. Smith will necessitate a choice between the two evils of subsidence and corrosion. If both are equally probable I should prefer to risk the latter by laying direct a wire-armoured cable well served and compounded and surrounding it with some substance such as clay brought from another site.

The figures given in Table A by Mr. Forrest show clearly the disadvantages of single-core vulcanized-bitumen cables wherever full use can be made of the higher permissible loadings of the other types mentioned. This is substantiated by the fact that very few authorities are now laying such cables.

I do not like the example taken by Mr. Davidson of jointing a three-core cable on to a single-core distributor, as this will to a large extent nullify the advantages to be gained by having all parts of a network composed of single-core cables. The lead "tee" box seems to be the best for efficiently bonding the lead and for providing a perfectly watertight joint. It is, however, mechanically weak and requires protecting; also some method of bonding the armouring has to be devised. Fig. D shows a type of box which, whilst retaining the advantages of the cast-iron box, provides a method of bonding that is at once both simple and effective.

The seeming dislike for conduits expressed by Mr. Groves is almost as surprising as is his affection for single-core vulcanized-bitumen cables laid solid. Even assuming the rapid localization of faults possible on this type of cable under certain conditions, I should think that the substitution of lead-covered cables for the vulcanized-bitumen cables would very greatly reduce the number of faults to be localized, a fact that seems to be supported by the experience of Mr. Blades in Birmingham which enables him to speak highly of solid-laid lead-covered cables. Mr. Groves will notice that the costs of distributors shown in Table 5 are not based on current loadings and that it is not the costs but the times taken to complete alternative services which I say are the same in practice. I have already dealt with this question of costs in my reply to Mr. Wigham.

As most undertakings are favoured with a monopoly in their area of supply, I have always felt that they are, in return, morally bound to give the best possible service to their consumers. A dissatisfied consumer cannot transfer his custom elsewhere as in most other commercial transactions. It is largely the fact that I have found the single-core system to cause the least amount of public inconvenience under fault conditions that has led me to favour this type of network. Perhaps Mr. Romero is right in suggesting that I attach too much importance to the fault question, but in writing the paper, the subject matter for which has been obtained exclusively from my own experience, I may have lost sight of the fact that I have perhaps had more than my share of this trouble.

The scrapping of a vulcanized-bitumen triple-concentric distributor and its substitution by, say, a lead-covered and armoured three-core cable is a policy which I, as a mains engineer, can heartily support. Unfortunately, directors or committees are sometimes hard to convince of the necessity of expending what may be a considerable sum from which no financial benefit will be derived other than a saving in running costs. There may be many reasons for this attitude, more particularly perhaps in privately owned concerns, and it is quite conceivable that, though such a large expenditure might not be sanctioned, it would be considered justifiable to spend an extra 25s. on each of a few looped-neutral services in view of the resultant saving in the event of faults that are very liable to occur on some old vulcanized-bitumen distributors. This could hardly be classed as an "expensive" precaution. In all the calculations given in the paper of the costs of laying single-core cables, allowance has been made for the increased costs of carting, carriage on returned empties, tiles and the laying of three cables instead of one.

Mr. Lovell's suggested anchoring of a drawn-in cable at every box seems as opposed to Mr. Groves's view that flexibility is d ired at this point as is the favour he shows to wooden troughing, contrary to the views of other speakers. I am inclined to agree with Mr. Crellin that having the smaller neutral conductor as the outer of a triple-concentric cable is to be regarded rather as a mechanical weakness than an advantage. I am glad that Mr. Lovell is one of the few critics who have expressed their appreciation of the difficulty of forming conclusions in a paper dealing with a subject in which no two jobs are alike.

In response to Mr. Mallinson's suggestion I have included in the paper, information as to the prices of copper and lead at the time the various costs were calculated.

The fires that occurred on consumers' premises mentioned by Mr. Lamb when the potential of the neutral was raised were probably due to no protection against this possibility, such as that described by Mr. Rawll, having been taken. I am pleased to find that Mr. Lamb has also experienced the benefit of the use of conduits under certain busy thoroughfares, as several of the speakers in the discussion express the view that these are the very places where conduits are impossible.

Mr. Henderson and Mr. McLellan have evidently

overlooked the qualification which follows my remarks apropos the necessity of making a triple-concentric cable dead whilst jointing. That there is some inconvenience and difficulty experienced is evident from Mr. Stronach's admission that only 60 to 70 per cent of the joints can be made with the cable alive. Mr. Henderson will also notice that only in Table 3, relating to feeders, are the calculations based on current-carrying capacity, whilst those for distributors shown in Table 5 are based on voltage-drop, the sizes of cables being the same in each case. As the remark on page 346 which he quotes is in reference only to distributors, his charge of inconsistency cannot be substantiated.

Mr. Berry speaks from the viewpoint of a very large undertaking where conditions are exceptional and different from the majority of cases. Where there are very many feeders resulting in short distributors I can quite appreciate that the limiting factors will tend to be the reverse of those stated in the paper, feeders being limited by voltage-drop and distributors by current-carrying capacity.

Testing for a fault with only the neutral core of a triple-concentric cable cut instead of all three cores will undoubtedly give unreliable results if lamps or a "megger" are used for testing. If the cable is tested by closing it in through a light lead fuse of about 15 amperes' capacity, however, absolutely reliable results are obtained. Should such a test be necessary during working hours and it is doubtful whether the fuse has blown owing to load or the effects of the fault, it is not a difficult matter to open the consumer's main switches and test again. The cases when this precaution is necessary are, however, extremely rare.

By referring to my reply to Mr. Henderson, Mr. Stronach will see that his first remark is inaccurate. I can quite understand his reluctance to speak with disfavour of the triple-concentric cable, but after having questioned my right to condemn such a type for distributors, that he should proceed in his concluding remarks to do the same thing himself by advocating a three-core cable for such work is at least surprising.

Mr. Mitchell has mentioned a substitute for bitumen which has given every satisfaction. It would be interesting to know whether this compound will flow at as low a temperature as bitumen which enables the latter sometimes to seal up and so arrest an incipient fault due to the slight local heat caused by the leakage current.

Mr. Spalding is correct in his assumption as to the reason why I have allowed for a neutral cable one half the size of the outer. Where there are several feeders feeding a congested area the adoption of a size such as he indicates would no doubt be justifiable.

I have not found it easier to secure efficient bonding on a multicore than on a single-core network, nor have I experienced any trouble due to the smaller size of neutral cable used on the latter. Any danger there is of mechanical damage is certainly eliminated in the multicore cable. I have, however, known several cases where the neutral of a triple-concentric cable has been burnt clear by a fault which left two live cores continuous, thus causing considerable damage to consumers' installations. I do not quite follow the description given by Mr. Spalding of the fault in a street lamp but if, as he says, the fault is a "dead" short-circuit caused by the fusion of the outer and neutral fittings, the limiting resistance in the station neutral earth circuit would appear to have no bearing in the situation as this is concerned only with earth leakages.

It is, of course, quite incorrect to add the figures shown in Table 4 to those of Table 3 in order to arrive at the whole cost of laying a feeder inclusive of excavating, reinstating, etc. Table 3 itself gives these total costs, Table 4 merely showing the proportion of these amounts, exclusive of cable, that will have to be re-incurred should it be necessary at any future time to increase the size of the feeder.

In the little experience I have had of fibre conduits I have known of no damage being done to the lead sheathing of the cables drawn into them. Their use was, however, discontinued in favour of the earthenware conduits.

THE USE OF SINGLE-CORE ARMOURED CABLES FOR ALTERNATING CURRENTS.*

By G. M. HARVEY, Associate Member, and A. H. W. BUSBY, Student.

(*Paper first received* 30*th September, and in final form* 20*th December*, 1924.)

SUMMARY.

The paper is intended to form a corollary to that of Professor Cramp and Miss Calderwood† and deals with the losses involved in the distribution of alternating currents in sheathed cables in which the sheath is of magnetic material.

Single-core rubber-insulated cables, each enclosed in a separate iron tube, and also single-core cables armoured with one or two layers of galvanized iron or steel wires, are dealt with, and experimental data are given showing the measured losses in each case.

It is shown that, while the losses due to induction in a tube are considerable, those in a wire-armoured cable are comparatively very small, and also that the distance separating the individual cables forming a circuit has very little effect in determining the losses involved. In the case of the wire-armoured cable, also, the connection of the sheaths of separate cables so as to form a closed sheath circuit has no appreciable effect upon the losses, and the current which will flow in such a circuit is so small as to produce no considerable heating.

INTRODUCTION.

The gradual increase in the voltages employed in the transmission of three-phase power has introduced serious problems in regard to the construction of three-core cables, the insulation of which is capable of withstanding the dielectric stresses involved, and for this reason the possibility of using three separate, single-core, armoured cables is of importance.

It was shown by Prof. Cramp and Miss Calderwood in their paper that in the case of a single-core cable sheathed in non-magnetic material, such as lead, the circulating currents to be expected in the sheath, and the consequent watts lost, are capable of mathematical determination. When, however, the material of the sheath is such as to affect the magnitude and distribution of the magnetic field set up between two such cables, these methods fail. The losses in single cables carried in iron pipes have also been investigated mathematically by Field,‡ but this calculation does not apply to two such cables laid side by side (whether with sheaths connected or not), and further assumes that the pipe is homogeneous over its cross-section, so that the determination cannot be applied to brazed or close-jointed tubing, nor to armoured cables.

In wiring houses also, for lighting on the conduit system from d.c. supplies, it is often convenient to convey single conductors in a tube in certain parts of the circuit. When the supply is alternating current, however, it has always been regarded as essential that every tube should contain the lead and return conductors of a circuit, as it was held that the inductive effect of a steel tube carrying a single conductor would lead to heating and excessive losses.

The research under review was undertaken for the purpose of investigating the conditions under which the use of single-core insulated cables, either enclosed in steel tubing of various types of construction or armoured with galvanized steel wires, is a practical and commercial possibility.

CONDITIONS INVESTIGATED.

Seven different sets of conditions were investigated, the description of the cables and methods of enclosure in each being as follows:

(A) 37/0·083 in. single-core, V.I.R.* cable in $1\frac{1}{4}$ in. (external diameter) heavy gauge, screwed, welded electrical conduit (see Table 1).

(B) 7/0·048 in. single-core, V.I.R. cable in $\frac{5}{8}$ in. (external diameter) heavy gauge, screwed, welded electrical conduit (see Table 2).

(C) 19/0·056 in. single-core, V.I.R. cable in $\frac{3}{4}$ in. (external diameter) light gauge, grip-connected, brazed-jointed electrical conduit (see Table 3).

(D) 7/0·048 in. single-core, V.I.R. cable in $\frac{5}{8}$ in. (external diameter) light gauge, grip-connected, closed-joint electrical conduit (see Table 4).

(E) 37/0·092 in. single-core, V.B.† cable, single armoured with 50 galvanized steel wires, each 0·08 in. diameter (see Table 5).

(F) 37/0·092 in. single-core, V.B. cable, double armoured with 107 galvanized steel wires, each 0·08 in. diameter (see Table 6).

(G) 19/0·072 in. single-core, V.B. cable, single armoured with 29 galvanized steel wires, each 0·104 in. diameter (see Table 7).

Further details of these cables are given in Table 8.

DESCRIPTION OF THE TESTS.

Fig. 1 shows the arrangement adopted for all the tests. The cable core was coupled in series with a variable resistance R and a shunt Sh, across which the current coil of a wattmeter W was connected. By means of the change-over switch S_1 a variable voltage, either from a d.c. generator or from an a.c. transformer,

could be applied to the cable, the current in which was indicated by the ammeter A_1. The potential coil of the wattmeter was connected across the ends of the cable, and the voltage across these ends, or that across the ends of the sheath (whether tubing or armour) could be read by means of the voltmeter V. The two sheaths were bonded solidly together at one end, while a switch S_2 and an ammeter A_2 were connected in series across the other ends. In this way the watts

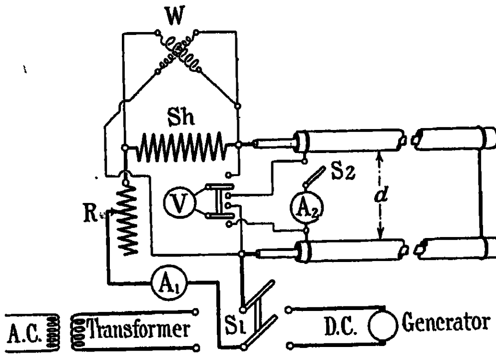

FIG. 1.—Diagram of connections for tests.

lost in the circuit, and the voltage-drop, could be read with the sheath circuit open or closed, while the current circulating in the sheaths, when these were bonded together at both ends so as to form a closed circuit, could also be read.

Owing to the short length of the cables which could be tested (up to 72 ft. of single conductor or 36 ft. of circuit) there was a large difference between the current

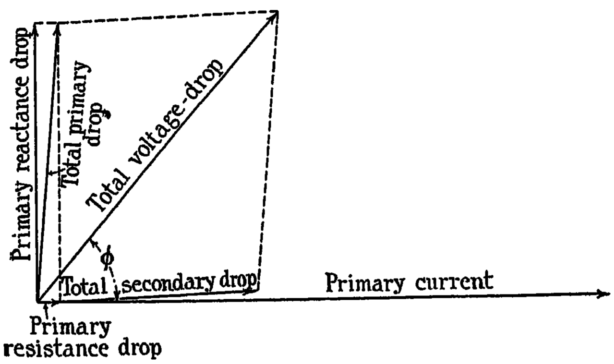

FIG. 2.—Vector diagram.

in the conductors and the potential difference between them. This necessitated the use of the shunt Sh and very careful calibration of the instruments against a Drysdale potentiometer on both direct and alternating currents.

In order to avoid possible errors due to adjacent magnetic material, etc., the wattmeter was placed in a separate room some yards from the cables under test, and the connecting leads to the current and potential coils of the instrument were of twisted flexible. A test at varying frequencies showed that the error due to self-induction was negligible.

Each test comprised three sets of readings, one set for each value of d (the distance separating the cable sheaths), viz. $d = 0$, $d = 12$ in., and $d = 48$ in.

Each set of readings included the following observations for each value of the main current :—

(1) Watts lost with direct current in the main conductors.

(2) Watts lost with alternating current in the main conductors
  (a) with the sheath circuit open, and
  (b) with the sheath circuit closed.

(3) Potential difference between the ends of the cable
  (a) with the sheath circuit open, and
  (b) with the sheath circuit closed.

(4) Current in the sheath circuit with this circuit closed.

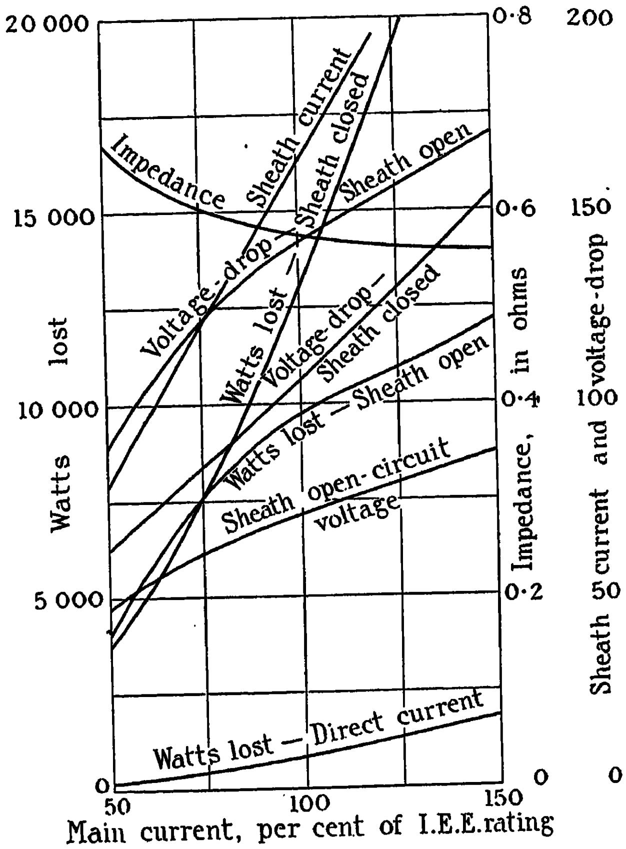

FIG. 3.—Test (A).

The frequency of the alternating supply throughout the tests was 50 periods per second.

Observations were also made of the voltage across the ends of the sheath circuit with this circuit open and with the sheaths 12 in. apart.

The main currents employed during each test were approximately those corresponding to a range of 50 to 150 per cent of the I.E.E. rating of the cable under test, with an upper limit of 300 amperes.

The readings taken under each set of conditions are set out in Tables 1 to 7, the values of watts lost and voltage-drop being adjusted to a length of circuit of 100 yards, or 200 yards of single conductor.

Table 8 shows, for purposes of comparison, the principal readings under each set of conditions corresponding to a current in the main conductor equal to the I.E.E. rating, and for sheaths 12 in. apart.

The readings given in Tables 1 and 5 are plotted in Figs. 3 and 4 against the current in the main cable as a percentage of the I.E.E. rating. These curves apply only to circuits in which $d = 12$ in.

Tests were also made upon samples, about 3 in. long, cut from the tubes and armoured cables, to determine

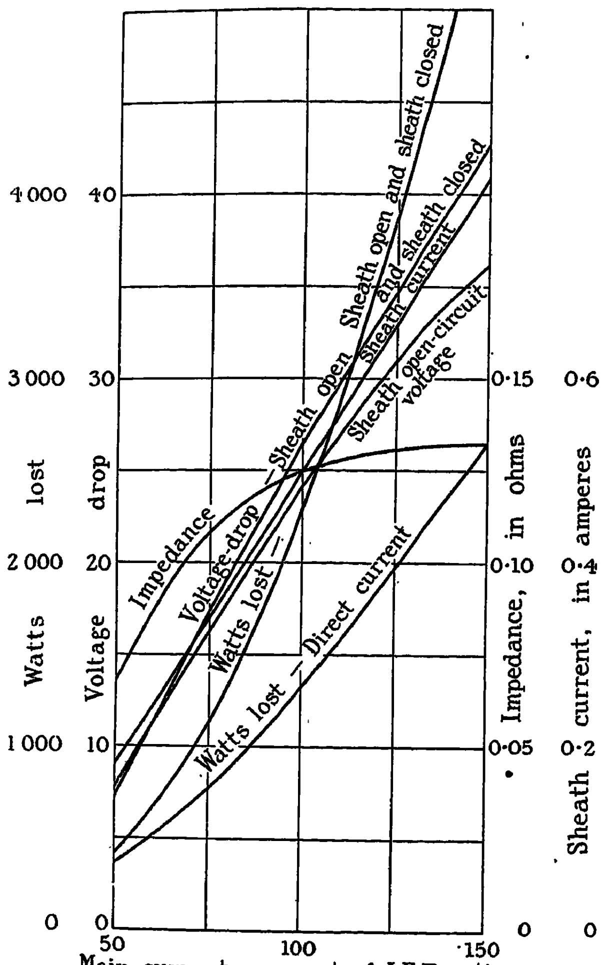

FIG. 4.—Test (E).

the permeability of the circumferential magnetic path in the sheath. In the case of the armoured cables, the permeability given in the table is that of the zone including the armouring and of width equal to the diameter of one armour wire. Primary and secondary coils were wound longitudinally upon the specimens, and the measurements of flux were obtained, by means of a ballistic galvanometer, for various values of H. In the case of the armoured cables, the copper conductors and a portion of the insulation were carefully removed from the specimens, so as to avoid disturbing the relative positions of the armouring wires. The permeability curves derived from these tests are plotted in Fig. 5.

In Fig. 6 the watts lost per ampere of main current per 100 yards of circuit are plotted, for each of the seven tests, against the main current as a percentage of the I.E.E. rating.

REVIEW OF THE RESULTS OBTAINED.

The outstanding facts to be derived from a study of the tables and curves are as follows:

Watts lost.—In the case of test (A) the loss is enormous, and on a 500-volt circuit would amount to 13·5 per cent of the power input for every 100 yards of circuit. In test (B) this figure is reduced to 9·7 per cent, in test (C) to 2·74 per cent and in test (D) to 3·68 per cent.

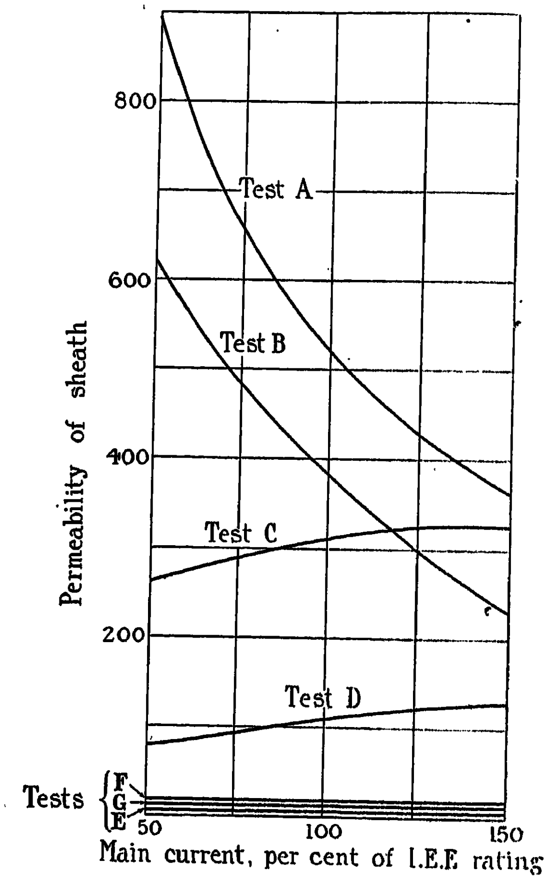

FIG. 5.

For the single-armoured cables [tests (E) and (G)] the loss is 2·16 per cent and for the double-armoured cable [test (F)] 4·27 per cent. The corresponding figures for watts lost due to dead resistance are: (A), 0·9 per cent; (B), 3·25 per cent; (C), 1·34 per cent; (D), 1·47 per cent; (E), 1·19 per cent; (F), 1·19 per cent; (G), 1·7 per cent.

The losses in the armoured cables appear high in comparison with the sheath currents, but, as will be explained later, this is largely due to the spiral lay of the armouring wires, and the loss is a "sheath loss" rather than a "sheath circuit loss." As defined in the

paper by Prof. Cramp and Miss Calderwood, " sheath loss " is the loss due to eddy currents confined to the sheath of one cable, while " sheath circuit loss " is due to eddy currents in the closed circuit formed by the sheaths of two cables when these sheaths are bonded together at each end. It will be noticed from Fig. 4 that the curves of watts lost with sheath open and with sheath closed coincide.

The watts lost in tests (A) and (B) are quite sufficient

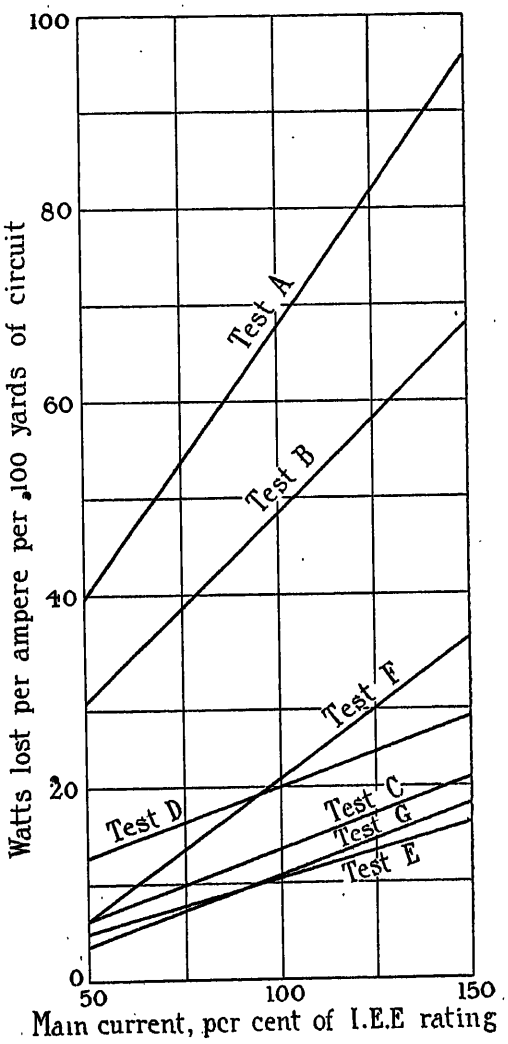

Fig. 6.

to cause serious heating of the tubing. In the other tests, however, the heating was too slight to be of serious importance and in the case of the armoured cables it was imperceptible.

From the point of view of practical working efficiency, therefore, it would appear that the use of any type of enclosure of a magnetic nature, except brazed tubing of light gauge, or single armouring, is impracticable, while even in these two types the losses will be approximately double those due to the dead resistance of the cables.

It will be noticed that the watts lost with the sheath circuit closed—the usual condition obtaining in practice—varies inappreciably with the value of d in cases (A), (B), (C), (D) and (F). In case (E), however, the value for $d = 12$ in. is 91 per cent, and for $d = 48$ in., 87·5 per cent of that for $d = 0$.

Sheath current.—The ratios of sheath current to main current given in Table 8 show a very marked difference between the tubing and the armoured cables. In test (A) the sheath current was but little less than the main current, and the tubing became unbearably hot to the hand. In tests (E), (F) and (G) the maximum current in the sheath, with a current flowing in the main conductor equal to 150 per cent of the I.E.E. rating, was less than 1 ampere.

The variation in sheath current with spacing of the sheaths was most marked in test (E), and was comparatively slight in all the other tests.

Voltage-drop.—The impedance of the system in tests (B), (C), (D), (E) and (F) varied between 2·24 and 6·25 times the dead resistance. In test (A) it was 22·2 times the dead resistance. In any case, a loss of 26·6 volts per 100 yards of circuit, or over 6 times the normal allowance for cables carrying direct current, is a very serious disadvantage.

The drop in voltage increases with increasing separation of the sheaths, the variation being slight, except in the armoured cables. In test (E) the increase from $d = 0$ to $d = 12$ in. was 30 per cent, and from $d = 0$ to $d = 48$ in., 39 per cent. In test (F) the increases were 11·4 per cent and 12·3 per cent respectively, and in test (G), 28·8 per cent and 52 per cent.

Theoretical Survey of the Experimental Results.

The lead and return conductors themselves, and the circuit formed by the magnetic sheaths enclosing them, may be regarded as forming the primary and secondary windings of a current transformer, each winding consisting of one turn.

Since the primary is situated within the sheath, there will be a certain amount of primary leakage reactance due to the flux within the inner circumference of the sheath, but the whole of the counter-flux set up by the current induced in the secondary must thread the primary circuit, so that there can be little secondary leakage reactance, and practically the whole of the secondary losses must be due to eddy currents and, to a small extent, to hysteresis.

This being so, the primary leakage reactance corresponding to any primary current can be calculated by deducting from the total reactance (obtained from the primary applied voltage with secondary on open-circuit) the mutual reactance obtained from the secondary open-circuit voltage under the same conditions.

Knowing this primary reactance, we are able to construct the vector diagram of the transformer under short-circuit conditions, i.e. with the sheath circuit closed (see Fig. 2).

Considering the case illustrated in Fig. 7, which represents the conditions of test (A) when the sheath circuit is open, the direction of the eddy currents in the sheath enclosing conductor " a," and due to the flux in the sheath only, will be as shown in the small

elements "a_1," "a_2," namely, away from the observer in "a_2" and towards the observer in "a_1."

Now consider conductor "a" with its magnetic sheath alone. If we assume that the resistance of the longitudinal paths of the currents in "a_1" and "a_2" is negligible, we shall have these currents concentrated in the inner and outer layers respectively of the sheath, and each equal in magnitude to the current in the main conductor "a."

Introducing now the second conductor "b" and its sheath, a portion of the flux due to the current in "b" will cut the sheath of "a" and will disturb the distribution of these currents. For non-magnetic sheaths, Prof. Cramp and Miss Calderwood have shown that the influence of this second field is of importance. In the case under consideration, however, the ratio of the flux in the iron of sheath "a," due to conductor "a," to that set up by conductor "b" is so great that the effect is negligible.

This conclusion is borne out by the experimental results, since the increase in sheath current for increasing distances d separating the sheaths is only 1 per cent in test (A); in test (E), when the permeability and sectional area of the iron path is greatly reduced, it reaches 40 per cent (see Table 8).

The relative magnitude of the flux in the sheath to that between the sheaths, is given approximately by :—

$$\frac{\Phi_1}{\Phi_2} = \frac{0\cdot 2I \log_e (r_1/r_2)\mu l}{2\{0\cdot 2I \log_e (d + r_1)/r_1\}l}$$

$$= \frac{\log_{10} (r_1/r_2)\mu}{2 \log_{10} (d + r_1)/r_1}$$

where Φ_1 = flux in sheath,
Φ_2 = flux between sheaths,
d = distance between sheaths,
r_1 = external radius of sheath,
r_2 = internal radius of sheath,
I = current in main conductor, and
l = length of one sheath, adjusted to 100 yards of circuit.

In the case of test (A), for $I = 184$ amperes and $d = 30\cdot 4$ cm, we have

$r_1 = 1\cdot 58$ cm, $r_2 = 1\cdot 375$ cm, $l = 9\,130$ cm, $\mu = 392$,

so that

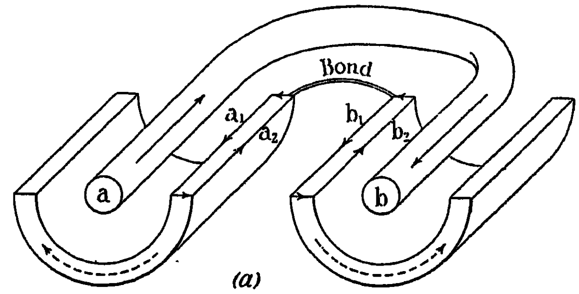
$$\Phi_1 = 0\cdot 2 \times 184 \times \log_e (1\cdot 58/1\cdot 375) \times 392 \times 9\,130$$
$$= 18\,570\,000$$
$$\Phi_2 = 2\{0\cdot 2 \times 184 \times \log_e (31\cdot 98/1\cdot 58)\} \times 9\,130$$
$$= 2\,012\,000$$
$$\frac{\Phi_1}{\Phi_2} = \frac{18\cdot 57 \times 10^6}{2\cdot 012 \times 10^6} \doteq 9\cdot 23$$

and the open-circuit voltages due to the two fluxes will be

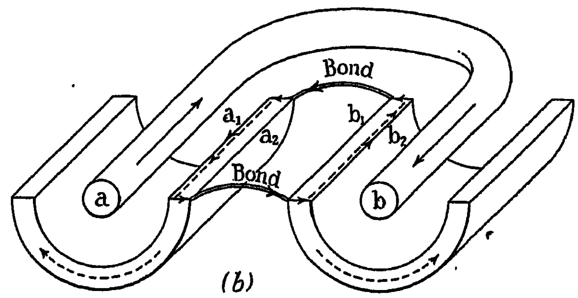
$$E_1 = \frac{2\pi \times 50 \times 18\cdot 57 \times 10^6}{10^8}$$
$$= 58\cdot 3 \text{ volts per 100 yards of circuit.}$$
$$E_2 = E_1 \times \frac{\Phi_2}{\Phi_1}$$
$$= 6\cdot 3 \text{ volts per 100 yards of circuit.}$$

Fig. 7 (*a*) represents diagrammatically a longitudinal section through the sheaths, the conditions being those described in the tests as "sheath circuit open." The arrows indicate the direction of flow of the sheath eddy currents, due to the flux in the sheath, under these conditions, the assumption being that the current will be more or less concentrated in the inner and outer circumferences of the sheaths, represented by the elements a_1, a_2, b_1, b_2.

If these were separate conductors forming inner and outer thin sheaths and separated by a middle layer of magnetic but insulating material, we could readily calculate the voltages which would be indicated by a voltmeter connected across the unbonded ends. The P.D. across the near ends of "a_1" and "b_2," for



(*a*)
Sheath circuit open



(*b*)
Sheath circuit closed

FIG. 7.—Distribution of sheath currents.

example, would be that due to the flux in sheath "b," while the P.D. between "a_2" and "b_1" would be due solely to the flux between the sheaths.

Since the whole sheath is homogeneous, however, and has a low transverse resistance, the connections of the voltmeter must be regarded as being made to every point in the sheath, both internal and external.

Under these conditions, the actual value of this "open circuit" E.M.F. may be calculated by the method given in Field's paper referred to earlier in the present paper. Field's calculations, however, assume a constant value of the permeability throughout the section of the sheath, although Thomson has shown* that the flux density and therefore the permeability vary over the section. It is necessary, therefore, to base the calculation upon the mean value of μ.

Taking the case of the large welded tube [test (A)],

* *Electrician*, 1892, vol. 28, p. 599.

the values of the terms in Field's formula are as follows :—

Resistance of total length of tube (including joints) $= 0 \cdot 0238$ ohm.
Area of section $= 1 \cdot 8$ cm^2.
$\rho = 18 \cdot 6$ microhms per cm cube.
Maximum value of current $= \sqrt{2} \times 184 = 260 = \Gamma_i$.
Frequency $= 50 = f$.
Mean value of permeability $= 518 = \mu$.
$m_i = 0 \cdot 000199 \sqrt{(\mu f / \rho)} = 7 \cdot 1$.
Mean circumference of pipe, $L = 9 \cdot 26$ cm.

$$\frac{\Gamma_i m_i}{L} = \frac{260 \times 7 \cdot 1}{9 \cdot 26} = 200$$

Thickness of pipe $= 0 \cdot 207$ cm $= h$.
$m_i h = 1 \cdot 47$.

$$P_i = \frac{\Gamma_i m_i}{l} \sqrt{\left[\frac{\cosh m_i h - \sinh m_i h}{\cosh m_i h + \cos m_i h}\right]}$$

$$= 200 \sqrt{\left[\frac{2 \cdot 29 - 2 \cdot 06}{2 \cdot 29 - 0 \cdot 1}\right]} = 64 \cdot 8$$

$$\frac{V}{\rho} = 64 \cdot 8 \{\sin \theta - \epsilon^{m_i h} \sin (\theta + 1 \cdot 47)\}$$

$$= 64 \cdot 8 \{\sin \theta - 4 \cdot 35 \sin (\theta + 1 \cdot 47)\}$$

$$\text{Mean square of } \frac{V}{\rho} = \frac{1}{\pi} \int_0^\pi \left(\frac{V}{\rho}\right)^2$$

$$= 2\,100 + 39\,500 - 18\,260\,(-0 \cdot 1)$$
$$= 43\,426$$

Root-mean-square of $V/\rho = 208$

$$V = \frac{208 \times 18 \cdot 6}{10^6} = 386 \times 10^{-5} \text{ per cm}$$

Total $V = 9\,130 \times 2 \times 386 + 10^{-5} = 70 \cdot 3$ volts.

This calculated figure agrees fairly closely with the observed value of 72 volts (see Fig. 3). The discrepancy is probably accounted for by the inclusion of the resistance of the joints giving a false value to the specific resistance.

Fig. 7 (*b*) shows the conditions when the sheath circuit has been completed by a bond of low resistance at each end. The currents in "a_2" and "b_1" now practically disappear and the current in the larger circuit embraced by "a_1" and "b_2" will be limited only by the resistance of the sheath circuit. Further, this current, instead of being a maximum at the inner and outer surfaces and falling to zero at the centre of the thickness of the sheath, is now a maximum in "a_1" and "b_2" and falls to zero at the outer surfaces ("a_2" and "b_1"), thus reducing the resistance of the sheath circuit. The open-circuit E.M.F. should therefore be greater than the E.M.F. with closed sheath circuit, and this is found to be the case, the observed open-circuit sheath voltage being in every case slightly higher than the value of the sheath voltage on closed circuit, obtained from the vector diagrams.

This redistribution of the eddy currents by the bonding together of the sheaths might be expected to cause very little difference in the watts lost between open and closed sheath circuit conditions, and this also is shown by the tests to be the case, as pointed out on page 375 when comparing the observed losses. As the sheath becomes thinner the reduction in its resistance to the sheath current on closed circuit becomes relatively less and the curves of watts lost for open and closed sheath circuits more nearly coincide.

For the armoured cables, the loss with sheath open is more marked and the loss with sheath closed is less marked, owing to the spiral "lay" of the armouring wires, different portions of the same wire being alternately internal and external to the field.

A peculiar feature of the curves of watts lost is that in tests (A) and (B) the loss with sheath open has actually a higher value than the loss with sheath closed, over the lower portions of the curves. This is most marked in test (B).

The effect is probably due to variations in the resistance of the eddy-current paths in the sheaths, the reactance of which is low, and in the distribution of these eddy currents over the sheath section. For low values of the main current the value of the flux in the sheath is relatively high, and the concentration of the eddy currents in the edges of the section, i.e. in the inner and outer layers of the sheath, will produce a high resistance and a large loss, since the sheath current is relatively constant, whereas, with sheath circuit closed, the path of the sheath currents will be of lower resistance.

Now the permeability of the sheath, as seen from Fig. 5, falls with increasing main current. As the permeability is reduced, the concentration of the sheath eddy currents in the outer layers of the sheath will be less pronounced, and the resistance of the path of these currents, and therefore the loss due to them, will increase at a lower rate than would be the case if the permeability remained constant. The sheath circuit current, however, flows in a circuit of more or less constant resistance, and the loss due to it follows approximately a square law.

It has been assumed throughout that the conductor is placed at the centre of the enclosing sheath, so that the flux in the latter is uniform over its circumference. In practice it is probable that the insulation of a conductor placed in a tube will be in contact with the sheath at a number of different points, and the flux in the sheath at these points will consequently be distorted. The extreme case would be one in which the sheath is so large compared with the conductor that the latter lies at the lowest point of the inner circumference of the sheath throughout its length.

In the cases under review, however, it is probable that the distortion produced in this way would take place at various points around the inner circumference, as well as longitudinally, and that the sum of these effects would produce little total difference in the general distribution of flux. In the armoured cables, of course, the conductor is fixed at the centre of the sheath.

The comparison on page 367 of the losses in sheathed cables carrying alternating current with those in the same cables when conveying direct current, is not altogether a just one. The difference between the curves of "watts loss—sheath circuit closed" and "watts loss—direct current" in the tables must, in

tests (A), (E) and (F) at any rate, contain, in addition to the loss due to sheath circuit current, a certain amount of additional copper loss due to skin effect. A comparison between sheathed and unsheathed cables, in both cases carrying alternating current, would therefore be more favourable to the former.

Conclusions.

From a survey of the results obtained from the tests, and of the factors contributing to those results, it is possible to derive the following conclusions:—

(1) The enclosure of a single conductor carrying alternating current at normal periodicities in a sheath of iron or steel for protective purposes need not necessarily involve excessive losses, nor produce excessive heating of the sheath.

(2) The higher the permeability of the sheath in a circumferential direction, and the greater the radial thickness of the sheath, the greater will be the losses and heating produced. Standard "heavy gauge" welded tubing is unsuitable, but the losses incurred by employing light gauge tubing, the seam of which is either brazed or merely closed, are of more reasonable magnitude. If the sheath is in the form of an armouring of galvanized steel wires, either single or double, the loss is still further reduced.

(3) It should be possible to construct a cable in which the permeability of the sheath is reduced to a negligible value by laying wires of non-magnetic material, such as aluminium, alternately with the steel wires, or by some similar means. In this case the additional loss due to the armouring will also be negligible, but the lead and return conductors must then be laid close together, as the conditions approximate to those of lead-sheathed cables, and the losses will be greater with increased separation. For the types of cable and sheath dealt with in the tests, the effect of increasing separation, up to reasonable distances, may be neglected.

(4) The loss in cables enclosed in light gauge, brazed or closed-joint tubing is but slightly greater when the sheath circuit is closed than when the circuit is open. In other words, the usual practice of securing the ends of the tubing to the metallic casing of switches, fuse-boards, motor terminal boxes, etc., will not sensibly increase the loss. In the case of armoured cables there is practically no increase from this cause.

THE USE OF SINGLE-CORE LEAD-COVERED AND ARMOURED CABLES FOR ALTERNATING CURRENTS.*

By PROFESSOR W. CRAMP, D.Sc., Member.

(*Paper first received* 30*th September, and in final form* 20*th December,* 1924.)

SUMMARY.

In a previous paper Miss Calderwood and the present author examined the losses in the lead sheath of a single-core cable when carrying an alternating current, and concluded that, provided the outgoing and return cables were laid within a certain limiting distance of one another, no difficulty would arise due to eddy currents in the sheaths at normal frequencies. In the present paper this work is extended to cover the case of single-core cables that are both lead-covered and armoured.

A theoretical investigation of the reactances and losses is carried out and is checked against the actual test figures obtained by Harvey and Busby. It is shown :—

1. That the flux in the armour, the reactance due to that flux, and the appropriate hysteresis and eddy losses can all be approximately predetermined.

2. That for low-tension transmission, lead-covered and armoured cables are impracticable with armouring as at present constructed.

3. That the use of such cables for e.h.t. transmission is not precluded by the magnetic conditions introduced by the armour, and consequently such cables are practicable. There would, however, be some difficulties to be overcome due to large capacity currents when the transmission distance is great.

In the joint paper with Miss Calderwood† the losses in lead-covered cables were examined, certain rules for their use were suggested and experiments upon armoured cables were foreshadowed. These experiments have been completed by Harvey and Busby,‡ and from them the limitations of armoured cables and of cables in tubes have been deduced in the preceding paper. There remains the most important case of cables which are both lead-sheathed and armoured.

1. CORRECTION TO PREVIOUS FORMULÆ.

In approaching this problem, approximations adopted in the first paper must be borne in mind. On pages 480 and 484 of the joint paper, attention was directed to these approximations, and it was pointed out that the effect of the reaction of the circuit eddies upon the exciting field would be a reduction in the eddy losses, which, however, would not affect the general conclusions. If we regard the core and its lead sheath as the primary and secondary of a 1 : 1 ratio current transformer, then the ratio of the R.M.S. currents in the sheath and core is given by the relationship

$$\frac{I_2}{I} = \frac{2\pi f M}{\sqrt{[(2\pi f L)^2 + R^2]}} \quad . \quad . \quad . \quad . \quad (1)$$

where M is the coefficient of mutual induction between the core and the sheath, L is Maxwell's coefficient of self-induction for the sheath circuit and R is the resistance of that circuit.

In the case of a lead sheath M and L are almost equal, so that the mean loss of power in watts per cm² of mean sheath surface becomes

$$P_1 = \frac{I^2}{4\pi r} \cdot \frac{(2\pi f M)^2 R}{(2\pi f L)^2 + R^2} \quad . \quad . \quad . \quad (2)$$

where I is the current in amperes in the core, r is the mean radius of the sheath in cm, and M, L and R refer to 1 cm run of the circuit, the two former being in henrys, the latter in ohms. Throughout this paper, the expressions "cm run" or "length of circuit" mean the same measure. Thus the phrase "per 100 yards of circuit" refers to a circuit consisting of outgoing and return leads each 100 yards long.

Substituting the values

$$M = L = \frac{9 \cdot 212}{10^9} \log_{10} \frac{1 - K}{K}$$

$$R = \frac{\rho}{\pi r S} = \frac{20 \cdot 8}{10^6 r S \pi}$$

where K, ρ and S have the same meaning as in the paper cited, and taking $f = 50$, we find :—

$$P_1 = \frac{\frac{4 \cdot 4 I^2}{r^2 S}\left(\log_{10} \frac{1 - K}{K}\right)^2 \times 10^{-6}}{8 \cdot 38\left(\log_{10} \frac{1 - K}{K}\right)^2 + \frac{43 \cdot 82}{r^2 S^2}} \text{ watts per cm}^2 . \quad (3)$$

If the first term in the denominator be neglected, this reduces to $P = S I^2\left(\log_{10} \frac{1 - K}{K}\right)^2 \times 10^{-7}$ nearly, as on page 481 of the joint paper, where, however, the symbol ρ has been inadvertently printed for P.

The correction introduced by Equation (3) is not important for the case of lead sheaths, as is proved by the following table, which refers to standard low-tension paper-insulated lead-covered cable having a nominal core area of 1 sq. in. and carrying the maximum current of 932 amperes allowed by the I.E.E. Wiring Regulations.

TABLE 1.

K	P	P_1	P/Q	P_1/Q	distance, l
			per cent	per cent	in.
0·01	0·0966	0·0769	537	427	83·4
0·1	0·0220	0·0210	123	116	8·34
0·2	0·0088	0·0865	49	48	4·17
0·3	0·0033	0·0033	18	18	2·78
0·4	0·00075	0·00075	4·2	4·2	2·08

NOTE.—l = distance from centre to centre of the cables.
Q = loss in the copper per cm² of mean sheath surface.

It will be noticed that the magnitude of the change is only of importance when the sheath circuit loss is quite inadmissible. In this connection the effect of frequency is of importance and might with advantage have been emphasized before. The sheath losses are proportional to the square of the frequency, so that where f is below 50, the safe distances given in conclusion No. (7) on page 483 of the original paper might well be increased.

2. APPLICATION TO ARMOURED CABLES.

This short analysis, together with the permeances and losses measured by Harvey and Busby, enables us at once to deal with cables that are both lead-covered and armoured. For the effect of the armouring is to add a new term to the values of M and L, which is usually large compared with that due to air alone; in consequence these coefficients become almost independent of the spacing of the cables, a result which was proved conclusively in the experiments.

As an example, take the case of a standard 0·5 sq. in. low-tension paper-insulated cable with the usual bedding (0·1 in. thick), and single-wire armoured with galvanized wire 0·104 inch in diameter. Then when two such cables placed parallel to one another with centres 2 in. apart are used for a single-phase circuit, power will be lost in the copper, in the lead and in the armour respectively. The sheath eddy losses in the lead are not increased by the presence of the armour and these remain negligible, although the armour eddy losses do not. When, however, the sheath circuit is closed as well as that of the armour, the values of M and L change and the sheath circuit eddy current rises. The dimensions of the cable are as follows:—

Diameter over conductor	..	0·927 in. (2·355 cm)
Diameter over lead	..	1·307 in. (3·319 cm)
Diameter over armour	..	1·715 in. (4·355 cm)
Mean radius of lead	..	0·6085 in. (1·545 cm)
Pitch radius of armour	..	0·8055 in. (2·046 cm)

To admit of direct comparison with the values in the first paper, the losses will be calculated per cm² of mean lead sheath surface, both armour and lead being assumed to be bonded at both ends.

Then when the cables are unarmoured,

$$M = \frac{9\cdot212}{10^9}\log_{10}\frac{1-K}{K} = \frac{3\cdot39}{10^9} \text{ per cm run}$$

and the power lost due to circuit eddy currents in the lead at 50 periods and with full I.E.E. current (540 amperes) in the cable is

$$P = 0\cdot0009 \text{ watt}$$

Considering now the flux in the armour, Harvey and Busby found in test G for $H = 16\cdot1$ the circumferential flux per cm axial length was 28·5, and moreover that the circumferential permeance was nearly constant. In the present instance $H = 0\cdot2 \times 540/2\cdot046 = 52\cdot78$, so that $M = 3\cdot46 \times 10^{-9}$ per cm run for the armour alone. Since the current in the armour is very small, we may add to this the increase in M due to the flux in the space between the cables, and M becomes $4\cdot61 \times 10^{-9}$. The circuit eddy loss in the lead is therefore increased from 0·0009 to 0·00166, i.e. by about 85 per cent; and the ratio of this to the copper loss at full load is as 1 : 10. So far there is nothing serious, but in addition there is the loss in the armour, which must be deduced from an analysis of the tests.

3. ANALYSIS OF THE LOSSES IN TUBES CONTAINING CABLES.

Taking first the case of the cables in tubes, we remark that there is no cause for, nor evidence of, a field in the tube other than that concentric with the cable. Also, the tube being reasonably homogeneous, the eddy currents as shown in Harvey's Fig. 7 represent the condition in the tube sufficiently closely, as is indeed proved by the agreement between the calculated and measured values of the open-circuit P.D. With the analogy of the current transformer in our minds, it is clear that, on closing the tube circuit, the difference between the measured values of d.c. and a.c. watts for a given current should be the sum of the eddy and hysteresis losses in the tube. Now the eddy losses should be (very nearly) the product of the sheath open-circuit voltage and the sheath circulating current, and the hysteresis loss can be calculated from the Steinmetz formula if a hysteresis coefficient is assumed. Thus in the case of 200 yards of tube A when the cable is carrying 184 amperes, the d.c. watts are 850, and the a.c. watts with sheath circuit closed are 13 000; so that the difference is 12 150. The open-circuit sheath voltage is 71·5 and the circulating current is 165 amperes, equivalent to 11 800 watts. Harvey's calculated mean magnetic density in the tube is 2 924 maxwells per cm². Therefore the hysteresis loss is approximately W_h = volume of 200 yards of tube × $2\,924^{1\cdot6}$ × 50

TABLE 2.

Test	Open-circuit voltage, V	Circulating current, I	Product, VI	A.C. watts – D.C. watts
	volts	amps.	watts	watts
A	71·5	165	11 800	12 150
B	38·5	24·8	955	1 260
C	21·5	22	473	510
D	27	7·3	197	145

$\times h \times 10^{-7}$ watts, at a frequency of 50, where h is the hysteresis coefficient. Taking the latter at the probable value 0·004, we have $W_h = 236$; and this added to 11 800 gives 12 036, as against the measured value 12 150. This agreement is as good as can be expected, and leads to the general conclusion that in the case of tubes the hysteresis loss is small compared with the eddy loss. Table 2 proves that contention for all the tubes.

4. Analysis of the Losses in the Armour of Cables.

The case of armoured cables is very different, as Table 3 will demonstrate.

Table 3.

Test	Open-circuit voltage, V	Circulating current, I	Product, VI	A.C. watts—D.C. watts
	volts	amps.	watts	watts
E	24	0·5	12	1 000
F	19·7	0·46	9	2 970
G	9·5	0·32	3	220

Obviously for an explanation of the loss in the armoured cables we must look further than the eddy component. If we take a ring of the armour 1 cm long, and compare the measured circumferential flux per ampere of current in the cable with that which would exist if the iron were removed, we get an idea of the apparent circumferential permeability of the armour. The tests of Harvey and Busby show that this is about 11. We know that the permeability of the wire itself must be far greater than this, however, so that while the circumferential flux is but small the flux *along* each armouring wire must be far greater. We may arrive at its value as follows :—

If l be the " lay " of the armouring and r its pitch radius, then the current I is surrounded once by a length of wire $l_1 = \sqrt{[(2\pi r)^2 + l^2]}$. If also μ be the permeability of the wire and r_1 its radius, and if the flux through the wire be uniformly distributed, then the flux along each wire

$$\Phi_w = \frac{4\pi I}{10} \times \frac{\mu\pi r_1^2}{l_1}$$

Writing $2\pi r/l_1 = \cos\theta$ and w = number of wires surrounding the cable, then the total flux along all the wires is

$$\Phi = 0 \cdot 2 I\mu w\pi r_1^2 \cos\theta/r$$

having a circumferential component (per cm axial length)

$$\Phi_c = 0 \cdot 2 I\mu w\pi r_1^2 \cos^2\theta/rl.$$

Neglecting the leakage from wire to wire, which must under the circumstances be comparatively small, the value Φ_c is that which was measured by Harvey and Busby. Now in case G the lay is $12\frac{1}{4}$ in., or say 12 times the pitch diameter, so that θ = about 75° and the circumferential component of flux per ampere in the cable calculated as above is $0 \cdot 000495\,\mu$, where μ is the real permeability of the armour wires. The test value for this flux is about 0·27, which would make μ about 546, a value that is quite possible. This is sufficient to check the probability of the assumptions just made and to prove the existence of a flux in the armour far greater than the circumferential flux.

5. Calculation of Armour Losses.

Adopting as a trial value $\mu = 500$, it should be possible to calculate the losses in eddy currents and hysteresis respectively and to compare the sum with the test-results. It should be remembered that with such values of μ, f and r_1 the product $r_1\sqrt{(\mu f/\rho)}$ cannot be regarded as small, and in consequence the flux distribution in the iron wire will not be uniform over the section and the calculation will be somewhat intricate. Moreover, since μ is not constant the result will be only a rough approximation, but having regard to the large ratio r/r_1 it is not unreasonable to treat each individual wire of the armour as a permeable conducting cylinder magnetized by an external force of value $H = 0 \cdot 2\sqrt{(2)} I \cos\theta \sin 2\pi ft/r$ parallel to the length of the wire and to calculate the resulting eddy loss by means of the Kelvin functions ber $[r_1\sqrt{(\mu f)/\rho}]$ and bei $[r_1\sqrt{(\mu f)/\rho}]$ *

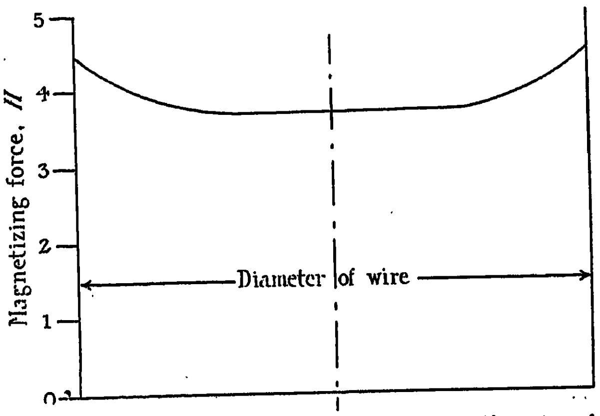

Fig. 1.—Variation of magnetizing force with diameter of armour wire.

For Harvey and Busby's case G, and with $\mu = 500$, ber$[r_1\sqrt{(\mu f)/\rho}] = 0 \cdot 8$ and bei $[r_1\sqrt{(\mu f)/\rho}] = 0 \cdot 8$ approximately, the corresponding differential coefficients being $-0 \cdot 4$ and $0 \cdot 8$ respectively.

Then the eddy losses per cm³ of iron are 0·0046 watt at 100 per cent of I.E.E. rating for the current in the core, corresponding to 0·0076 watt per cm length of cable. In the same way we may arrive at an approximate value for the hysteresis loss. For, writing $r_1\sqrt{(\mu f)/\rho} = x$, and $r'\sqrt{(\mu f)/\rho} = x'$, where r' is the radial distance measured from the centre of the iron wire, the magnetic density in the wire at radius r'

$$B = \frac{0 \cdot 2\sqrt{(2)}\mu I \cos\theta}{r} \cdot \frac{\sqrt{[\text{ber}^2(x') + \text{bei}^2(x')]}}{\sqrt{[\text{ber}^2(x) + \text{bei}^2(x)]}}$$

from which the distribution of flux over the area of one wire may be calculated (see Fig. 1). The variation

* Lord Kelvin: "Mathematical and Physical Papers," vol. 3; A. Russell: "Alternating Currents," vol. 1, ch. 16.

is not very great, but it is enough to make a sensible difference in the eddy losses compared with those calculated upon the assumption of constant density. The average value of B for test G is thus 2 418; whence taking a hysteresis coefficient of 0·003, and using the Steinmetz index, the watts dissipated in hysteresis per cm length of cable at 100 per cent of I.E.E. rating for the current in the core become 0·0064. Adding these to the eddy losses already calculated, we obtain $0{\cdot}0076 + 0{\cdot}0064 = 0{\cdot}014$ watt in iron loss per cm of cable. Now in test G, the difference between the a.c. and d.c. watts when 100 amperes were flowing in the cable was 12, and the length of cable was 26 ft. 7 in. Thus the watts per cm length of the cable were 0·014. This agreement seems to the author to be more than a mere coincidence; it appears indeed to justify the method of analysis and to prove the following points:—

(A) That the flux density in the armour is far greater than that based upon the circumferential flux as given by Harvey and Busby.

(B) That the consequent loss is at least largely due to hysteresis.

(C) That the eddy loss is due chiefly to currents concentric with the armouring wires, and not, as in the case of tubes, to currents flowing longitudinally.

6. Application to Low-Tension Cables.

Returning now to the 0·5 sq. in. lead-covered and armoured cable, we can calculate the loss in the armour on the above basis. With full I.E.E. rating (540 amperes) the result is:—

(1) Hysteresis loss per cm length	0·0854
(2) Hysteresis loss per cm² mean lead sheath surface	0·0088
(3) Eddy loss per cm length	0·1706
(4) Eddy loss per cm² mean lead sheath surface	0·0176
(5) Copper loss per cm length	0·1610
(6) Copper loss per cm² mean lead sheath surface	0·01658

The sum of (1) and (3) is 0·256, and we may roughly compare this figure with that derived from test G by increasing the latter in proportion to the square of the magnetizing force and to the volume of the armouring. This gives for test G, at full I.E.E. rating, 0·206, and at 150 per cent of that rating 0·3470; whence the calculated value is obviously of the right order, and out of all proportion greater than the loss in the lead sheath.

Thus we reach the following conclusion:—

> In low-tension lead-covered and armoured cables the loss in the armour is far greater than that in the lead, and is of such magnitude as to render the use of these cables impracticable for single-phase circuits unless special armouring of high resistance and low permeability is adopted.

With regard to the last suggestion, the case of mining cables calls for special comment, for an armour having a high resistance to eddy currents would almost certainly be impracticable from the standpoint of rule 125 (b) of the Mining Regulations.

7. Application to High-Tension Cables.

The case for high-tension cables differs from the above, due to the much larger ratio of diameter over armour to diameter of conductor. For example, assume that power at 22 000 volts is to be supplied by means of a pair of single-phase paper lead-covered and armoured cables. Then a 0·1 sq. in. cable with standard thicknesses of paper, lead and armouring would have an external diameter and size of armour wire almost the same as those of the 0·5 sq. in. low-tension cable which formed the subject of the last example. The core, however, being only 0·415 in. diameter will carry at most 191 amperes at full I.E.E. rating, and in consequence the maximum possible magnetizing force, the eddy currents and hysteresis losses are correspondingly smaller. The comparison is shown in Table 4.

Table 4.

Actual Losses per cm Length of Cable (spacing 2 in. centres).

	Cable size	0·1 sq. in. (h.t.)	0·5 sq. in. (l.t.)
Losses	(1) In the copper ..	0·1 watt	0·16 watt
	(2) In the armour (eddies)	0·021 watt	0·17 watt
	(3) In the armour (hysteresis) ..	0·016 watt	0·08 watt
	(4) Total armour loss ..	0·037 watt	0·25 watt
	Ratio (armour loss)/(copper loss), per cent	37	156

The loss in the lead is in both cases small compared with that in the armour, and consequently is neglected, but it is abundantly clear from the figures that a good commercial possibility exists for high-tension single-phase armoured cables. For if, in the case of 22 000 volts, the armour loss is only 37 per cent of that in the copper, it follows *a fortiori* that it will be still less with higher pressures where the insulation is thicker. Suppose, for example, that it were required to transmit 191 amperes at 132 000 volts by means of a pair of single-phase armoured cables, the pressure between core and lead being thus 66 000 volts. If we assume first that no intersheath is used and that the R.M.S. potential gradient is not to exceed 40 000 volts, the core will have to be hollow, of an area of 0·1 sq. in., having a diameter of 1·28 in. (3·3 cm). The internal diameter of the lead will be 3·52 in. (9 cm). Taking the thickness of the lead as 0·12 in. and the diameter of the armour wire as 0·104 in., with the usual allowances for bedding, the mean diameter of the armour becomes 4 in. (10·2 cm). Then assuming the same lay for the armour, with $\mu = 500$ and $h = 0{\cdot}003$ the losses per cm length of the cable at full load are:—

In the copper	0·1 watt
In the armour (hysteresis loss)	0·009 watt
In the armour (eddy loss)	0·008 watt
Ratio (armour loss)/(copper loss), per cent	17

This would not be a serious matter, and could in any case be easily compensated by increasing the area of the copper core from 0·1 sq. in. to 0·12 sq. in.; or by adopting an armour wire of special material.

8. Reactance of High-Tension Armoured Cables.

Harvey and Busby have called attention to the importance of the reactance drop in an armoured cable. They have indicated how this can be calculated for a cable enclosed by a tube, but the case of armouring is entirely different. The value of x, the reactance of a wire armour, can be calculated most easily by writing

$$x = \frac{2\pi f \Phi}{10^8 I}$$

where Φ is the flux produced by and encircling the current I.*

Thus if $H = 0{\cdot}2I \cos \theta / r$,

a = sectional area of one armour wire,

w = number of armour wires,

we have Ix = reactance drop per cm due to iron

$= 2\pi f H \mu a w 10^{-8}/l$

In Harvey's case G, with $d = 12$ in., at full I.E.E. rating from this formula

$Ix = 0{\cdot}012\ \mu$ volts per 100 yards of circuit due to the iron

and $Ix = 4{\cdot}8$ volts per 100 yards of circuit due to the air.

9. Impedance of E.H.T. Armoured Cables.

Now the energy voltage absorbed by the losses in the cable can be deduced from those losses as already calculated, and the resulting predicted impedance drop can then be compared with the measured value.

Thus in case G the calculated watts lost in the iron were 0·014 per cm at full load (97 amperes) and this has been shown to be substantially equal to the measured value. The corresponding loss in 100 yards of circuit is 260 watts. Thus this component of energy voltage is $260/97 = 2{\cdot}67$. The resistance of the same length is 0·085 ohm, giving an energy component = 8·25 volts. The total energy component should therefore be about 11 volts. The idle component due to the iron with $\mu = 500$ is $0{\cdot}012 \times 500 = 6{\cdot}1$ volts, and that due to the flux in air is 4·8, giving a total again of nearly 11. The impedance drop therefore is $11\sqrt{2} = 15{\cdot}5$ volts. The measured value is 16·5. This is certainly as near as one could expect from the nature of the calculations, especially when it is remembered that the tests in this case show a considerable variation in μ at about this current. Thus it may be said that the method of predicting the results again is justified and is consistent with all that has gone before.

If we take case E, a similar calculation shows that the predicted result agrees with the test figure if $\mu = 700$. With regard to the error in case G it should be remarked that analysis of the test figures indicates that the discrepancy lies in underestimating the idle component. This is without doubt due to neglecting the flux leaking from wire to wire along the armour, to which attention has been called earlier in this paper.

The above method may now be applied to ascertain the probable impedance drop at full load in the 132 000-volt cable. We have already found the energy losses per cm length to be 0·117 watt, so that the energy voltage-drop per cm is 0·117/191 = 0·000613, corresponding to 4·451 volts per 100 yards of circuit. Suppose the cables to be again 12 in. apart. Then the idle voltage component corresponding to the same length due to the flux in the air is 5·04 volts, while that due to the flux in the armour ($\mu = 500$) is 12·12. Thus the reactance voltage is 17·16, which when combined with the energy component gives an impedance drop of about 18 volts, or nearly 3·6 times as much as for the unarmoured cable. There is, however, no reason why such a pair of cables could not be laid close together, when the impedance drop could be reduced to about 14 volts per 100 yards' run, or say 25 000 volts (i.e. about 19 per cent) in 100 miles' run. This is not an impracticable figure; and we conclude as before that the presence of armouring is no bar to the successful application of lead-covered cables to e.h.t. transmission.

A far more serious question is the great capacity current inseparable from such a system. For on the assumption that the lead sheath and armour are both earthed, as would be necessary to prevent danger, the capacity of the paper-insulated 132 000-volt cables would be about 0·3 μF per mile. At 50 periods per sec. this means a capacity current of about 6 amperes per mile, or 1 200 amperes per 100 miles' run in a cable whose normal full-load current does not exceed 191 amperes. Special means would obviously have to be adopted to overcome this disadvantage, but such matters do not fall within the scope of this paper.

10. Effect of an Intersheath.

The introduction of a conducting intersheath reduces the diameter of the cable for a given voltage, and in consequence both the inductive and capacity reactances are somewhat increased. Thus cables with intersheaths are less favourable from the point of view of this analysis; not to such an extent, however, as to render them entirely impracticable. For while the loss per cm^3 of armour wire is somewhat larger, the volume of the armouring is distinctly less, so that the net result is only a small change. On the other hand, the intersheath is a help in dealing with the capacity currents. We may summarize our conclusions as follows:—

(1) Both the losses and the reactance due to the presence of armour wires about a lead-covered cable can be fairly predicted.

(2) Lead-covered armoured cables for single-phase low-tension transmission are impracticable on account of the large losses and high reactance introduced by the armouring, unless the armour wires be made of special material having very high resistance and low permeability. Such armouring, however, would be inadmissible under the General Regulations made under the Coal Mines Act, 1911.

(3) Lead-covered armoured cables for single-phase e.h.t. transmission are quite practicable in so far as losses and inductive reactance are concerned; but their high capacity when used for long distances would need special consideration.

DISCUSSION ON "RAILWAY ELECTRIFICATION IN FOREIGN COUNTRIES." *

WESTERN CENTRE, AT CARDIFF, 7 JANUARY, 1924.

Mr. J. W. Burr: It is obvious that this country is a long way behind in the matter of railway electrification, and this seems to be due to indecision as to whether single-phase, three-phase, or direct current should be used. I recently read a statement to the effect that a considerable reduction in the weight of locomotives was being brought about, and that a locomotive weighing about 60 tons could be made to give about 2 000 h.p. How does this figure compare with those mentioned by the author?

Mr. H. Kilgour: To the list of railways cited by the author might have been added one possessing some rather interesting features: this is the light railway running from Indianapolis to Rushville, a distance of about 45 miles. The motor coaches carry transformers and the motors are of the commutator type adapted to run on about 500 volts, either direct or alternating. Within the boundary of Indianapolis the supply is direct current, at the city boundary the supply is 3 000 volts (a.c.) and transformers are used, while at the Rushville city boundary the supply is at 500 volts (a.c.) and the transformers are cut out. The expresses make the journey in about 45 minutes, the right of way being private. The equipment was supplied by the Westinghouse Co. and, since I last saw the railway in 1906, has probably been considerably changed, as experience had even then shown that the motors suffered rather rapid deterioration and needed frequent attention.

Mr. S. B. Haslam: In 1901–2 I was connected with the Taff Vale Railway when that company were seriously considering the question of electrification, and, in association with the late Mr. T. Hurry Riches, the locomotive superintendent at that time, I went into the subject fairly closely. The outcome of careful deliberations was a decision that electrification was not suited for the short runs with very heavy goods traffic such as obtained in South Wales, but a sort of half-way system was adopted of running motor coaches on the line. The result of those deliberations was described in a paper read before the Institution of Mechanical Engineers.† At that time the only possible electrification was on the 500-volt d.c. system. In those days also the third-rail system was considered highly dangerous and the directors would not consider anything but the overhead line system, the cost of which on a 500-volt d.c. system put the matter right out of court. Recent investigations on the question have, however, shown the question in a very different light. It has always been a moot point among railway engineers as to how to deal with goods traffic in a district such as South Wales, in which the goods traffic predominates. Such runs as that from Cardiff to Penarth offer ideal conditions for electrification, and further up the Rhondda Valley it is surely a very different question, not so far as the actual running is concerned but as regards the collecting of the coal trains and the delivery and sorting of the empty trucks.

Major E. I. David: The decision of Sweden to adopt railway electrification was a sequel to the British coal strike of 1921. The Government of Italy was forced to take steps for electrification because of that strike and because of the abnormal prices of British coal which ruled in 1921. Switzerland's decision to electrify its railways was not prompted by commercial considerations but by a purely patriotic motive. The capital cost of most of its large hydro-electric stations was in the neighbourhood of £120 to £140 per kW, equivalent to a yearly capital charge of from £14 to £15. If the stations had been run on coal the capital charges would not have been more than £25 per kW installed. In fact, the actual running costs were higher after electrification than before. At the time that the Swiss railways were being electrified there was produced in that country a most efficient turbine-driven condensing locomotive. The turbine and gear were made at Zurich, and the whole equipment ran very smoothly. The air-cooled condenser was fixed in a cab at the back of the locomotive, and the vacuum was 27 inches when the machine ran at 40 m.p.h. The overall efficiency was about 70 per cent, an abnormally high figure for so small a turbine. As to the position of the South Wales railways, these short-distance lines, with fixed and definite gradients in the downward direction appear to be ideally situated for a system of electrification, particularly one which could employ regenerative control. The question of erecting super-power stations need not arise, because the stations of the South Wales Electrical Power Co. or other large private generating plants could be used without any restrictions. A system employed so successfully on motor-cars, namely, a driving motor at right angles to the axis of the axles, has not been attempted on railway work. From 400 to 500 h.p. has been transmitted in this way on some large racing cars and there seems, therefore, to be no reason why from 2 000 to 3 000 h.p. should not be transmitted in the same way. By this means absolute flexibility is obtained in a vertical direction. Variable-speed a.c. commutator motors have been used for electric winder drives giving regenerative control, and the only objection that I could raise was the large number of brushes (about 200 sets) on each motor. We are constantly being told that railway engineers have to solve most difficult problems, particularly in regard to suburban trains, the London Underground Railways being instanced. It is pointed out that the trains have to accelerate up to 30 or 40 miles in the space of $\frac{3}{4}$ mile and stop in another $\frac{1}{4}$ mile.

* Lecture by Dr. S. P. Smith (see vol. 62, p. 317).

† *Proceedings of the Institution of Mechanical Engineers*, 1906, pts. 3 and 4, p. 651.

The problem of the colliery winding engine is, however, that it has to accelerate to 60 m.p.h. and to come to rest in about 45 seconds over a distance of some 700 yards.

Prof. F. Bacon: The number of different electrical systems in vogue on the Continent is very large and it is useful to learn the circumstances which led to the adoption of those systems. I do not think that British engineers pay sufficient attention to what is being done in other countries. Apart from such men as the author, who pay frequent visits to European countries, the average British engineer has a habit of neglecting the lessons which can be learnt from Continental experience. I should like to ask the author whether he found the overhead constructional work on the Continent somewhat shoddy and of a kind that would not be tolerated in this country. Even such good engineering countries as Switzerland and Italy do not seem to have much respect for high-tension lines; they hang them up in the same casual way that we adopt in the case of telephone wires. It is difficult to see from the lantern-slides of the driving mechanisms how the flexibility is obtained. With these arrangements of links and cranks is there ever any difficulty in starting?

Mr. W. Nairn: In dealing with the question of substations and the transformation of high-tension three-phase currents to direct current, Mr. Roger Smith in a recent paper mentioned an apparatus which he called a transverter. I should be glad if the present author could give any information as to this.

Mr. W. J. Bache: Is the connecting-rod system of drive being superseded simply because the geared drive offers greater advantage, or are the inherent faults of the connecting-rod drive the cause of it being substituted by the geared system?

Dr. S. Parker Smith (*in reply*): With reference to Mr. Burr's remark, it might be mentioned that three-phase locomotives weighing 60 tons and rated at 2 000 h.p. were working in Italy as long ago as 1909. It is well known that the weight per horse-power in three-phase locomotives is very low, but great advance in this direction with other types has resulted from the adoption of gearing and high-speed motors.

Mr. Kilgour cites an interesting case of a light railway in the United States worked on a mixed system. In some cases these have been converted to d.c. working—the system that should have been adopted from the outset for the prevailing conditions.

The lecture was confined chiefly to main-line working. As Mr. Haslam says, views regarding the use of a third rail have changed greatly since 1901–2. An overhead line with 500 volts would be generally condemned. Possibly the present-day solution of his problem would be a d.c. system with third rail and locomotives, while battery locomotives would be used for shunting, etc.

Major David's figures illustrate well how much countries are now prepared to pay for economic independence. The high cost of Swiss stations was doubtless due in great part to the war, but probably the annual capital charge would be less than the figures given owing to the long period taken for repayment of hydro-electric works. Experiments are being made with a driving motor at right angles to the axis of the axles, but results do not appear to be forthcoming as yet.

In reply to Prof. Bacon's question, the overhead constructional work on Continental railways is usually of a lighter type than that met with here, though, generally speaking, it would be going too far to call it shoddy. Flexibility in the driving mechanisms is usually obtained by mounting springs inside the pinions of the gearing.

Replying to Mr. Nairn's question, as far as the lecturer is aware the transverter is not yet out of the experimental stage.

The geared locomotive, referred to by Mr. Bache, finds favour because the high-speed motors used with it lead to reduced cost and weight.

DISCUSSION ON

"PULVERIZED FUEL AND EFFICIENT STEAM GENERATION." *

WESTERN CENTRE, AT BRISTOL, 4 FEBRUARY, 1924.

Mr. A. J. Newman: I am convinced that one of the great reasons for the large development of pulverized coal in America can be traced to the fact that some of the larger concerns want large boilers, and I think it is the largeness of the boilers rather than the greater efficiency that has tended to develop other means of firing than mechanical stoking. My own view is that the alteration of existing plant seems impossible on account of the large furnaces that are necessary with pulverized coal. I feel that there is more than a little danger from ash and clinker troubles, but the author states that this has been removed by the introduction of a water screen, and that there is no slagging is certainly a point in favour of the Lopulco system. The figure given by the author of 2·5 per cent ash emission is, in my opinion, very low. In existing plants it is almost impossible to bring it down to 2·5 per cent.

Mr. W. E. Hardy: When reading the paper I had some difficulty in reconciling some of the author's remarks. In the summary prefacing the paper he says: ' The author is of opinion that the advantages in the aggregate of pulverized fuel are so great that they constitute almost a revolution in steam-boiler practice." Then under the heading of "Conclusion" he says: "It is, therefore, not altogether an easy problem to decide whether for a new plant pulverized fuel should be used in preference to mechanical stoking." Again, in speaking of a number of the big American stations, he states that " the decision to adopt or reject pulverized fuel has in a number of cases been a very close one." The author has, however, now definitely stated that he is in favour of pulverized fuel. In the last Annual Return made by the Electricity Commissioners the best overall efficiency of any power station in Britain is given as 17·8 per cent. Can the author say what is the figure for the Lakeside station?

Mr. J. W. Fidoe: The boiler plant described is in essentially larger units than that used in the majority of power stations, and this factor may to some extent affect the comparison of results. The minimum size of boiler for which the central pulverizer system is suitable appears to be between 50 000 and 80 000 lb. of steam per hour, but the units described are much larger. Boiler efficiency is limited by unburnt coal in the ashes, and by radiation and heat lost in the chimney gases, and as it does not seem possible to reduce these losses below 8 per cent the results stated represent a near approach to economic possibilities. The large combustion chamber with its double walls is a new feature permitting pre-heating of the air and at the same time reducing radiation loss; the application of double walls to boilers fitted with mechanical stokers is well worth consideration, since air leakage in boiler settings is one of the difficulties in the way of maintaining high efficiency. The ash and clinker produced in the combustion of coal is a problem which the users of mechanical stokers have to consider. Coals with a high ash content can be burnt successfully if the clinkering is not excessive, but it appears that by pulverizing the fuel inferior grades can be burned, provided the volatile matter is not too low. The melting point of the ash in coal is a chemical question, and in the use of mechanical stokers is generally ignored, but by taking samples and analyses of the ash much trouble can be avoided and higher boiler efficiencies obtained. A coal having an ash high in silica and low in bases, or vice versa, does not readily clinker, but if mixed with another coal containing ash of different composition troublesome clinkering will occur. The use of the water screen in the bottom of the combustion chamber indicates a preference for a coal with a fusible ash, and I should like to ask if this is so. In previous experience with pulverized coal firing of boilers much trouble has been caused by dust being blown out of the chimneys, and one large plant in this district had to be shut down on that account. The explanation given as to the dust produced being of so fine a character as not to settle within a wide radius of the boiler house is very interesting, but will need further confirmation before it can be generally accepted. The use of mechanical stokers has been hampered in the past by the limitation of width to about 8 ft., rendering several grates necessary if large boilers were to be used. The construction of the firebrick arches presented a serious drawback to greater widths of grates, while the necessary division walls meant a loss of 18 in. in width of furnace for each stoker, with consequent reduction of grate area and coal burnt. The flat suspended arch has removed the trouble with the brickwork, curved surfaces and division walls being no longer required, but there is still a limit to the width of the ordinary mechanical stoker. At the present time a new type of stoker with a width between side walls of 12 ft. is being installed locally, and, judging from its design, there does not appear to be any mechanical obstacle to making grates of double that width with an area of over 500 sq. ft. in a single unit. Progress on these lines will provide a formidable competitor in the firing of large boilers, as the cost of setting and driving equipment should be less than for the pulverizing system.

Mr. W. Nairn: I had occasion to burn oil fuel during the coal strike of 1921 and, as it was not a commercial proposition to continue on oil when coal again became available, I considered whether it would be possible to use pulverized coal in the oil furnaces. I found, however, that the combustion space was much too small to permit of the use of pulverized fuel, and

* Paper by Mr. D. Brownlie (see vol. 62, p. 385).

accordingly mechanical stokers were re-installed. I mention this fact to make it clear that there are very few boiler plants in the country to-day with settings suitable for pulverized fuel and one hears of proposals to install pulverized plants on Lancashire boilers, a duty for which they are quite unsuitable.

Mr. T. Hood : The question of fuel economy is one that every engineer should have at heart. My knowledge of local affairs confirms the author's remarks respecting the serious waste that is prevalent. In a certain colliery not far from Bristol, using Cornish boilers and non-condensing engines with steam at 60 lb./sq. in., the fuel consumed is one-third of the total coal wound from the pit. On the other hand, the consumption at the Great Western Colliery, Pontypridd, is, I believe, 2 per cent of the total coal wound. It would appear that colliery owners are not entirely blameless in this vital question. There are many technical institutions such as those in London and Sheffield where fuel technology is closely investigated, and I should very much like to see established, all over the country, centres at which any industrial owner could apply for guidance respecting the virtues of different kinds of apparatus that are claimed to increase boiler house efficiency.

Mr. R. Hodge : In view of the author's statement that the approximate cost for large stations employing pulverizing plant is about equal to that of mechanical stoking plant, it would be interesting to have his opinion as to what the percentage increase (if any) in prime cost would be for a new station employing three 5 000-kW turbo-alternator sets, assuming the steam consumption to be approximately 11·5 lb. of steam per kWh on boiler plant working at 200 lb./sq. in., the total steam temperature being approximately 600° F.

Mr. H. F. G. Woods : The point in the paper which particularly impressed me was the possibility of using the bye-product breeze of the low-temperature carbonization process. In this connection it would be interesting if the author could state the minimum volatile percentage with which the Lopulco system will satisfactorily deal, since, as there does not appear to be any immediate prospect of obtaining large and regular supplies of low-temperature coke, it would seem that a most advantageous application of that system would be to employ it for the use of coke-oven breeze. With regard to the first cost of the pulverized fuel system as compared with that of a plant employing mechanical stokers, the cost of buildings in each case must, of course, be taken into account. The great height of the boiler houses necessary with plants employing the Lopulco system must make a heavy additional cost which will be a serious offset against the undoubtedly numerous advantages of the pulverized-fuel system. It would be instructive if the author would give some indication of the extent to which the cost of buildings is affected by the installation of pulverized-fuel plant.

Mr. D. Brownlie (*in reply*) : Many of the points raised have already been dealt with in my general reply to the whole of the discussion, but I would say very briefly that pulverized fuel is a revolution in steam generation because it has altered entirely all our views on the subject and has also resulted in great improvements in the competitive system of mechanical stoking.

Since the paper was written, boiler plant efficiencies as high as 92·5 per cent are being obtained in the United States with both methods of firing, and I believe that the overall thermal figure at Lakeside is approximately 17 250 B.Th.U. per kW, although it must be remembered that this covers many items other than merely steam generation and pulverized fuel. Finally, mechanical stokers are now being constructed up to 24 ft. in width because of the developments of the suspended arch, and, so far as I know, the Lopulco system will burn fuel containing as low as 3 per cent volatile matter.

DISCUSSION ON "THE DESIGN OF APPARATUS FOR THE PROTECTION OF ALTERNATING-CURRENT CIRCUITS." *

WESTERN CENTRE, AT PLYMOUTH, 17 APRIL, 1924.

Mr. W. Nairn: The most important application of the author's system is the complete protection of any feeder or distributor in the most complicated networks. Such protection in the case of ordinary three-core cables has until now been obtained with the Merz-Price system of protection, and one of the principal objections to this system is the difficulty of balancing the transformers. This difficulty leads to the irritating opening of healthy sections during the passage of fault currents and also entails extra work when cutting in a new substation on a ring main. If the new substation B was between substations A and C, the transformers in C have to be removed to B to balance with those at A and a new set of six transformers have to be installed at B and C. To make the protective gear completely reliable, I should like to know if the author has any suggestion to make for the supply of current for the tripping circuits in substations. This supply is now often taken from primary batteries; these require an inordinate amount of supervision and, if this is not given, the protective gear may fail at the crucial moment and the benefits of protection will be nullified.

Mr. H. F. G. Woods: I am of opinion that systems employing pilot wires should be avoided in connection with the protection of transmission lines, since the pilot wires themselves constitute a source of weakness which adds additional risk to the continuity of the supply. Personally I believe that the plain straightforward overload and reverse-current protection of parallel feeders is preferable to the use of a system employing pilot wires, although the objection to the former is that it is not in all cases sufficiently discriminative. The author's system of biased relay protection introduces a stabilizing factor which would appear to have done much to solve the problem of providing efficient protection without pilots. The system also offers the advantage that it is possible to tap off small loads at intermediate points on parallel feeders. The switchgear shown on the lantern slide is now being erected in the main substation at Torquay, and the author's system of feeder protection is being used in connection with it to protect two parallel feeders between that substation and the power station at Newton Abbot, about 7 miles away. At an intermediate substation about half way between Newton Abbot and Torquay, a supply is being tapped off each line alternatively to the extent of some 200 kVA.

Mr. J. H. Thomas: It seems to me that the introduction of the biasing transformer, which is the chief point of novelty, is adding a good deal of complication without giving sufficient compensating advantages. The biasing principle has been generally applied in connection with relays and is, I believe, a satisfactory method. The particular relay which I have in mind is the McColl relay, in which the biasing can be done either mechanically, the bias being obtained by adjusting the balance of the beam, or electrically. Referring to Figs. 6, 7 and 9, the biasing transformer does not appear to have much advantage over the use of biased relays. The phantom switch arrangement is certainly very ingenious. With regard to the use of biasing transformers with split-conductor systems, it seems to me again that they add an additional complication without sufficient compensating advantages, and it is sometimes said that the ordinary arrangement is too sensitive. The later figures in the paper seem to be very complicated, and it must be borne in mind that the internal connections of the biasing transformers are not shown in these. It seems to me that we should endeavour to use the simplest possible arrangement utilizing standard and strong apparatus.

[The author dealt with the questions raised in this discussion in his reply published in the *Journal*, 1924, vol. 62, p. 619.]

* Paper by Mr. A. S. FitzGerald (see vol. 62, p. 561).

DISCUSSION ON

"POWER CIRCUIT INTERFERENCE WITH TELEGRAPHS AND TELEPHONES." *

NORTH-EASTERN CENTRE, AT NEWCASTLE, 10 NOVEMBER, 1924.

Mr. W. T. Dalton: I recognize some of the rotary converter tests as being those taken on the Newcastle machines when I was present, and I should like to mention that the diagram and description of Prof. Miles Walker's method for ascertaining the pitch note (vol. 62, p. 843) was employed by him during the tests and investigations which were carried out on the converters to which I refer. The bottom oscillograph in Fig. 14, showing converter No. 1 running alone, was taken after this machine had been altered as the result of the tests referred to in the paper. The work of altering the main poles was carried out in our own workshops, all north poles being moved 0·419 inch in one direction and all south poles the same distance in the opposite direction, thus giving alternate wide and narrow gaps between adjacent poles. The commutating poles were not altered. The commutation of this machine after the alterations was unaffected and it ran perfectly. Converters that have since been ordered of the same kilowatt capacity have been constructed with the same arrangement of pole spacing. It must not be argued from this that the same treatment could be applied to all machines, as some later rotary converters of smaller size and different speeds were supplied with the main poles skewed only, with satisfactory results. Referring to Fig. 15 (No. 4 rotary) no explanation is given as to why the current in the negative cable is greater than that in the positive cable. The positive and negative sides of this machine are each connected to the switchboard by two 0·750 inch cables in parallel. Mr. Aldridge mentioned in the London discussion that the curves marked 15 (Fig. D) were taken simultaneously each from 100 turns of wire wound directly over the respective cables. With two cables in parallel, however, the total current of the machine may not divide equally between each cable, due to a possible difference of contact resistance at the terminals. Whether this is the correct explanation could only be proved by repeating the test with the 100 turns of wire embracing both parallel cables on the positive and negative sides respectively. Interference on telephone and telegraph lines may be classed under three headings: (1) Earth current interference, (2) induction interference, and (3) electrolytic action on underground cables and pipes. Some 24 years ago I was present at some tests on an overhead telegraph line where it was alleged that a tramway running parallel with it caused disturbances. A special car was run when the rest of the system was shut down, and the times of switching the car controller on and off, and the times of the kicks recorded on the tape of the siphon recorder connected to the telegraph line, were found to coincide. This was a simple problem, as by duplicating the line, thereby doing away with the earth return, the trouble was overcome. This shows that the interference was due to the telegraph line being in electrical contact with the power lines, not through any fault, but simply because both parties were using the earth as a return. Tramways in this country, however, are constructed with an uninsulated return, and I do not see how they could be run otherwise except at great sacrifice of efficiency, but I should like to ask the author if, having regard to the great development of electrical power that is now taking place in this country, he is able to predict that the future will see a telephone system designed with its lines and all parts of its equipment insulated from earth. Such a desirable state of affairs would remove much of the trouble from which modern telephone systems appear to suffer. I agree that we must try to appreciate each other's difficulties with a view to solving these problems of interference, but it is unfortunate that in the development of the rotary converter and modern telephone systems the designers of each appear to have unintentionally reached a state of affairs whereby the former creates disturbances for the latter to receive with such completeness that had they deliberately set out to achieve this result they could not have been more successful. This paper will cause future users of converters to insert clauses in their specifications to provide for the machines which they purchase being free from the liability of causing interference to telephone and telegraph lines, and had some of the information contained in the paper been kept less secret when converters were first found to give trouble due to tooth harmonics it would have warned designers and purchasers of what they should guard against, in which case some of the later machines might never have had to be altered. Some of the converters referred to in the paper had been in service five or six years before any complaint was made as to their causing interference, and power undertakings do not welcome the suggestion that they must pull their plant to pieces and reconstruct it. The author, in replying to a speaker in the discussion at another Centre, appears to regard the risk of interference due to electrolytic action as being serious. While there may be isolated cases of such trouble, I do not think that there is much danger to be feared from this cause on British tramways. If there is any doubt as to the correct disposition of the negative feeders on a tramway, investigations may be carried out by constructing a model of the system. A suitable room should be available where a skeleton map of the system can be chalked on the floor. (A convenient scale would be 4 ft. to the mile, or 1/1 320th.) The track and negative feeders would be constructed of wire of correct

* Paper by Mr. S. C. Bartholomew (see vol. 62, p. 817).

resistance (to scale), the former being pinned to the floor over the chalk lines, care being taken to see that all the joints were carefully soldered. The negative feeders would be made up as wire spirals, each having a resistance equal to the value of the corresponding feeder multiplied by 1 320. The method of loading up the track would be obtained by taking average readings from all the feeder ammeters in the power station or substations and dividing by 1 320. Current representing the tramway load could be fed into the various routes, and the model then explored with a voltmeter. The results can be compared with the voltmeters on the Board of Trade panels, and the negative cables on the model may then be altered to meet any desired conditions. It is possible to imitate the boosting of the rails on such a model. The rails of a tramway system with the negative cables form closed circuits of low resistance, and the current values follow Kirchhoff's law of superposed currents. There should therefore be no difference of voltage between the various points on the rails where the negative cables are connected to the rails. Any such negative point that is at a higher potential in relation to another negative point should have the corresponding feeder increased in section, or the negative points at lowest potential should have resistance inserted.

Mr. F. G. C. Baldwin: The subject dealt with is one which has been regarded by many as most contentious, and it is one upon which widely different opinions have been expressed. It is, however, a fact that the problem is equally important to electrical engineers generally, both those engaged in the lighter and those in the heavier branches. Although different interests are concerned and divergent views are held, it is pleasing to testify to the very amicable relationship which obtains in this district between engineers of the Post Office and of power supply and electric traction undertakings, and which the activities of the Institution have done much to engender. The problem of interference, serious as it is at present, is likely to become of even greater importance as the telephone and telegraph and electric power supply systems develop, a development which all electrical engineers are anxious should take place in the fullest measure. To the interference already experienced in ordinary telephone and telegraph working must now be added the possibility of interference to broadcasting. There are now approximately a million listeners licensed to receive broadcasting, and it is essential that their interests should be safeguarded. It would seem that the increase of extra-high-tension overhead lines may be injurious to undisturbed reception in broadcasting, by reason of the fact that such lines virtually constitute transmitting aerials. Can the author say if any cases of interference to broadcasting from this cause have occurred, or if interference is anticipated? It is customary, and perhaps not unnatural, to chafe under control, but attention is drawn to the chaos which has resulted in America from the absence of suitable control in regard to broadcasting and to the contrast between that state of affairs and the far superior arrangements in vogue in this country. This has a parallel in the matter of interference. It is believed that in America it has been necessary to set up numerous committees throughout the United States for the purpose of dealing with local questions of interference. In this country the services of such committees have been rendered unnecessary by the system of control which is in operation.

Mr. C. Whillis: The author apologizes for presenting certain portions of his subject matter in an elementary way, but no apology is needed in this connection. If co-operation is to be effective, each side must understand the problems with which the other contends, and in my experience this is just the rock on which co-operation is likely to split. The power engineer, for example, has difficulty in realizing the extreme sensitiveness of a telephone receiver, while the telephone engineer labours under a similar disadvantage with regard to many power problems. Such difficulties are very clearly dealt with by the author and it is quite certain that his paper, carefully studied by both the interested parties, will go a long way to produce that sympathetic appreciation of mutual difficulties which is essential to successful co-operation. Fig. 18, which shows the twist system of transposition of communication line wires, does not tell the whole story. A uniform system of this kind is satisfactory for circuits of moderate length and light gauge, but with long circuits of heavier gauge, trouble is experienced between contiguous groups, and it is necessary to introduce transposition crosses in addition. Should power circuits exist alongside sections of a long route, tertiary effects would accentuate this trouble. For the reasons stated in the first paragraph on page 840, I think that it is somewhat dangerous to set up different standards of permissible interference for telephone and telegraph routes. In this country telephone and telegraph circuits are so intimately associated, both on open routes and in cables, and main routes are so interconnected with cross-country routes, that the risks of tertiary effects are very great. On page 846 the author indicates that extremely high voltages are in some cases impressed on communication lines. It would appear that such voltages might be a source of danger not only to internal plant but also to men working on communication lines at points remote from the existing power system. Have any such cases arisen in this country?

Mr. R. W. Gregory: Mr. Dalton has mentioned his experience with a machine which, after running without causing interference for five or six years, became a trouble to the telephone system when changes in design were made to the latter. This, of course, shows us that it is advisable to look to the future. It is quite certain that, if this country is to be "electrified," we must look for large developments in the mileage of overhead power lines during the next few years, and at the same time we must expect a large increase in the number of telephone subscribers in the country before "saturation" is reached. Moreover, I take it that the tendency in telephony, as in power supply, is to increase the amount of automatic apparatus. I should be glad if the author would say whether the automatic telephone systems which may be adopted in the future are any more liable to interference than the existing manual systems, and also whether any

special precautions against interference are necessary owing to the use of automatic telephony.

Mr. H. Kitchen: The balancing of lines and apparatus is common to all metallic circuits installed by the Post Office Engineering Department, and every care is taken to eliminate electrical disturbances from outside sources. Whether these methods are successful or otherwise, the public is left to judge. Recently a valve amplifier has been introduced by the Post Office, and this device can be attached to any subscriber's telephone. This innovation is a boon to those who are somewhat deaf, but it has the drawback inherent to all amplifying devices, that it not only amplifies the sound waves but increases other noises. Minute disturbances, which are not noticeable on a long trunk circuit under ordinary conditions, become audible when an amplifier is used, and the elimination of extraneous noises becomes a more pressing proposition. Mr. Gill's Presidential Address quoted by the author has already borne fruit, and a committee of telephone experts from most of the European countries has decided upon a programme of long trunk lines, which will place England in communication with places as far distant as Genoa and Madrid. The problem of the elimination of disturbances due to electric tramways, railways and other systems will be a very difficult one. Can the author say whether any special measures have been decided upon?

[The author's reply to this discussion will be found on page 394.]

North Midland Centre, at Leeds, 9 December, 1924.

Mr. W. E. French: I should like to supplement the author's remarks on slot harmonics by some facts which may not be common knowledge; any statement on slot harmonics is of importance, as they seem to be among the main offenders in power-circuit interference. Before dealing with these harmonics proper, it is necessary to touch on "phase-changed" higher harmonics, which Zenneck first observed with the simple

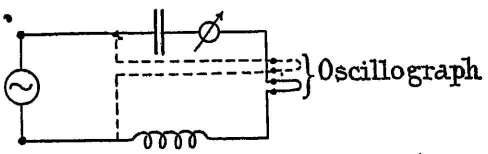

Fig. H.

experimental circuit shown in Fig. H. A circuit containing capacity and self-induction in series is connected to the terminals of an alternator. The wave-shapes are taken by an oscillograph. By choosing suitable values for the adjustable capacity and self-induction the natural frequency of this circuit can be tuned to any harmonic present in the generator. In this way it

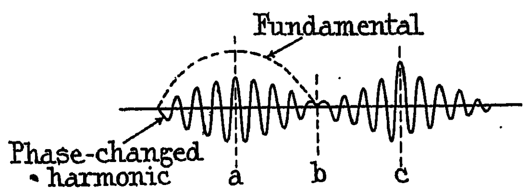

Fig. J.

becomes possible to sift out any desired harmonic, and subject it separately to investigation. They will mostly appear as pure sine waves and are classed as normal harmonics. There are, however, other harmonics possible (shown in Fig. J), and known as abnormal harmonics. It will be noticed that after one-half of the fundamental period has elapsed, a phase-change of 180 degrees in the E.M.F. or current wave has taken place at a time indicated in the diagram at "a." From here onwards there exists in the resonance circuit an E.M.F. which is in opposition, and which gradually reduces the amplitudes to zero; this occurs at the point "b," where the phase-change becomes definitely visible. An inspection of Fig. J might suggest that this curve is the resultant or beat curve of two having different frequencies. This is not the case, and there is only one single harmonic present. Such phase-changed harmonics have been investigated by Zenneck and Rogowski, and a very complete discussion will be found in *Annalen der Physik* (1906, vol. 20). The next step is to show that such abnormal harmonics may be present in generators. In most textbooks the calculation of the induced E.M.F. is based on a distribution of the flux densities such as

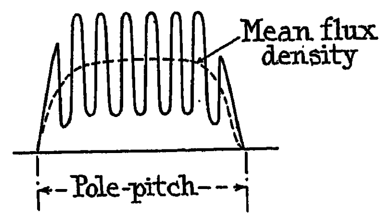

Fig. K.

occur with smooth-core armatures; this is somewhat misleading as it tempts the unwary to overlook the influence of the field fluctuations. The latter are a result of the varying values of the permanence as slots and teeth pass a given point of the pole shoe. The field curve will in reality assume a shape similar to that shown in Fig. K. The field curve has decided higher harmonics with amplitudes varying about the mean curve of flux density, the latter serving as the basis of calculation of the generated electromotive force. The period of these harmonics depends on the slot pitch, and their frequency can be calculated from the relation given by the author, viz. $F = N \times S \times R/60$. Their amplitude must depend on the relative values of width of tooth, teeth saturation and radial length of air-gaps. It is not unusual to design alternators with an even number of teeth per pole. The result is that the higher harmonics will also be even. On the other hand it is well known that normal, even harmonics can have no existence in the wave-shape of such machines.

Therefore tooth ripples of an even order can enter into the alternator wave-shape only as phase-changed higher harmonics, when the symmetry of the alternator wave is preserved. The presence of the phase-changed harmonic may be explained as follows: Let there be a whole number of slots per pole arc in Figs. L (*a*) and L (*b*). In the position " a " the number of flux-carrying teeth is a minimum, while in position " b " that number becomes a maximum; thus the permeance of the main flux undergoes considerable periodic fluctuations. Hence the main flux will be subject to periodic variations, the period of each change corresponding to the slot

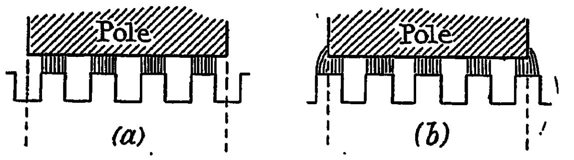

FIG. L.

pitch. These flux pulsations will be most effective when coil centres and pole centres coincide. When the coil sides are under the pole centres the flux pulsations will be of minimum effect. The flux pulsations are of the same phase, but of opposite sense under consecutive poles. The position of centre-line coincidence of coil and pole being that of maximum flux linkage with respect to the higher harmonics, their maximum voltage will be induced in this position. As the coil travels in the direction of the arrow (Fig. M) the coil linkage with the flux pulsations will decrease until zero linkage is reached in the neutral zone. The resultant E.M.F.

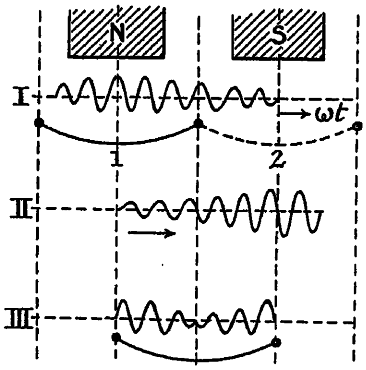

FIG. M.

curve so obtained is shown in Fig. M, I. Simultaneously, as the coil passes from right to left, it will gradually be subjected to the influence of the south pole until the coil centre reaches mid-pole position south. The resulting E.M.F. curve is shown in Fig. M, II. If these two curves are superposed, the E.M.F. curve due to the field pulsations is found, and is shown in Fig. M, III. This curve is obviously a phase-changed higher harmonic as demonstrated by the experiments of Zenneck. The influence of this harmonic on the fundamental E.M.F. wave is comparatively small. In this connection it must be remembered that the phase-change takes place when the coil sides are in the centre-pole position. As this is also the position of maximum E.M.F. of the fundamental, the phase-change of the harmonic will occur near the minimum value of the fundamental E.M.F. wave. Superposing the higher harmonic on the fundamental in this sense (Fig. N) it will be seen that its effect is not marked, and that the resulting wave closely

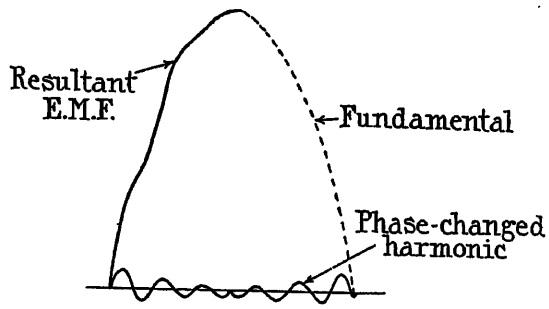

FIG. N.

approximates to a sine curve. Another case may be cited, when the pole arc contains a fractional number of the slot pitch [Figs. O (*a*) and O (*b*)]. Here no pronounced variation exists in the permeance of the main field, the number of flux-carrying teeth remaining sensibly the same. An inspection of the positions

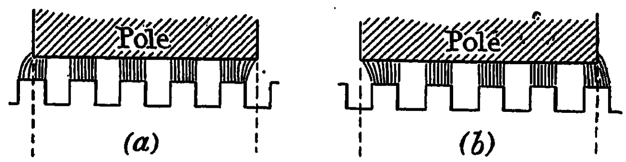

FIG. O.

[Figs. O (*a*) and O (*b*)] will show the possibility of a flux-swing in a direction opposite to the armature rotation. This oscillation must have a maximum effect on the coil sides which are in the centre of the poles, thus producing a phase relation of the phase-changed higher harmonic with respect to the fundamental wave, which is

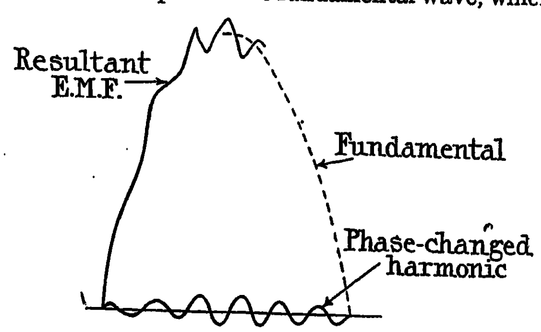

FIG. P.

exactly opposite to that in the previous case, i.e. the phase-change will occur in the neighbourhood of the maximum of the fundamental wave. Again, superposing the higher harmonics on the fundamental in this sense (Fig. P), it will be observed that its effect is considerable. These harmonics are also present in non-salient-pole alternators. The remedies are similar in both types of

machines, viz. high tooth saturation, relatively large air-gaps with small slot-openings; in salient-pole generators a pole arc which is as near as possible a whole multiple of the slot pitch; with non-salient-pole machines a different number of teeth in rotor and in stator. Another method is the "skewing" of the field, mentioned by the author as applicable to the salient and non-salient types for the suppression of higher harmonics. In conclusion I would suggest the following additions to the author's bibliography:—

WORRALL, G. W., and WALL, T. F.: *Journal I.E.E.*, 1906, vol. 37, p. 148.

ZENNECK, J., and STRASSER, B.: *Annalen der Physik*, 1906, vol. 20, p. 759.

ROGOWSKI, W.: *Ibid.*, 1906, vol. 20, p. 766.

ARNOLD, E., and LA COUR, J. L.: "Die Wechselstromtechnik," vols. 4 and 5.

Mr. G. W. Hammond: In case it may be thought that to some extent the Post Office maintenance may be at fault, I think it worth while to mention that so far as overhead lines are concerned a very high standard is set up, and in the case of underground cables a standard of no less than 10 000 megohms per mile of wire is insisted upon before the cables are accepted from the contractors. I have in mind one of the earlier cases of the high-tension power lines constructed in this district, where there are road crossings and the power wires at the crossings are carried on the same poles as the main trunk line. Interference in the nature of a high-pitched note was reported on a circuit some 200 miles in length, and it was finally located to a section of line 10 miles long. Careful investigation was made on this stretch of route, and the trouble was definitely established to originate at a joint power pole crossing. The line conditions specified for such crossings are that the power wires should cross at right angles to the main trunk lines, but owing to physical difficulties it was not possible to attain the ideal at this particular point. The high-tension wires approached the trunk line at an angle approaching 60°, and the same physical difficulties caused the Post Office construction to be imperfect in the matter of symmetrical twist. The resulting defect was this high "singing" note, which was, I think, "D" in the second octave above middle. We overcame the difficulty as a temporary measure by running over the four spans a length of lead-covered 1-pair cable of 40 lb. conductor, the lead covering acting as a screen and giving the required immunity from interference. The transmission was degraded by reason of the harmonic from the high-tension supply. It was less degraded by the introduction in the particular case of the short length of lead-covered cable. I have in mind a case more recent than the one I have just quoted, of a London line running to an East Coast town. That would appear to be sufficiently remote from the West Riding, but the circuit was routed via a main cable passing through Leeds. The main cable had a high order of insulation, in the neighbourhood of 18 000 megohms per mile. It was balanced for wire-to-wire and wire-to-earth capacity, and was loaded with impedance coils to neutralize the capacity effects. A high note was observed on this particular circuit, and it became intolerable, or at any rate the disturbance was amplified, due to the fact that the circuit was in repeater at Birmingham and at Leeds for the purpose of improving the transmission. In improving the transmission we also amplified the disturbance. This disturbance was finally and definitely found to be brought into the cable from an overhead line which ran parallel for a short distance to a West Riding traction system. So far as the other circuits on that particular overhead route were concerned, some disturbance was noticeable, but it was not of such a pronounced character as that which was reported in connection with the long-distance circuit. The two instances I have quoted may be thought to be exceptional, but there are quite a number of circuits which are to some extent degraded in transmission but which are not sufficiently interfered with to warrant them being reported by the Post Office Traffic Department.

Mr. W. R. T. Skinner: I should like to have the author's opinion as to the use of drainage coils on telephone circuits for the purpose of keeping down to a reasonable value the average potential of the latter with respect to earth. This is particularly necessary in connection with communication circuits supported on poles carrying power lines working at high voltages, as, in such cases, it is not uncommon for excessively high and dangerous voltages to be induced in the communication circuits unless some method of reducing the potential is adopted. If repeating coils are used at the instruments and the distance between the latter is not very great, the centre point of the winding connected to the line can be earthed and drainage coils, as such, eliminated, besides introducing additional protection in the form of insulation between the two windings of the repeating coils. There may be a slight objection, from the operating point of view, to the transposition of power lines, in that with a transposed system it is not quite so easy to follow one particular wire, when making a pole-line inspection from the ground, as it is when the wires maintain the same relative positions throughout the length of the line. In this connection, if transposition is not resorted to, it is, I believe, better to adopt a triangular spacing of power wires rather than a horizontal or vertical spacing. Of the two last-named arrangements probably horizontal spacing is the better if the communication circuit is carried beneath the power wires on the same poles, as it would appear to give a better balance of line constants. It is fortunate that both the communication engineer and the power engineer are interested in the removal of harmonics and the elimination of residual currents.

Mr. A. C. Mayman: In investigating a case of disturbance recently I noticed one effect which does not appear to be mentioned in the paper, namely, the inductive effect seemed to have two components. There was a high singing note due to slot harmonics, which did not seem to give much cause for complaint as speech could take place without interference. In addition, however, the rising note of a car motor was superimposed. A tramway system was concerned and the cars climbed a stiff hill. When they were fairly

well loaded, on going up this hill they created a disturbance which was more pronounced than the high harmonic note. I should like to ask the author whether the elimination of the high note will bring in its train the elimination of the rising note due to the car motor, and, if not, what he would suggest would be the best course to adopt. It would appear that the flux thrown out by the harmonic is the cause of the car pulsation being carried into the telephone line.

Mr. J. W. J. Townley: The particular aspect of the paper that appeals to me is the question of responsibility for dealing with the troubles which the author describes. The individuals responsible have been placed in the following order, the designer, the power engineer, and the Post Office engineer, but I would suggest that these three be bracketed together, because however much we may take care of power plant that is now being put down, or will be put down in the future, to eliminate possible causes of disturbance, there is a considerable amount of plant in existence in the country to-day which is a potential source of trouble to the Post Office. The re-arrangement of power circuits or the laying of new Post Office lines may result in disturbances on communication circuits which may not be foreseen, and for the power engineer to provide remedies or modify existing plant might be exceedingly costly. It is very desirable, therefore, that curative methods as well as preventive methods should be devised. For this reason I suggest that these curative methods should be investigated, and a considerable amount of research work in this direction is essential. There would appear to be a wide field for the engineer who will specialize in this work and act as a liaison officer between the power engineer and the engineer who is responsible for the communication circuits.

Mr. S. C. Bartholomew *(in reply)*: As was to be expected, some of the points mentioned in the discussions in London and Liverpool have again been raised at Newcastle and Leeds in more or less the same form, and I trust my answers will be consistent.

Mr. Dalton has kindly supplied fuller details of the manner in which certain rotary converters were improved at Newcastle. I have had a word with Mr. Aldridge on the explanation advanced by Mr. Dalton for the difference in the characteristics of the harmonics in the positive and negative leads to the rotary converter, referred to in the London discussion. Mr. Aldridge points out that it is hardly likely that the difference in the alternating current in the two leads could be caused by a difference in contact resistance, as in that case there would be the same difference in the direct current carried by them. If there is a big discrepancy in the loads carried by the two cables, is not one overheated? Mr. Aldridge suggests on further consideration that the most likely cause for the difference in the ripple is as follows: Resonance conditions exist between the capacities of the generator, transformer and the positive lead and the inductance of the positive lead and part of the transformer; similarly between the capacities of the generator, transformer and negative lead, and the inductance of the negative lead, and both are excited from and in resonance with a ripple. As the capacity of the positive lead will be different from that of the negative lead the resonant frequency will be different. The negative lead, having a direct earth at the busbar, together with the rail earth, will in any case tend to reduce the resistance of the negative lead circuit and cause a greater current at the point where the test coil was placed.

I am sorry that I cannot "predict that the future will see a telephone system designed with its lines and all parts of its equipment insulated from earth." In modern telephone systems the earth is used only for signalling purposes, but very great expense and complications would result if it were not so utilized. I agree that interference would be reduced if the telegraph and telephone services were worked without earth connections, but there are limits beyond which the Administration cannot go. It must not be overlooked that but for power circuits there would be many parts of the country where single-wire telephone services would be practicable, and it can be claimed that the extra cost of the second wire has been borne by the Telephone Service without a murmur. I do not, of course, put forward the claim that single-wire telephone circuits would be satisfactory for general use in towns even if there were no power circuits, but undoubtedly the latter have absolutely prohibited their use in certain districts where single-wire working would have been possible.

Mr. Dalton raises an interesting point in connection with the publication of information that rotary converters were likely to cause interference, and suggests that earlier publication would have been a warning to purchasers and designers. When trouble was first experienced it was confined to machines made by one company, and it would have been a very questionable proceeding indeed for a Government department to have called public attention to such a failing. As stated in the paper, later experience showed that other makes of machines were equally offensive in this respect. Some publicity was given to the matter, however, in a paper read before the Institution of Post Office Electrical Engineers and reproduced fairly fully in the technical Press in January 1915. It is agreed that a considerable period elapsed between the time the converters were brought into use at Newcastle and when attention was called to the interference. Many factors contributed to this. No notification is given when there is a change in the methods of generation or distribution of energy, and the local telephone staff would naturally not associate the disturbance with the tramway system which had been in operation for so many years without causing trouble. War conditions produced staff difficulties which had a great deal to do with the toleration of unsatisfactory services for a certain period before the origin of the trouble was traced. Mr. Dalton's remarks on electrolysis and the proper layout of tramway systems to avoid its effects are of great interest. This question is not a dead one in view of the great increase in the use of lead-covered cable.

Mr. Baldwin calls attention to the certain great development of the telephone system and the power systems in this country, and as a consequence the growing importance of the matter under discussion. This is now recognized universally. Whilst I agree

that some of the functions exercised by the Co-ordinating Committees in the United States, such as the notification of prospective routes for new circuits, etc., are covered in this country by the statutory obligations of electricity undertakings to notify parties concerned of the installation of new power lines, there are other functions involving research work dealt with by the Committees which have, so far, only been lightly touched upon here.

I have already dealt with the matter of interference with broadcasting. Briefly there are three kinds of interference. The first and least troublesome is that caused to receiving sets in the neighbourhood of tramways and electric railways. So far as I can gather, these cases are not numerous. Secondly, interference with land lines used for connecting up the various transmitting and relay stations for simultaneous broadcasting. This type of disturbance may affect, in certain cases, practically the whole of the listeners in the United Kingdom. Lastly there is the interference which may affect the listeners over a wide area in the neighbourhood of works employing the Cottrell precipitators and Lempke rectifiers used for depositing blast-furnace gases. High-frequency radiation of oscillations of a broadcast wave-length may be set up and trouble has been caused here and in America on that account. A cure has been found by increasing the natural wave-length of the system by installing suitable inductances in the line. The Inductive Co-ordination Committee of the National Electric Light Association (America) has appointed a sub-committee to deal with interference of power circuits with radio or wireless reception. The purposes of the Committee are (*a*) to serve as a clearing house for information on the subject, (*b*) to conduct or supervise experimental work upon the location of sources of interference, and (*c*) to furnish the necessary information to the public.

As Mr. Whillis points out, it is sometimes found necessary where long routes are concerned to supplement the twist system of transposition by crosses. Mr. Whillis inquires as to whether cases have occurred of dangerously high voltages being induced in neighbouring telephone circuits. Since the preparation of the paper I have obtained further information and experience on this question. At the recent International Conference on Long-Distance Telephone Lines held in Paris, when the subject of power circuit interference was under discussion, particulars were given of two cases where telephone linemen at work on open lines had been electrocuted by the inductive effects brought about by faults on neighbouring power lines. In one of the cases the telephone lineman was killed in Italy whilst the actual power circuit which was faulty and produced the inductive effects was situate in Switzerland, the connecting medium being a telephone line passing through the two countries! The other case occurred in France. There have been cases in this country where telephone operators have received electric shocks in a mild form. These happenings have an important bearing on the question of earthing the neutral point on three-phase systems, as it is the unearthed system which is more likely to produce dangerous effects of this character. This is due to the fact that with the neutral point unearthed the occurrence of a fault on one phase does not operate the circuit breaker and in the event of one of the other phases making earth also at a distant point very severe disturbances are set up by the strong out-of-balance current passing between the two faults.

Mr. Gregory calls attention to the advisability of looking to the future in view of the anticipated growth in extent and design of both power and telephone systems. The automatic telephone system when operating under speaking conditions does not differ from the modern manual system as both types use common battery working of a similar character. The earth is used in connection with dialling in some cases between exchanges but, as pointed out in my reply to Mr. Cornfoot (see vol. 62, page 76) in the Liverpool discussion, from experiments made in London it is not anticipated that false signalling owing to leakage currents will be a serious matter. Unless these conditions tend to get worse, special precautions do not appear to be necessary.

Mr. Kitchen's reference to the development of long-distance telephony in Europe is *à propos*. The subject of power circuit interference is one of the principal matters being considered at the moment by the International Conference dealing with the question of long-distance telephony, and recommendations drawn up by a sub-committee recently sitting in Paris will be submitted to a full Conference to be held in the same city in the early part of June next. It is possible that modifications will be made to the recommendations at the full Conference, and the moment is not opportune for going into the proposals in detail. It is interesting to note that at some of the meetings of the sub-committee dealing with this question of power circuit interference, representatives were present from the Union Internationale des Chemins de Fer, and from the Conference Internationale des Grands Réseaux Electriques à très Haute Tension: these representatives of the electric railway and power interests were present on the invitation of the International Telephone Conference and took part in the discussion on the proposed recommendations governing the operations of the two parties. An attempt has been made to lay down minimum conditions as regards separating distance, design of plant, etc., which will ensure that there shall be no excessive interference with speech or danger to telephone plant or personnel in any of the countries concerned.

I very much appreciate the contribution from Mr. French which gives detailed information on the development of harmonics in generating plant and supplements in a most valuable manner the paper and the references in the bibliography.

The two cases of trouble instanced by Mr. Hammond are very illuminating, the case of interference at a joint pole where the angle of crossing was 60° being particularly so. It has been laid down that at this and similar types of crossing, i.e. where both the power line and the telephones are overhead, the angle of crossing should be 90°, and the need for this has frequently been challenged. Both on grounds of safety and interference, the right-angled crossing is to be preferred. The other case is a further example of interference being felt on circuits not directly con-

nected with the seat of the disturbance, the trouble being carried up by the secondary effects from intermediate circuits. To trace the origin of such trouble is very difficult, especially in cases where the disturbance is produced by one particular machine which may not be in use continuously.

Mr. Skinner asks my opinion as to the use of drainage coils on telephone circuits for the purpose of cutting down to a reasonable value the potential to earth. Apart from experiments I have had no experience of such coils on public telephone circuits. These coils offer a low-impedance path for currents induced between the telephone wires and earth, and so tend to reduce the voltage. They are no doubt very necessary on telephone circuits used in connection with the operation of power systems where the wires are in fairly close proximity to the overhead high-pressure lines, but so far their use on public telephone lines has not been found to be necessary and it is to be hoped that the conditions will not arise that will require their use on such circuits. In America the coils are called "bleeding" coils and I gather that in some cases they have been fitted on the public telephone circuits. The reduction of the voltage between the telephone wires and earth will in certain cases reduce the disturbing noise if the noise is due to this voltage acting upon a line balanced as regards insulation and capacity; on the other hand the coils will offer a low-impedance path for induced currents and if there are irregularities in the series resistance or impedance of the telephone wires the noise may be increased. Further, they must be very well balanced or they will be the cause of noise themselves by introducing unbalance into the circuit, and in addition they result in speech transmission losses. I do not think that the transposition of power lines would add very greatly to the difficulties of operation.

In reply to Mr. Mayman, I am of opinion that if the slot harmonic were removed or reduced the rising note from the motor on the car would also be reduced. I have not so far had experience of cases where it has been necessary to take special steps to reduce the latter.

In view of the possibility that the extension of power plant may be a source of trouble in the future as conditions change, Mr. Townley lays stress on the need for developing curative as well as preventive measures. Any research work in this connection would be very helpful and Mr. Townley will, no doubt, be pleased to hear that a committee of the British Electrical and Allied Industries Research Association is now looking into the whole subject.

A NEW METHOD OF HIGH-FREQUENCY RESISTANCE MEASUREMENT.

By Professor E. MALLETT, M.Sc., Member, and A. D. BLUMLEIN, B.Sc., Student.

(*Paper first received 29th September, and in final form 5th November,* 1924; *read before the* WIRELESS SECTION *7th January,* 1925.)

SUMMARY.

The paper deals with a new method of high-frequency resistance measurement involving the application of a circle diagram to a resonance curve. Various methods of measurement are evolved and experimental results are given. The application to the accurate determination of wave-length is suggested.

TABLE OF CONTENTS.

1. INTRODUCTION.

A method of high-frequency resistance measurement is developed in which the resistance of an oscillatory circuit is measured at resonance without any electrical connections being made to it. The circuit, the resistance of which is to be measured, is coupled magnetically with a coil, and the magnitude of the ratio of the effective impedance of the coil to that of the coil alone is measured at various points as resonance of the circuit is passed through by alteration of the frequency of the supply. A resonance curve of the impedance ratio is plotted against the supply frequency, and from this curve the high-frequency resistance of the circuit is determined by the use of a graphical construction involving a circle diagram. The construction gives also the value of the resonant frequency of the circuit.

Alternatively, if the tuning of the oscillatory circuit can be varied by means of a variable condenser, the impedance ratio curve can be obtained without variation of the supply frequency.

2. THEORY, SHAPE OF CURVE, AND CONSTRUCTION.

In a previous paper * a method was described of using a resonance curve of the type shown in Fig. 1 to obtain the natural frequency and the decay factor of a telephone diaphragm. To effect this a geometrical construction was evolved and the same construction and method were shown to be applicable to coupled circuits.

For the sake of completeness the theory may be briefly restated. Consider a coil of impedance Z_1 (see Fig. 2) coupled magnetically to a resonant circuit of impedance Z_2. Let M be the mutual inductance and V the alternating voltage applied to the terminals of the first coil, which will be called the coupling coil.

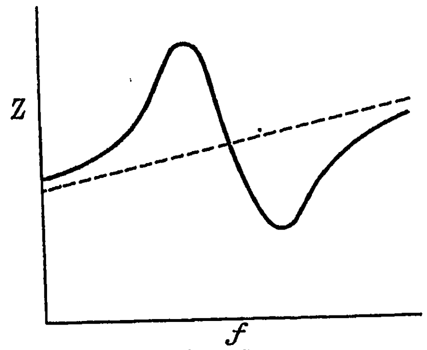

FIG. 1.

Then if I_1 and I_2 are the currents in the first and second circuits respectively:—

$$V = Z_1 I_1 + j\omega M I_2 \quad . \quad . \quad . \quad . \quad (1)$$

$$0 = Z_2 I_2 + j\omega M I_1 \quad . \quad . \quad . \quad . \quad (2)$$

From (2) we obtain:—

$$I_2 = -j\frac{\omega M}{Z_2} I_1$$

Putting this value of I_2 in (1) we get:—

$$V = Z_1 I_1 + \frac{\omega^2 M^2}{Z_2} I_1$$

The effective impedance Z is V/I_1, and

$$Z = \frac{V}{I_1} = Z_1 + \omega^2 M^2 \frac{1}{Z_2}$$

Taking the ratio Z/Z_1 we get:—

$$\frac{Z}{Z_1} = 1 + \frac{\omega^2 M^2}{Z_1} \cdot \frac{1}{Z_2} \quad . \quad . \quad . \quad . \quad (3)$$

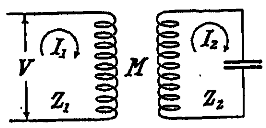

FIG. 2.

No account has been taken of the self-capacity of the coupling coil, and therefore to make the theory applicable it is essential that the coupling coil should have a natural frequency well above the natural frequency

* E. MALLETT: *Journal I.E.E.*, 1924, vol. 62, p. 517.

of the circuit to be tested, i.e. well above the frequencies * used in the tests.

In Fig. 3 is given the vector interpretation of Equation (3). If in the arrangement of Fig. 2 the supply frequency were increased from below to above the resonant frequency of the second circuit, the locus of the end of the vector OP representing Z_2 would move upwards along a straight line PQ. The end of the vector OP′ representing $1/Z_2$ would then move round the circle OP′Q′ in a clockwise direction, starting from the origin. The diameter OR of the circle is $1/R_2$. This circle is the inverse of the previous straight line, and the line OP′ corresponds to the line OP where $\angle$ P′OX $= \angle$ POX.

For small changes of frequency, if Z_1 is far removed from resonance ω^2M^2/Z_1 will be proportional to ω and will not alter appreciably in magnitude or phase angle, and the locus of the vector $(\omega^2M^2/Z_1)(1/Z_2)$ will be obtained by turning the circle through the angle of $1/Z_1$ and multiplying its diameter by $|\omega^2M^2/Z_1|$. This operation gives the circle OP″Q″ with a diameter OD at an angle XOD = the angle of Z_1. Marking

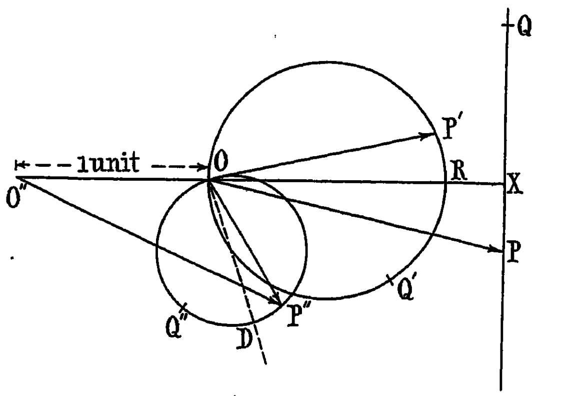

Fig. 3.

off OO″ horizontally equal to unity, any vector O″P″ is evidently equal to the vector sum of 1 and $(\omega^2M^2/Z_1)(1/Z_2)$ and so is equal to Z/Z_1.

The maximum and minimum values of Z/Z_1 can be found by drawing a line from O″ passing through the centre of the circle OP″Q″. The points at which this line cuts the circle then give the maximum and minimum values of Z/Z_1. Conversely, knowing the maximum and minimum values of Z/Z_1, by a suitable construction the circle can be drawn.

Consider a curve of Z/Z_1 plotted against f as in Fig. 4. By drawing lines parallel to the f axis touching the curve at its maximum and minimum points, two vertical distances ON and OM are marked off equal to the maximum and minimum values of Z/Z_1. Then with centre O and radii OM and ON arcs are drawn, and finally a circle is drawn to touch these two arcs and to pass through the point A, such that OA = 1. Take any point P on the circle and draw OP. Then OP represents Z/Z_1 in magnitude and phase. A and O in Fig. 4 correspond respectively to 0 and 0″ in Fig. 3.

As the frequency increases from a low to a high value the end of the vector OP moves round the circle in a clockwise direction from A back to A. This is not strictly true as the value of ω^2M^2/Z_1 varies, but for small changes of frequency close to resonance this is applicable, and with the circuits commonly used in wireless most of the circle is described with a very small frequency-change.

To find the frequency corresponding to any point P, on the locus circle, an arc is drawn with centre O through P to meet the Z/Z_1 axis in L, and then a line drawn through L parallel to the f axis to meet the curve in P′, the point on the resonance curve corresponding to the point P on the circle.

There is an ambiguity in finding P′, as according to the construction the horizontal line cuts the curve in two points; but this ambiguity is removed when it is remembered that, as the circle is described clockwise from A, the resonance curve is drawn to the right from A′.

The vector AP represents in magnitude and phase $(\omega^2M^2/Z_1)(1/Z_2)$. At resonance $1/Z_2 = 1/R_2$ and AP lies on the circle diameter AD, the angle of which is the angle of ω^2M^2/Z_1. If therefore A is considered as the origin and the diameter AD as the line of refer-

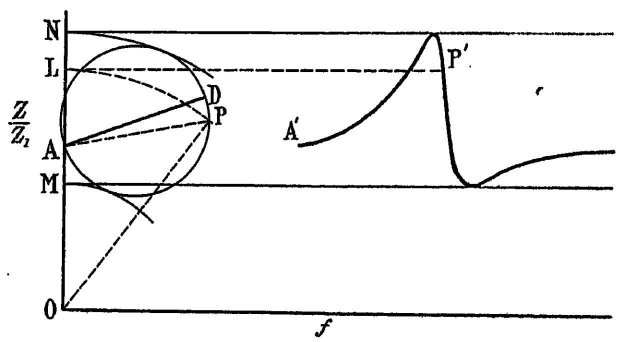

Fig. 4.

ence, AP then represents the vector $|\omega^2M^2/Z_1|(1/Z_2)$; and since ω^2M^2/Z_1 is now a magnitude, AP represents to some other scale the vector $1/Z_2$. The angle PAD is then the phase angle of $1/Z_2$.

Call this angle PAD α, the phase angle of Z_2, or − (the phase angle of $1/Z_2$).

Then

$$\tan\alpha = \frac{\omega L_2 - 1/(\omega C_2)}{R_2}$$

where L_2, C_2 and R_2 are respectively the inductance, capacity and resistance of which Z_2 is composed.

Let
$$\omega_0 = \frac{1}{\sqrt{(L_2C_2)}}$$

Then
$$\begin{aligned}\tan\alpha &= \frac{\omega L_2 - 1/(\omega C_2)}{R_2}\\ &= \frac{L_2}{R_2}\left(\omega - \frac{1}{\omega L_2 C_2}\right)\\ &= \frac{L_2}{R_2}\left(\omega - \frac{\omega_0^2}{\omega}\right)\end{aligned}$$

* See Appendix 2.

Differentiating with respect to ω, we obtain :—

$$\frac{d \tan \alpha}{d\omega} = \frac{L_2}{R_2}\left(1 + \frac{\omega_0^2}{\omega^2}\right)$$

For values of ω close to resonance we have $\omega_0 \doteqdot \omega$

so that $$\frac{\omega_0^2}{\omega^2} \doteqdot 1$$

$$\therefore \quad \frac{d \tan \alpha}{d\omega} = \frac{2L_2}{R_2}$$

and $\dfrac{d\omega}{d \tan \alpha} = \dfrac{R_2}{2L_2} = \Delta$, the decay factor.

Now for any point P on the resonance curve (see Fig. 4) the corresponding point on the circle can be found, and hence tan α which equals tan PAD. By repeating this process for other points on the curve, the values of tan α corresponding to various values of ω are obtained, and a curve of tan α against ω can be drawn. For small changes of ω this curve will be a straight line. The value of ω at which tan $\alpha = 0$ gives the resonant frequency, and the slope $d\omega/(d \tan \alpha)$

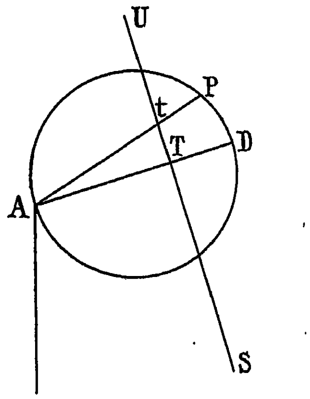

FIG. 5.

of the straight-line portion of the curve $= \Delta$, the decay factor of the circuit.

This gives $R_2/(2L_2)$, and, if we know the value of L_2, we can find R_2 the resistance required.

Instead of measuring off the angles α and finding their tangents from tables, the ω — tan α curve may be obtained graphically. A line STU (see Fig. 5) is drawn at right angles to the diameter AD of the circle at a distance AT equal to unity to some suitable scale. Then the tangent of the angle α of any vector AP is obviously given to the same scale by the length Tt and is negative above T and positive below T. This length is then marked off from a suitable base line drawn for convenience below the original resonance curve so that the same frequency scale is used for the new ω — tan α curve.

Approximate construction.—A simplified construction can be employed when the variation of Z/Z_1 is small compared with unity.

In Fig. 6 is shown a typical Z/Z_1 curve. As before, lines are drawn parallel to the ω axis through the maximum and minimum points to N and M. As the variation of Z/Z_1 is small the origin will be a long way away, and so arcs drawn with O as centre through N and M will, for a short length, be practically parallel to the ω axis.

The circle can therefore be drawn between the parallels M and N. Any point P′ will have its corresponding point on the circle found by drawing PP′ parallel to the ω axis to meet the circle in P.

As before, tan α is plotted against ω and the slope of the line gives Δ.

This construction can only be used when the variation of Z/Z_1 is small. By a method of trial and error it has been found that the approximate construction can be applied to curves with a variation of Z/Z_1 less than 0·2. For example, if a curve has maximum and minimum values of $Z/Z_1 = 1{\cdot}07$ and 0·92 the variation of Z/Z_1 is 0·15 and the approximate construction may be used.

Method employing constant frequency and variable tuning of the circuit under test.—For circuits that are tuned by a variable condenser a modification is applicable, in which ω is kept constant and ω_0 is varied by varying the capacity in the circuit under test. ω^2M^2/Z_1 will then be constant and, as before,

$$\Delta = \frac{d\omega_0}{d \tan \alpha}$$

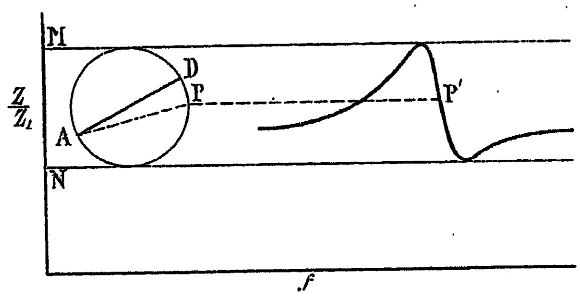

FIG. 6.

Z/Z_1 is plotted against ω_0 instead of ω and the construction is the same as before.

The essential points therefore based on these considerations are briefly as follows :—

The determination of high-frequency resistance.—(*a*) Measurements of the magnitude of the apparent impedance of the coupling coil are taken for various values of ω,

(i) With circuit to be tested magnetically coupled to the coupling coil (this gives Z) ; and
(ii) Without the circuit to be tested (this gives Z_1).

(*b*) A curve of Z/Z_1 is plotted against ω.

(*c*) The locus circle, as determined from the maximum and minimum values of Z/Z_1, is drawn.

(*d*) A curve of tan α against ω is plotted and a straight line drawn through the points obtained.

(*e*) The slope $d\omega/(d \tan \alpha)$ of this line is measured and is equal to Δ, the decay factor of the circuit to be tested ; hence the desired resistance is determined.

(*f*) The value of ω when tan $\alpha = 0$ is the resonance value.

3. Various Methods of Measurement.

It is evident from the above that the determination of the decay factor depends upon the accurate measurement of (i) frequency-changes and (ii) impedance ratios.

A circuit diagram of the whole of the apparatus finally used in the "Voltmeter method" is given in Fig. 7, but the oscillator and amplifier arrangement to the right of the diagram was used finally in each method. This consists, it will be seen, of a small oscillating valve supplying an E.M.F. to an amplifying valve, from which the necessary current for the impedance measurement was obtained. In this way, by using a negative grid on the amplifying valve no external load is placed on the oscillating valve, so that circuit changes taking place beyond the amplifying valve do not have any effect on the frequency of the oscillating valve. The usual precautions were taken to obtain as pure a wave-form as possible. The oscillating valve was only just maintained, and it was worked with sufficiently high anode potential and negative grid bias to prevent grid current flowing. Careful adjustments were made so that the anode current as measured on a d.c. instrument was the same when oscillating as when not oscillating. The same adjustment was made on the amplifying valve, and care was taken that the a.c. grid potential supplied from the oscillator was never sufficient to cause the amplifying valve to work on the curved portions of its characteristic.

125	13·3	89	13·3	81	25·06	1·031

In order to make the frequency-changes as easily determined as possible, the oscillatory circuit of the oscillator valve was made up for a given frequency with as large a capacity and as small an inductance as possible, and the very small frequency-changes required were effected by means of vernier condensers, and were in most cases very nearly simply proportional to the alteration of the vernier capacity, as is shown in Section 5.

(*a*) *Voltmeter-ammeter method.*—The obvious way of measuring the magnitude of the impedance of a network at any frequency is to pass a current of that frequency through the network and to measure both the current and the voltage across the network, and this was the first way in which results were obtained. The current was obtained from the amplifier valve through a transformer or large condenser across an anode resistance so as to separate out the d.c. anode current. The current was measured by a Duddell thermo-milliammeter, and the voltage by one of Prof. Mather's sensitive electrostatic instruments. Since the voltage was measured over both the coupling coil and the milliammeter, Z_1 of the formula included the resistance of the latter.

The first series of measurements was made on a 750-turn "duolateral" coil, tuned with a variable air-condenser, at a frequency corresponding to about 9 000 m. The coil had an inductance of 31 900 μH and a self-capacity at this wave-length of about 22 $\mu\mu$F. The resistance of the coil and condenser was found to be of the order of 100 ohms at this frequency.

One series of readings is given in Table 1. Both the milliammeter and the voltmeter were square-law instruments and the impedance was calculated as $\sqrt{(R_v/R_a)}$, where R_v and R_a were the ammeter and voltmeter readings respectively. Only a few readings were taken for Z_1, and the rest were interpolated. The frequency was varied by varying a small condenser in the oscillator anode circuit. As the capacity in the oscillator anode circuit was large, over a small range $\omega \propto (k - C_1)$, where C_1 is the capacity of the small variable condenser. Between 10° and 170° the small condenser had a straight-line law, and so Z/Z_1 was plotted against the reading of the small condenser and the change of ω per scale division calculated. The same method has been applied in other cases where the variation of ω was small.

From the curve, $\Delta = 1\,848$; $R = 118$ ohms.

The curve obtained and the construction to find Δ are given in Fig. 8.

The slope of the $\omega - \tan\alpha$ curve is 12·2 condenser divisions per unit change of $\tan\alpha$. The change of ω per scale division of the condenser is 151·5.*

Then

$$\Delta = d\omega/(d\tan\alpha) = 12{\cdot}2 \times 151{\cdot}5 = 1\,848$$

Assuming that the high-frequency inductance is the same as its low-frequency value we have

$$R = \Delta \times 2L = 1\,848 \times 2 \times 31\,900 \times 10^{-6}$$
$$= 118 \text{ ohms.}$$

This result is not very reliable as the method did not prove at once satisfactory; and it was not developed in view of the simpler methods now to be described.

FIG. 8.

(b) *Voltmeter method.*—Since only the ratio of the impedances is required, as long as the current through the coupling coil remains constant whether the resonant circuit is coupled with it or not, the required impedance ratio will be obtained as the ratio of the voltages across the coil in the two cases. It does not matter if different currents are used at different frequencies. At first an attempt was made to keep the current constant (as indicated by a crystal and galvanometer across a series resistance) by altering the coupling between the amplifier and oscillator, but it was soon found that the oscillator was better left alone and in any case the adjustment was laborious. Then it appeared that if the whole

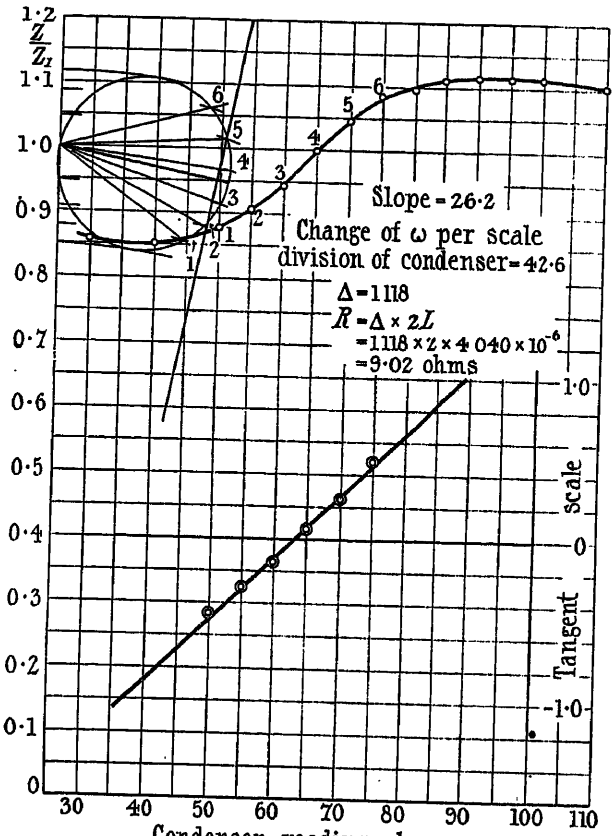

FIG 9.

impedance of the circuit containing the coupling coil was large compared with that of the coupling coil itself the current would remain sensibly constant with constant E.M.F., and that in order to obtain a sufficiently large impedance the internal resistance of the amplifying valve could be used by placing the coupling coil direct in the anode circuit.

Since the grid of the amplifier valve was very negative and no grid current flowed, the a.c. voltage E_g passed on to the grid of the amplifying valve from the oscillator was constant for any one frequency. The a.c. portion of the anode current of the amplifier valve is then

$$\frac{\mu E_g}{R_0 + Z}$$

where R_0 is the internal resistance and μ the amplification factor of the amplifier valve, and, as before, Z is the effective impedance of the coupling coil.

Provided therefore that the alterations of Z are small compared with the value of $(R_0 + Z)$, the current through the coil will not vary appreciably and we can measure Z by measuring the potential across the coupling coil; this measurement can be made by means of a calibrated rectifying valve. The small alterations of current that do take place do not affect the resistance determinations.*

110	1·62	1·47	1·102

Change of ω per scale division of condenser = 42·6.
From the curve Δ = 1 118; R = 9·02 ohms.

The general arrangement is shown in Fig. 7. The grid voltage of the rectifying valve could be adjusted by means of a potentiometer to allow for the d.c. voltage across the coupling coil due to the steady plate

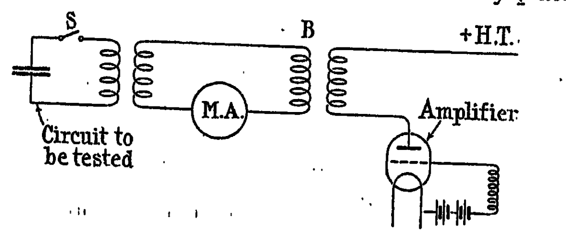

FIG. 10.

current of the amplifying valve. The rectifying valve consisted of a D.E.R. type valve working with an anode voltage of about 35 and a negative grid bias of about 4·5 volts.

The procedure was as follows:—

The potentiometer was adjusted to make the grid of the rectifying valve full negative. Then, with the amplifying valve turned off, the filament current of the rectifying valve was adjusted to give a definite predetermined anode current representing zero a.c. volts on the calibration curve. This adjustment was

† See Appendix 1.

repeated several times during a quarter of an hour to allow the rectifying valve to settle down. The amplifying valve was then turned on, and its filament voltage adjusted to the right value. This caused the anode

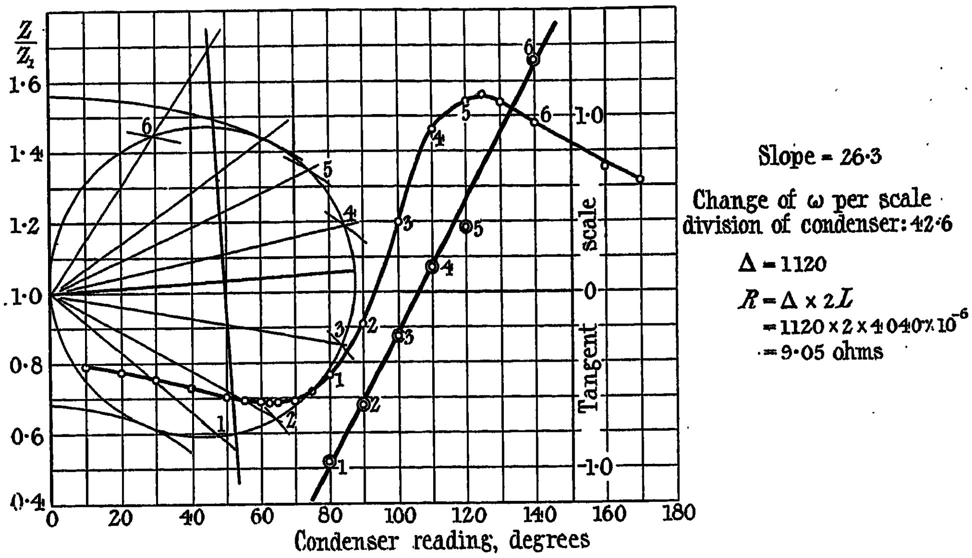

FIG. 11.

current of the rectifying valve to decrease due to the potential of its grid being reduced by the P.D. across the coupling coil. This was allowed for by adjusting the potentiometer until the anode current of the rectifying valve was again at its previous value. The oscillating valve was then turned on and readings were taken.

In the actual arrangement shown there was a very convenient method for determining Z_1. It was found that if the switch S in the circuit to be tested (see Fig. 7) is opened, the effect is the same as actually removing the resonant circuit. Therefore the order of measurements was arranged as follows:—

(i) Switch opened and V_1 measured.
(ii) Switch closed and V measured.
(iii) Switch opened and the previous value of V_1 checked.

Then

$$\frac{Z}{Z_1} = \frac{V}{V_1}$$

on the assumption that the current has not changed during the operations.

On repeating a previous reading, V and V_1 were sometimes found to have changed a little, but the ratio Z/Z_1 remained the same.

Table 2 and Fig. 9 give details of a measurement made in this way. These results are referred to again in Section 4.

(c) *Ammeter method.*—Another method has been evolved similar to the last in which a current measurement only is made. The arrangement is shown in Fig. 10. The amplifier and oscillator are arranged as before (see Fig. 7). As before, the a.c. anode current of the amplifier valve is constant for any one frequency; this gives a constant E.M.F. in the coil B. The impedance of the coil B and of the milliammeter are included in Z_1, and the effective impedance is inversely proportional to the milliammeter reading. Three readings are taken at each frequency; two with the switch open gave Z_1, and one with the switch closed gave Z. The required impedance ratio Z/Z_1 is given by I_1/I. Table 3 and Fig. 11 give results of a measurement made in this way.

160	5·815	4·30	1·352
170	5·82	4·43	1·314

Change of ω per scale division of condenser = 42·6.
From the curve, $\Delta = 1\,120$; $R = 9 \cdot 05$ ohms.

Of the three methods the first is the most complicated and least satisfactory for general engineering work. The ammeter method requires the simplest assemblage of apparatus but necessitates a closer coupling to the resonant circuit. Probably the voltmeter method will be the most generally useful and accurate.

4. Experimental Results.

Altering coupling and adding resistance.—The coil, the resistance of which was found by the voltmeter and by the ammeter method (Tables 2 and 3 and Figs. 9 and 11) consisted of 189 turns of No. 22 S.W.G. d.c.c. wire wound on a former 7 inches in diameter and $7\frac{1}{2}$ in. long. To reduce the dielectric losses the coil had been thoroughly "baked" with both direct and high-frequency alternating current. The inductance of the coil was 4 040 μH, its d.c. resistance 4·6 ohms and its self-capacity about 7 $\mu\mu$F. It was tuned by means of a variable air-condenser. The coupling coil was wound of finer wire on a former of smaller diameter, and had an inductance of 700 μH and a self-capacity of 10 $\mu\mu$F. The two coils were mounted so that their axes were in line and their distance apart could be readily altered.

As will be seen from Figs. 9 and 11, the resistance obtained at a frequency value corresponding to 3 800 m by the voltmeter method was 9·02 ohms and by the ammeter method 9·05 ohms. The mutual inductance between the two coils was very much greater in the second case, and the remarkably close agreement of the two determinations indicates that the degree of coupling is as it should be by the simple theory, i.e. without effect, and that each method can give equally good results. Further measurements at different couplings by the voltmeter method confirmed that the coupling was without appreciable effect, although the agreement was not quite so striking. Leaving out one determination at 8·70 ohms which was rejected as the points obtained did not lie well enough on a straight line, the difference between the greatest and least figure obtained at different times and different couplings was just over 1 per cent.

As a check measurement a fine eureka wire resistance was added to the oscillatory circuit with the coupling coil in the same position as that used in Fig. 9, with the results given in Fig. 12. The high-frequency resistance of the circuit was now measured as 17·30 ohms, a difference of 8·28 ohms from the determination of 9·02 ohms without the added resistance. The actual value of the added resistance was 8·38 ohms, so that the actually measured resistance of the wire at high frequency was only about $1\frac{1}{4}$ per cent in error. It must be added here that some other determinations in the same way did not check up nearly so well, although the points obtained for the Δ — tan α curves lay on straight lines. The difficulties in adding resistance to the circuit seem to be similar to those encountered in the substitution or added-resistance method of high-frequency resistance measurement. It would appear to be quite possible that the high-frequency resistance measurements here described are more accurate than their check by adding resistance.

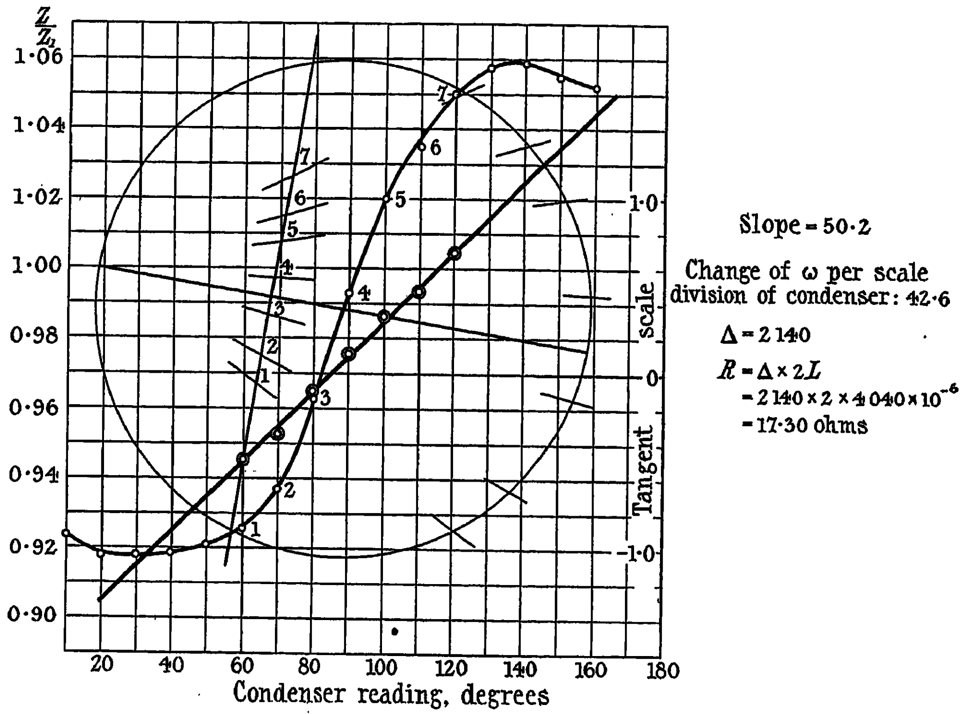

Fig. 12.

Measurements have been made over a considerable frequency range and with coils of very different resistances. Some of the results are given below.

50 ohms at 500 metres.—A series of measurements

was made on a small "reaction coupling coil" from a broadcast receiving set, and consisting of two coils wound on an ebonite bobbin, with the ends brought out to four pins arranged to fit a valve socket.

The resistance of the larger of the two coils was measured at 500 m. This coil had an inductance of 284·7 μH and its resistance was found to be about 50 ohms. Measurements were taken by varying both ω and ω_0. The results of the latter measurement are given in Fig. 13 as an example of the results obtained in this way.

In these cases the variations of ω were too large for it to be permissible to plot the ratio Z/Z_1 against the reading of the vernier condenser in the oscillator experienced due to "feed back" through the inter-electrode capacity of the amplifier valve. This was avoided by making the amplifier coupling coil (coupled to the oscillator) an effective capacity, i.e. using a coil working well above its natural frequency.* This prevents any regenerative feed-back taking place.

The results were :—

Varying ω : resistance = 46·3 ohms.
Varying ω_0 : resistance = 44·6 ohms.

The difference is 3·8 per cent. The results are sufficiently close to show that the two methods agree; the first measurement was not particularly good as judged by the straight line.

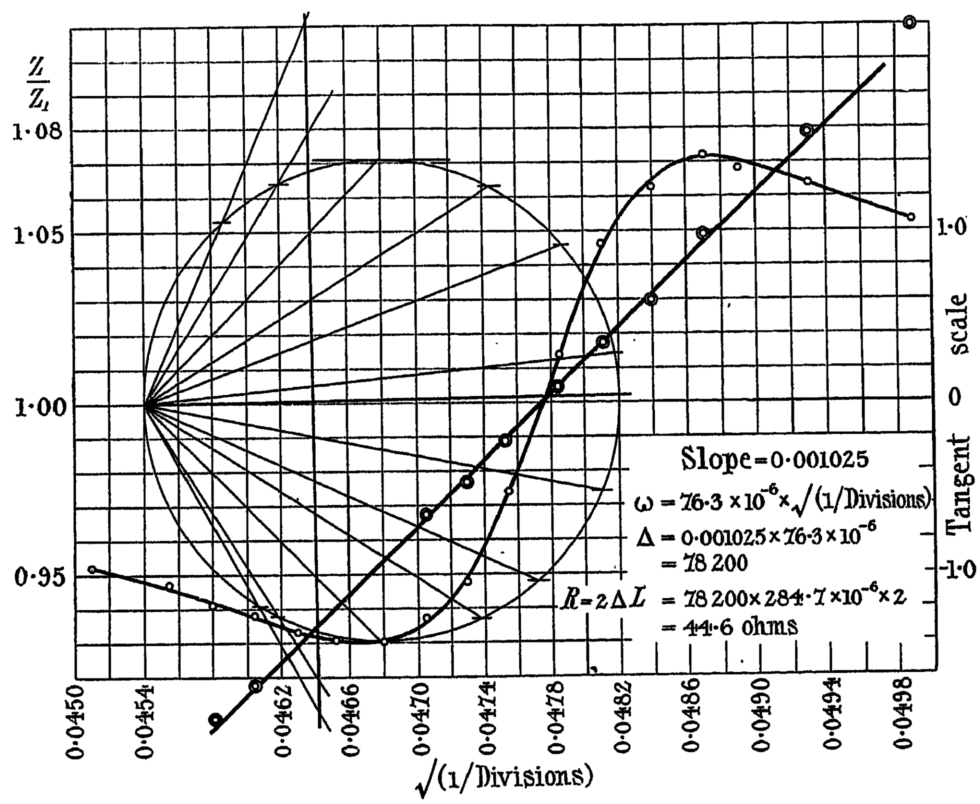

FIG. 13.

anode circuit. From the known wave-length and inductance of the oscillator anode coil, the effective capacity in parallel with it could be calculated. This was expressed in scale divisions of the vernier condenser. We then get :—

$$\omega = \frac{1}{\sqrt{(LC)}} = \frac{1}{\sqrt{[Lk(\text{scale divisions})]}} = K\frac{1}{\sqrt{(\text{divisions})}}$$

where total capacity $C = k$ (scale divisions of vernier condenser).

Z/Z_1 is therefore plotted against $1/\sqrt{(\text{divisions})}$ and the value of K calculated. This saves considerable time in calculating the results. The same method has been applied when plotting against ω_0.

While taking these measurements, trouble was

80 and 8 *ohms at* 300 *metres*.—Two more measurements were made on the same "reaction coupling coil"; the resistance of both coils was found at 300 m. The results obtained with the small coil are given in Fig. 14, as they bring out an interesting point (see Appendix 2).

The figures are :—

Large coil.
Inductance = 284·7 μH.
Resistance = 78·7 ohms.

Small coil.
Inductance = 23 μH.
Resistance = 7·75 ohms.

Taking into consideration the high frequency used,

* See A. S. BLATTERMAN: *Radio Review*, 1920, vol. 1, p. 633.

these results are not altogether unsatisfactory. No special precautions were taken to avoid stray resonances or capacities, and the oscillator and amplifier shared common and not too large filament batteries. (The measurements were made before the apparatus of Fig. 7 was assembled.) The large coil gave better results and the points lie on quite a good straight line. Though the curve is not good for the small coil, the points define the straight line within 2 or 3 per cent.

It is interesting to notice that the ratio of the resistances of the large coil at 300 and 500 m is $78 \cdot 7/45 \cdot 5 = 1 \cdot 73$, and the ratio of the frequencies is $1 \cdot 67$.

5 ohms at 500 metres.—The resistance of a toroidal coil of inductance 158 μH and resistance about 5 ohms was measured at 500 m. Mutual coupling was obtained by linking two turns of wire through the toroid and supporting them from an insulator. These two turns were put in series with a small coil so as to bring the combined inductance up to such a value that a P.D. to be measured of about $1 \cdot 3$ volts was obtainable, as the voltmeter in use was most sensitive for voltages round about $1 \cdot 3$. Z_1 then consisted of the two coupling turns and the small coil in series with them.

The variation of $Z/Z_1 = 1 \cdot 117 - 0 \cdot 912 = 0 \cdot 205$; this is just above the limit below which it is permissible to use the approximate construction. Both the rigid and the approximate constructions have been drawn and give practically identical figures of $4 \cdot 68$ ohms.

5. Frequency Determinations.

The resonant frequency of the oscillatory circuit is found from the $\omega/\tan \alpha$ line where it cuts the tan α axis, and a determination of resonant frequency made in this way is capable of considerable accuracy.

A very close approximation with the circuits in general use in wireless work is obtained by taking the resonant frequency as being that at which the impedance of the coupling coil with the oscillatory circuit open is the same as that with the oscillatory circuit closed, with the additional condition, of course, that the observation is made at the central portion of the curve where the impedance is changing rapidly with frequency. This fact was used to check the assumption made throughout that the change of frequency was determined by the change of the vernier condenser of the oscillator, and to find the $\delta\omega - \delta C$ calibration of the oscillator.

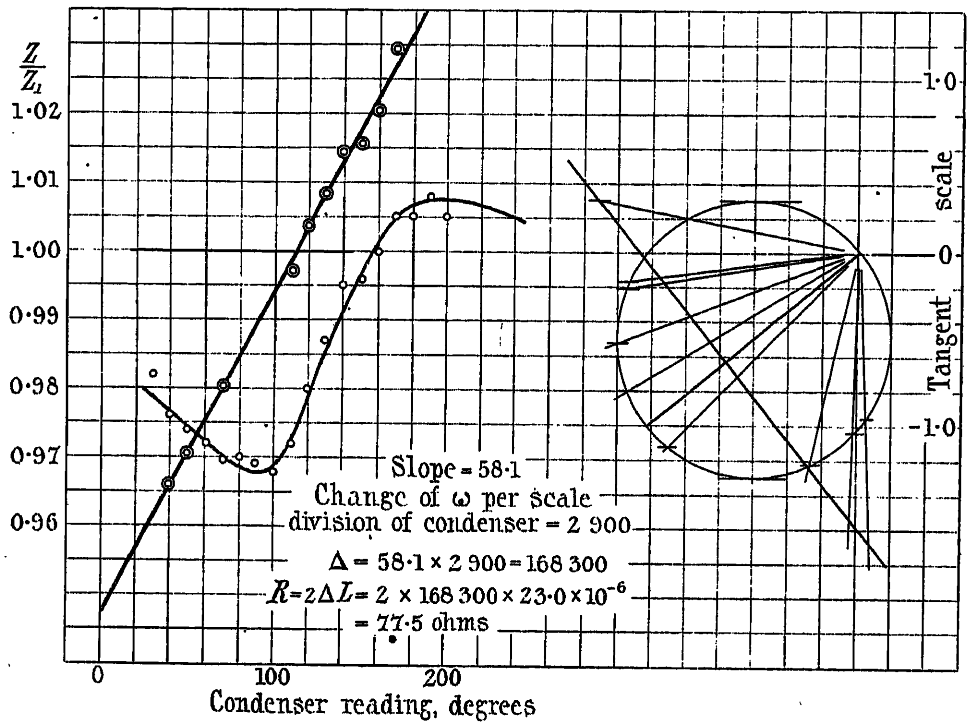

Fig. 14.

With the apparatus set up as in Fig. 7 and the oscillator condensers adjusted for resonance of the oscillatory circuit as determined by the open-circuit voltmeter reading being the same as the closed-circuit reading, the smaller of the two oscillator vernier condensers was removed and the remaining one adjusted to restore the oscillator to its original frequency, this being done by bringing the voltmeter reading back to its original value (on the central part of the curve). This smaller condenser C_2 was then put in parallel with the oscillatory circuit condenser C (see Fig. 15) and the latter reduced until the reading of the voltmeter was again the same. The value of the remaining oscillator vernier C_1 was now altered a little, and C_2 adjusted until the closed-circuit voltmeter reading was the same as the open-circuit reading, that is until the oscillatory circuit was again very nearly tuned to the oscillator. The corre-

sponding readings of the condensers are given in Table 4 and plotted in Fig. 16.

The fact that these points lie on a straight line justifies the assumption made.

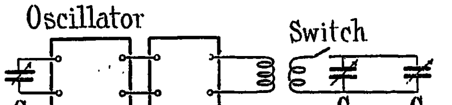

FIG. 15.

Calibration of the verniers gave for the straight-line part of the calibration curve :—

$$C_1 \quad .. \quad \delta C_1 = 6 \cdot 57 \ \delta\theta_1 \ \mu\mu F$$
$$C_2 \quad .. \quad \delta C_2 = 0 \cdot 638 \ \delta\theta_2 \ \mu\mu F$$

where θ_1, θ_2 are the readings in degrees.

TABLE 4.

θ_1	θ_2
150	143
140	116
130	89
120	61
110	33

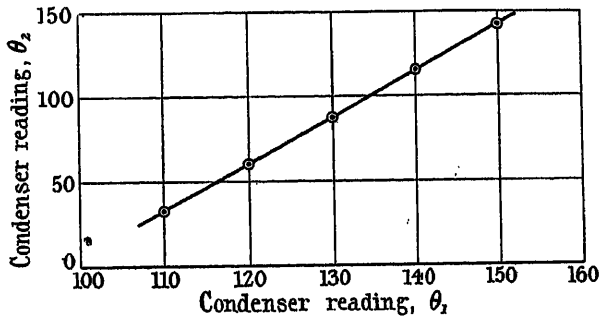

FIG. 16.

With C_2 at 20°, the capacity of C and C_2 together measured 998 $\mu\mu$F; the inductance of the coil was 4 040 μH and its self-capacity 7 $\mu\mu$F. Its ω_0 is accordingly

$$\frac{1}{\sqrt{(LC)}} = \frac{10^9}{\sqrt{(4\,040 \times 1\,005)}}$$
$$= 0 \cdot 495 \times 10^6$$

corresponding to a wave-length of 3 810 m. This was checked by a heterodyne wave-meter.

$$\text{Since } \omega = \frac{1}{\sqrt{[L(C + \delta C)]}} = \omega_0\left(1 - \frac{\delta C}{2C}\right)$$

$$\delta\omega = -\frac{\omega_0}{2C}\delta C$$

$$= -\frac{0 \cdot 495 \times 10^6}{2 \times 1\,005} \times 0 \cdot 638 \ \delta\theta_2 = 157 \cdot 1 \ \delta\theta_2$$

as determined from the oscillatory circuit.

The slope of the line of Fig. 16 is

$$\frac{d\theta_2}{d\theta_1} = 2 \cdot 79$$

so that a change of reading of C_2 corresponds to $2 \cdot 79$ times the change of C_1. $\delta\omega$ therefore, calculated from the oscillator, is given by

$$\delta\omega = 157 \cdot 1 \times 2 \cdot 79 \ \delta\theta_1$$
$$= 438 \ \delta\theta_1$$

and when the vernier C_2 is replaced in its position in parallel with C_1 on the oscillator side, the changes of ω will be given by

$$\delta\omega = 438 \times \frac{0 \cdot 638}{6 \cdot 57}\delta\theta_2 = 42 \cdot 6 \ \delta\theta_2$$

The success of these measurements suggests a possible frequency standard. If the natural frequency of the oscillatory circuit were known, it would be easy to find the setting of the oscillator which gives that frequency, and hence to calibrate it. If the oscillator is that of a wave-meter and a number of standards are available, the calibration of the wave-meter would be a far simpler matter than it is at present. The method of the harmonics could be used conveniently to fill in the gaps between the standards.

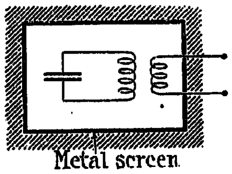

FIG. 17.

The standards could be made up and completely screened and sealed and would consist of a highly efficient oscillatory circuit with a coupling coil, only the terminals of the latter being brought outside the box (Fig. 17). If some device is included for operating a contact in the oscillatory circuit, the whole construction for determining the frequency by drawing the $\delta\omega/\tan\alpha$ curve could be gone through and the frequency obtained very accurately.

But for most purposes a sufficient approximation would be to take the resonant frequency as being that at which the voltmeter reading is midway between the maximum and minimum readings, thus avoiding the necessity for any switch at all. If this is done on Fig. 9 (voltmeter reading) the resonant frequency is obtained at a condenser setting of $63 \cdot 5$, instead of $63 \cdot 2$ from the exact determination. The difference is thus extremely small in this case. In the ammeter method it will be seen from Fig. 11 that the two readings are 106 and 97, a difference of 9, corresponding to a percentage difference in the frequency of

$$\frac{9 \times 42 \cdot 6}{0 \cdot 495 \times 10^6} \times 10^2 = 0 \cdot 078 \text{ per cent.}$$

If, therefore, the frequency of the screened and sealed circuit is determined in the first instance by taking

it as that which gives a reading midway between the maximum and minimum, an accuracy sufficient for all practical purposes should be possible.

Such a standard should be of value to a transmitting station in keeping its wave-length close to that assigned to it. The standard for the station could be made up and sealed by some central authority. At the station it would be connected up in either the voltmeter or ammeter scheme, and a glance at the instrument reading would show any departures. If desired a recording instrument could be fixed so as to have a continuous record of the wave-length transmitted, and incidentally of the times of transmission. Further, the possibility might be considered of making the alterations of current work a relay instead of an indicating instrument, and through the relay controlling in some way the station oscillator so as to keep the transmitted wave-length constant automatically.

Probably the simplest possible arrangement for direct readings of the wave-length would be the ammeter

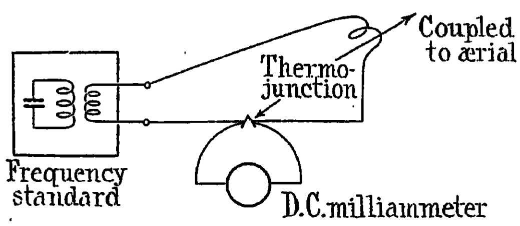

FIG. 18.

one, in which case a thermo-junction could probably be used as indicated in Fig. 18. The only precaution to be taken would be to be sure that the natural frequency of the coupling-coil circuit is far above the frequency in use.

6. MUTUAL INDUCTANCE.

The diagrams obtained make it possible to calculate the mutual inductance between the two coils when their inductances are known. It is clear from the expression $Z/Z_1 = 1 + (\omega^2 M^2/Z_1)(1/Z_2)$ and from what has gone before that at resonance, when $Z_2 = R_2$, the second term gives the diameter of the circle as drawn from the maximum and minimum values of Z/Z_1, and that this is $(\omega^2 M^2/Z_1)(1/R_2)$. Neglecting R_1 in comparison with ωL_1, and calling the diameter of the circle D, we have:—

$$D = \frac{\omega^2 M^2}{\omega L_1} \cdot \frac{1}{R_2} = \frac{\omega M^2}{L_1} \cdot \frac{1}{R_2}$$

and

$$M = \sqrt{\left[\frac{L_1 R_2 D}{\omega}\right]}$$

Applying this expression to the results of Figs. 9 and 11, we have from Fig. 9:—

$$L_1 = 700\ \mu\text{H}$$
$$\omega = 0{\cdot}495 \times 10^6$$
$$R_2 = 9{\cdot}02 \text{ ohms}$$
$$D = 0{\cdot}27$$

and

$$M = \sqrt{\left[\frac{700 \times 9{\cdot}02 \times 0{\cdot}27 \times 10^{-6}}{0{\cdot}495 \times 10^6}\right]} = 58{\cdot}6\ \mu\text{H}$$

From Fig. 11 we have:—

$$L_1 = 700\ \mu\text{H}$$
$$\omega = 0{\cdot}495 \times 10^6$$
$$R_2 = 17{\cdot}23$$
$$D = 0{\cdot}141$$

and

$$M = \sqrt{\left[\frac{700 \times 10^{-6} \times 17{\cdot}23 \times 0{\cdot}141}{0{\cdot}495 \times 10^6}\right]} = 58{\cdot}6\ \mu\text{H}$$

The values given agree very closely, as indeed they should, since the positions of the coils were the same in these two experiments. The measurement of inductance in this way may be useful.

The expression for M can be put into a somewhat different form, viz.:—

$$M = \sqrt{\left[\frac{L_1 R_2 D}{\omega}\right]} = \sqrt{\left[\frac{2L_1 L_2 D}{\omega} \cdot \frac{R_2}{2L_2}\right]}$$

$$\therefore \frac{M}{\sqrt{(L_1 L_2)}} = \sqrt{\left[\frac{2D\Delta}{\omega}\right]}$$

$M/\sqrt{(L_1 L_2)}$ is the coupling coefficient τ between the two coils, so that without any knowledge whatever of the circuit constants the measurements described of the

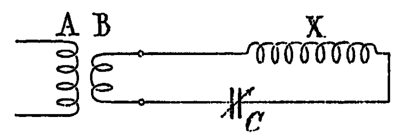

FIG. 19.

decay factor and circle diameter, together with the resonant frequency, give τ.

In the above case (Fig. 9)

$$\tau = \sqrt{\left[\frac{2 \times 0{\cdot}27 \times 1\,118}{0{\cdot}495 \times 10^6}\right]}$$
$$= 0{\cdot}035$$

The agreement obtained suggests that if the coupling remains the same in any series of measurements, and the resistance is measured by drawing out the circle and straight line in one, the resistances in the remaining cases can be determined from a knowledge of the circle diameter only, that is by a measurement of the maximum and minimum values of the ratio Z/Z_1. This leads to a scheme in which only part of the oscillatory circuit B is coupled with the coupling coil A (see Fig. 19). The coils A and B are set up permanently and the resistance/frequency curve of the coil B obtained. The coil X whose resistance is to be measured is then inserted and the circuit is tuned by the condenser C. The knowledge of the mutual inductance between A and B and the resistance of B found from the initial calibration would enable the resistance of X to be obtained from maximum and minimum readings. Some preliminary experiments have been made in this direction, but without very good results. The scheme is perhaps too similar to the substitution method.

7. CONCLUSIONS.

The method of resistance measurement described depends on the knowledge of two quantities only, the

frequency and the value of Z/Z_1. The instruments used to measure Z/Z_1 need not have absolute calibrations as long as they give an accurate measure of the quantity involved.

The essential requirement for accurate measurement is constancy of valve conditions; and, as it is impossible to prevent these changing a little, quick working becomes a necessity. Much time was saved by fitting a critically damped galvanometer in the rectifying-valve voltmeter circuit; this enabled much better results to be obtained.

The advantages of the method are briefly:—

(*a*) The circuit to be tested has no electrical connections made to it and its tuning need not be altered, thus making the method suitable for measuring the resistance of coils at their natural frequency, and in other circumstances where change of tuning is impossible.

(*b*) No absolute measurements need be made except that of condenser change. Other measurements need be only " comparative."

(*c*) The resistance is determined by a number of points lying on a straight line. An estimate of the accuracy of a measurement may be obtained by observing whether or not the points do lie on a straight line.

The value of the mutual coupling does not appreciably affect results, as is shown by the agreement obtained at varying couplings. At tight couplings there may be an error due to losses in the search coil, produced by flux from the circuit to be tested. These losses would appear as extra resistance in the circuit to be tested.*

There can be little doubt that the decay factor of the circuit under test in the circumstances and surroundings under which the test is made is quite accurately obtained. The inaccuracies all occur in converting this decay factor to a resistance, and for many purposes in wireless work this conversion is unnecessary.

The graphical construction appears a little complicated and laborious at first sight, but this is more apparent than real. The measurements and construction with the toroidal coil, made after most of the apparatus had been assembled, were completed within two hours, which included setting up some of the apparatus. The fact that a number of points are obtained which should lie on a straight line is a very helpful guide as to the accuracy of the results, and for this reason it is advisable (at least until one is fairly sure of the constancy of the valve conditions) to include some points outside the steep part of the curve.

Any capacity coupling between the two coils is not sufficient under the circumstances of the tests to influence the results. It was found that to produce a resonance curve with condenser coupling alone, a far greater value for the condenser was necessary than any possible between the coils in their usual positions.

The measurement of the departure of the frequency of a supply from the natural frequency of a given standard circuit can certainly be made with very great accuracy, and this method of frequency determinations may be of value.

A considerable field of investigation is opened up by the results obtained, and it is hoped to continue the work in the Telegraph and Telephone Laboratories of the City and Guilds (Engineering) College, where the whole of the present work was carried out, and where we have had the advantage of discussing our results with Prof. C. L. Fortescue, O.B.E.

* See Appendix 2.

APPENDIX 1.

The Effect of Current Variation.

In the voltmeter method (and similar considerations apply also to the ammeter method) it has been assumed that the current remains constant. This, however, is not strictly the case.

If μ is the amplification constant of the amplifier valve, R_0 its internal resistance and e the voltage applied to the grid by the oscillator, we have for the current through the coil:—

$$i = \frac{\mu e}{R_0 + Z}$$

$$i_1 = \frac{\mu e}{R_0 + Z_1}$$

for the oscillatory circuit closed and open respectively.

In measuring the voltage across the coil, we have accordingly measured iZ and i_1Z_1 respectively, and our ratio is $iZ/(i_1Z_1)$ instead of Z/Z_1 required by the theory. We have for this ratio

$$\frac{iZ}{i_1Z_1} = \frac{\mu e Z}{R_0 + Z} \div \frac{\mu e Z_1}{R_0 + Z_1}$$
$$= \frac{R_0 + Z_1}{R_0 + Z} \times \frac{Z}{Z_1}$$

Substituting the value of $Z = Z_1 + (\omega^2M^2/Z_2)$ the ratio becomes:—

$$\frac{R_0 + Z_1}{R_0 + Z_1 + (\omega^2M^2/Z_2)} \times \frac{Z_1 + (\omega^2M^2/Z_2)}{Z_1}$$
$$= \frac{1}{1 + [1/(R_0 + Z_1)][\omega^2M^2/Z_2]} \times \left(1 + \frac{\omega^2M^2}{Z_1Z_2}\right)$$
$$\doteqdot \left(1 - \frac{1}{R_0 + Z_1} \times \frac{\omega^2M^2}{Z_2}\right)\left(1 + \frac{1}{Z_1} \times \frac{\omega^2M^2}{Z_2}\right)$$
$$\doteqdot 1 + \frac{\omega^2M^2}{Z_2}\left\{\frac{1}{Z_1} - \frac{1}{R_0 + Z_1}\right\}$$
$$= 1 + \frac{\omega^2M^2}{Z_2}\left\{\frac{R_0 + Z_1 - Z_1}{Z_1(R_0 + Z_1)}\right\}$$
$$= 1 + \frac{\omega^2M^2}{Z_2}\left\{\frac{1}{Z_1 + (Z_1^2/R_0)}\right\}$$

neglecting the product of the two small terms.

For the multiplier of ω^2M^2/Z_2 we have therefore a vector constructed as shown in Fig. 20, where OA $= Z_1$, AB$=Z_1^2/R_0$, OB$=Z_1+(Z_1^2/R_0)$ and OD$=1/[Z_1+(Z_1^2/R_0)]$.

The effect of this on the circle will be to depress its diameter through an angle equal to XOD greater than 90°, and this must be taken into consideration in an explanation of the angles of the circle diameter found. Within the limits of the accuracy of the above

calculation there will be no effect on the resistance determination. Also, since OA is very nearly equal to OB, i.e. $Z_1 + Z_1^2/R_0$ very little different from Z_1, the calculation of M in Section 5 will hardly be affected.

In the well-known resistance-variation method of high-frequency resistance * this change of anode current may be very important.

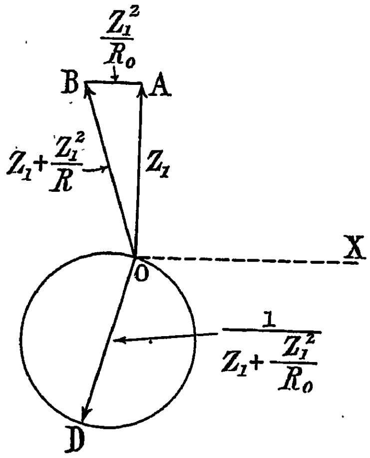

FIG. 20.

In the case shown in Fig. 21 the secondary circuit is tuned and the current I measured by a thermo-junction A. Then a resistance r is added and the current I_1 measured, and $R_2 = \dfrac{r}{(I/I_1) - 1}$ is the formula given for the required resistance.

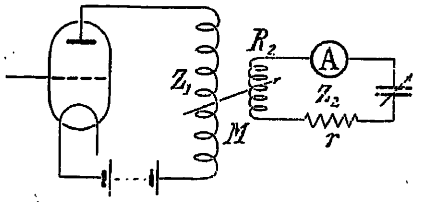

FIG. 21.

Actually, however, if i_a is the anode current, then the E.M.F. into the secondary circuit is $j\omega Mi_a$, and $I = j\omega Mi_a/R_2$.

But
$$i_a = \frac{\mu e_g}{R_0 + Z_1 + (\omega^2M^2/R_2)}$$
so that
$$I = \frac{j\omega M\mu e_g}{R_2(R_0 + Z_1) + \omega^2M^2}$$

Similarly, after r has been added to the secondary,
$$I_1 = \frac{j\omega M\mu e_g}{(R_2 + r)(R_0 + Z_1) + \omega^2M^2}$$
$$\therefore \frac{I}{I_1} = \frac{(R_2 + r)(R_0 + Z_1) + \omega^2M^2}{R_2(R_0 + Z_1) + \omega^2M^2}$$
$$\therefore \left(R_2 + \frac{\omega^2M^2}{R_0 + Z_1}\right)(I - I_1) = I_1 r$$
and
$$R_2 = \frac{r}{(I/I_1) - 1} - \frac{\omega^2M^2}{R_0 + Z_1}$$

* See Bureau of Standards Circular No. 74, p. 180.

If, therefore, no correction is made, the resistance as determined by the usual formula will be too great by an amount $\omega^2M^2/(R_0 + Z_1)$, which may be quite appreciable. It is evident also that adding different resistances r will not solve the difficulty, since the correction $\omega^2M^2/(R_0 + Z_1)$ is independent of r.

APPENDIX 2.

THIRD (UNTUNED) CIRCUIT EFFECTS.

In Fig. 3 we saw how the angle XOD which the circle diameter makes with the horizontal (the whole diagram is turned through a right angle in the constructions from the experimental results, so that O″OX is drawn vertically upwards) is determined in the simple theory by the angle of the impedance Z_1, and how this is modified in the experiments by the small current variation (Appendix 1).

These considerations will explain the angles obtained in most of the experiments, but an exception is found in Fig. 14 where the angle XOD is very large, about 135°. This diagram was obtained at 300 m from the smaller winding of a reaction coil in which the two windings had inductances of 285 μH and 23 μH respectively, and were so tightly coupled that if one had been used as a coupling coil to measure the resistance of the other the voltmeter readings would not have come conveniently within the calibration curve. A separate small coupling coil was therefore wound and slipped over both. Evidently at 300 m the larger coil approached somewhat near to its natural frequency, and thus constituted a third circuit coupled both to the circuit under test and to the coupling coil.

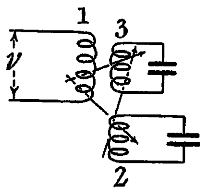

FIG. 22.

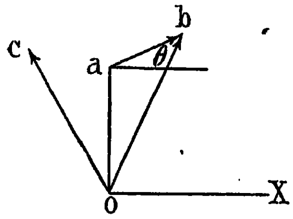

FIG. 23.

The equations for the E.M.F. in the three circuits of Fig. 22 can be written :—
$$\left.\begin{aligned} v &= Z_1i_1 + j\omega M_{13}i_3 + j\omega M_{12}i_2 \\ 0 &= Z_3i_3 + j\omega M_{13}i_1 + j\omega M_{23}i_2 \\ 0 &= Z_2i_2 + j\omega M_{12}i_1 + j\omega M_{23}i_3 \end{aligned}\right\}$$

The manipulation of these is simplified somewhat if, following Wegel,* we write Z_{11} for Z_1, Z_{22} for Z_2, Z_{33} for Z_3 and Z_{13} for $j\omega M_{13}$, Z_{23} for $j\omega M_{23}$ and Z_{12} for $j\omega M_{12}$.

Then the equations become
$$\begin{aligned} v &= Z_{11}i_1 + Z_{13}i_3 + Z_{12}i_2 & (4)\\ 0 &= Z_{33}i_3 + Z_{13}i_1 + Z_{23}i_2 & (5)\\ 0 &= Z_{22}i_2 + Z_{12}i_1 + Z_{23}i_3 & (6) \end{aligned}$$

* R. L. WEGEL: *Journal of the American Institute of Electrical Engineers*, 1924, vol. 40, p. 791.

Eliminating i_3 from (4) and (6) by means of (5) we obtain :—

$$v = \left(Z_{11} - \frac{Z_{13}^2}{Z_{33}}\right)i_1 + \left(Z_{12} - \frac{Z_{23}Z_{13}}{Z_{33}}\right)i_2$$

$$0 = \left(Z_{12} - \frac{Z_{23}Z_{23}}{Z_{33}}\right)i_1 + \left(Z_{22} - \frac{Z_{23}^2}{Z_{33}}\right)i_2$$

When the third circuit is absent ($M_{13} = M_{23} = 0$) we have :—

$$v = Z_{11}i_1 + Z_{12}i_2$$
$$0 = Z_{12}i_1 + Z_{22}i_2$$

as before, giving as our impedance ratio

$$\frac{Z}{Z'} = 1 - \frac{Z_{12}^2}{Z_{11}} \cdot \frac{1}{Z_{22}}$$

In the case with the third circuit present we obtain by symmetry :—

$$\frac{Z}{Z'} = 1 - \frac{[Z_{12} - (Z_{23}Z_{13}/Z_{33})]^2}{Z_{11} - (Z_{13}^2/Z_{33})} \cdot \frac{1}{Z_{22} - (Z_{23}^2/Z_{33})}$$

This equation is now examined vectorially. Z_{11} and Z_{33} are assumed to be sufficiently far from resonance to be taken as constant while the vector $Z_{22} - (Z_{23}^2/Z_{33})$ passes through resonance. It is at once clear that our measurements and construction will give the decay factor and resonant frequency of the vector $Z_{22} - (Z_{23}^2/Z_{33})$ instead of the vector Z_{22}; and that we are now unable to measure these quantities for the vector Z_{22} alone. Also, if the coupling coil is not coupled with the third circuit (i.e. if $Z_{13} = 0$), this is the only effect of the third circuit, since in this case the ratio $[Z_{12} - (Z_{23}Z_{13}/Z_{33})]^2/[Z_{11} - (Z_{13}^2/Z_{33})]$ becomes Z_{12}^2/Z_{11} as before. But if Z_{13} is not zero this ratio will have an angle differing from 90° when the angle of Z_{33} differs from 90°, and its angle will determine the angle of the circle diameter.

If we take
$$\angle Z_{11} = 90°$$
$$\angle Z_{33} = -\theta$$

and draw (see Fig. 23)

$$\text{Oa} = Z_{13}$$

$$\text{ab} = \left| -\frac{Z_{23}Z_{13}}{Z_{33}}\right| \angle\theta$$

then
$$\text{Ob} = \left(Z_{12} - \frac{Z_{23}Z_{13}}{Z_{33}}\right)$$

and
$$\text{Oc} = \left(Z_{12} - \frac{Z_{23}Z_{13}}{Z_{33}}\right)^2$$

drawn so that $\angle$ cOX = 2 $\angle$ bOX.

Oc is the numerator of the ratio. In the denominator we draw (Fig. 24) Od = Z_{11}

$$\text{de} = \left| -\frac{Z_{13}^2}{Z_{33}}\right| \angle\theta$$

and obtain
$$\text{Oe} = \left(Z_{11} - \frac{Z_{13}^2}{Z_{33}}\right)$$

The ratio is therefore given by Of (Fig. 25) where $\angle$ fOX = $\angle$ cOX − $\angle$ eOX and the circle diameter by OD drawn in the opposite direction to Of since it is given by

$$-\frac{[Z_{12} - (Z_{23}Z_{13}/Z_{33})]^2}{Z_{11} - (Z_{13}^2/Z_{33})} \cdot \frac{1}{R_2'}$$

where R_2' is the value of $Z_{22} - (Z_{23}^2/Z_{33})$ at its resonance.

This explains the large angle obtained in Fig. 14. The decay factor of the coil so determined is that of the coil in the presence of the second coil (third circuit),

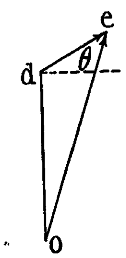

FIG. 24.

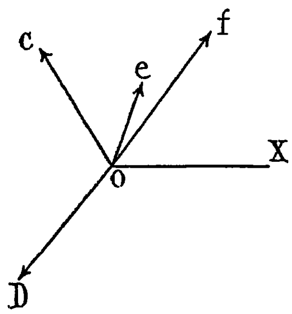

FIG. 25.

and is correctly measured, but the "resistance" has not the simple meaning it has when there is no second coil present. The calculation of the mutual inductance from the circle diameter will also be upset. The angle of the circle diameter thus has a considerable importance in the interpretation of the results; and checks by adding resistance, and measurements of the mutual inductance, cannot be expected to succeed unless the angle conforms with that required by the simple theory, including the current-variation correction given in Appendix 1.

This third-circuit investigation has a more general application to coils. It is usual to take the self-capacity

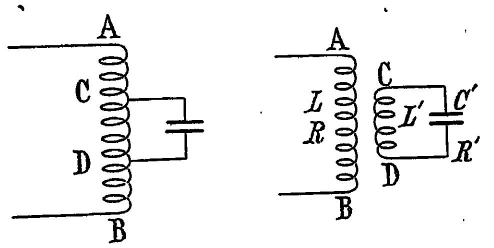

FIG. 26.

of a coil as being in effect a capacity shunting the whole coil AB (Fig. 26). But consisting as it does of a distributed wire-to-wire capacity, perhaps a closer approximation would be given by imagining it shunting only a part, CD, of the coil. Then if the resistance coupling is neglected in comparison with the magnetic coupling, the effect of the self-capacity can be allowed for by a separate circuit having inductance, capacity and resistance, the latter having a value determined not only by the wire resistance of the coil AB but also by the dielectric losses. This constitutes a "third circuit" within

is controlled from the side of a resonance curve, would meet the difficulty cited by Col. Lefroy.

Mr. Cobbold draws attention to the wonderful properties of a quartz crystal resonator. The crystal is a mechanical resonator which can take the place of the oscillatory circuit in the suggested scheme for a wave-length standard over a certain wave-length range. Curves taken * with (a) an ordinary inductance-condenser oscillatory circuit and (b) a quartz crystal under the same conditions are shown in Fig. B. The frequency at resonance is $0\cdot1144 \times 10^6$ cycles/sec. (wave-length 2 164 m), and the frequency scale (horizontal) is 1 255 cycles per sec. per inch. If it is reckoned that the cross-over of the two curves in (a) can be read to within 1/100th inch, the accuracy obtained is $1\cdot255$ cycles in $0\cdot1148 \times 10^6$, or nearly 1 in 10 000, and that is with an ordinary oscillatory circuit with only a moderately good coil. In addition, although the resonance is obviously much sharper with the crystal as shown in (b), the resonant frequency can hardly be read off to a greater accuracy, but this could be obtained by using a smaller vernier condenser. It might therefore be claimed that, far from being out of date, the authors' suggested method for a wave-length standard can be used with the latest form of "oscillatory circuit," the quartz crystal.

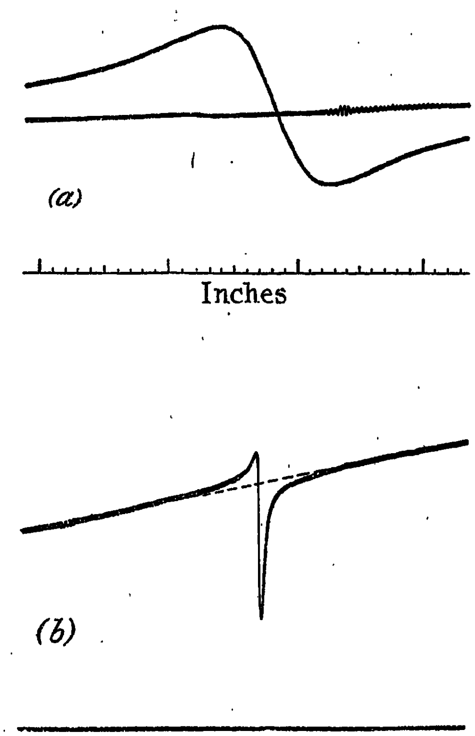

FIG. B.

* By Messrs. E. H. Harding and V. J. Terry, senior students at the City and Guilds (Engineering) College.

But however the crystal is used, it would appear that the precise frequency that is indicated so sharply is not necessarily exactly that of the crystal alone, but (what may be somewhat different) that of the crystal with its associated electrical circuits, and if these circuits have to accompany the crystal its advantage from the point of view of portability will not be so marked. One advantage that the electrical oscillatory circuit would appear to have over the quartz crystal lies in the ease with which it may be adjusted to any desired wave-length.

Mr. Sutton's difficulty when measuring the resistance of a coil at its natural frequency can be overcome quite simply by having a few turns of the "coupling coil" coupled tightly with the coil under test, and the rest not coupled at all. Short-circuiting the few coupled turns will have very nearly the same effect as opening the switch in the oscillatory circuit, and the small inaccuracy introduced can quite easily be corrected. If z is the impedance of the few turns and l their inductance, and Z_1 and L_1 the corresponding values for the rest of the coupling coil, we have with the switch open (see Fig. C),

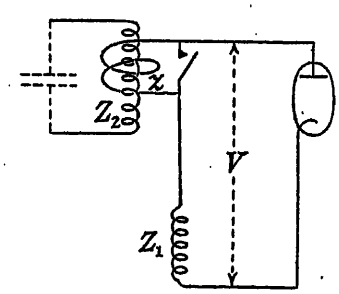

FIG. C.

$$V = \left(Z_1 + z + \frac{\omega^2 M^2}{Z_2}\right) I$$

and with the switch closed

$$V_1 = Z_1 I$$

Hence
$$\frac{V}{V_1} = \frac{Z_1 + z}{Z_1} + \frac{\omega M^2}{Z_1 Z_2}$$

$$\doteqdot 1 + \frac{l}{L_1} + \frac{\omega^2 M^2}{Z_1 Z_2}$$

and the height of the horizontal OA in the construction of Fig. 4 is to be taken as $1 + (l/L_1)$ instead of unity. This procedure could, if desired, be applied to the proposed wave-length standard.

PROCEEDINGS OF THE INSTITUTION.

719TH ORDINARY MEETING, 6 NOVEMBER, 1924.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 23rd October, 1924, were taken as read and were confirmed and signed.

A list of donations to the Benevolent Fund (see vol. 62, page 974) was taken as read and the thanks of the meeting were accorded to the donors.

Messrs. J. R. Bedford and J. Hollingworth were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Members.

Coulston, Percy Barrett.
Lucas, John George.
Price, Joseph Paul.

Associate Members.

Crisp, Miles Henry T.
Day, Francis John.
Hayden, Henry Stock.
Jack, James Mackenzie, B.Sc.(Eng.).
Phillips, Albert Charles.
Thwaites, Richard Alan S., B.Sc.(Eng.).

Graduates.

Amerasinghe, Richard Peter.
Blaquiere, Henry Arnold.
Dunphy, John.
Durrell, William Henry.
England, William Charles.
Hannant, Herbert William M.
Hodge, Thomas.
Laughland, Andrew Percy.
Le Tall, John William, B.A.
Murray, Robert Bruce.
Thompson, Francis Sinclair, B.A.
Waldeck, Thomas Ernest.

Students.

Andrews, Harold Copper.
Ashbee, Ronald Henry.
Ashley, Hugh Hartridge.
Best, Arthur Andrew.
Blakey, Arthur.
Blanden, Frank.
Brickell, Robert Patrick.
Broadbent, Herbert.
Busteed, John William.
Causon, Geoffrey Stephen.
Choudhury, Benoy Chandra.
Clemence, Edward.
Clunie, Matthew.
Coe, David Kenneth A., B.Sc.(Eng.).
Corke, Leslie Cuthbert W.
Davidson, George.
Dean, Jalal.
Dick, Robert.
Dommisse, David Rowell.
Edwards, John Charles.
Farmer, Bernard James.
Fryer, Leslie.
Gall, Alexis Charles.
Gray, Charles Marshall.
Greenway, Horace Eldred.
Greenwood, Ernest Rupert.
Grindrod, Maurice John, B.Sc.
Hammett, William Henry.
Hardwick, John Rosewell.
Harris, Arthur Cyril S.
Harris, James Harold, B.Sc.(Eng.).
Harris Leonard, Frederick.
Henson, William Joseph R.
Illingworth, Thomas.
Josephs, Henry John.

Students—continued.

Kunning, George Alexander.
Lambert, William John.
Lawrie, James Saunders.
Lyall, James Soutar.
Martin, Eric.
Matthews, Charles Edward.
Mellor, Clarence Hedley.
Mullens, Harold Hill.
Nettleton, Claude Stafford.
Newman, Augustus James.
Pawley, Edward Lewis E.
Pedrick, Sydney.
Pengelly, Percy Joseph.
Petrie, William Henry.
Poushkine, George.
Priestley, Frank.
Quenzer, David John.
Rawlinson, Robert (Jun.)
Renshaw, Alfred Percy B.
Sackey, Ebenezer Amos.
Samphier, Leonard Ralph.
Schalit, Salomon.
Scott, Frank Calder.
Smith, Arnold James.
Stewart, John McCulloch.
Stringer, Charles Hubert.
Sykes, John Henry M.
Tatton, Eric.
Thomas, Trevor Henry.
Thorne, Edward Charles.
Tumath, Harold Edward W.
van der Straaten, Philip George.
Waldram, John Malyon, B.Sc.(Eng.).
Williams, Oswald David.
Wilson, Ronald Dennis.
Wright, Hugh Crossley.
Youel, Edward.

TRANSFERS.

Associate Member to Member.

Cameron, Ernest Gordon.
Gaze, Harry Philip.
Lisle, Arthur, M.B.E., B.Sc.(Eng.).
Lower, Richard Anthony.
Mills, Ernest Arthur.

Graduate to Associate Member.

Bleach, Chris Charles.
Havekin, Thomas, B.Sc.
Taylor, Herbert Willott.
Thadhani, Gopaldas Tharumal, B.Sc.

Student to Associate Member.

Amis, Frederick Henry, B.Sc.(Eng.).
Bickell, Stanley Feneley.
Chandler, Wilfred Hardinge.
Dyson, Albert.
Jepson, Cecil.
Pinkney, William Halewood.

Student to Graduate.

Atkins, James Walter.
Beynon, John Henry.
Ferranti, Vincent Gerard S. Z. de.
Fleming, William Kirkland.
Hollis, George Richard.
Kulkarni, Purushottam P., B.A., B.Sc.(Eng.).
Langley, John Edward.
Messent, Keith Santo, B.E.
Moore, Raymond Edward.
Pendleton, Edward.
Purnell, Percival Lawrence.
Russell, Frank Gerald.
Sahgal, Amar Chand, B.Sc.
Spring-Smyth, Harold William.
Thomas, Joseph, M. (Eng.).

The President: I have to announce that the Council have unanimously elected Sir Oliver Lodge an Honorary Member of the Institution. Sir Oliver has been a Member of the Institution since 1889 and his work in electrical engineering has been of a most varied kind. His early work was in connection with the flow of electricity through metals, electrolytes and dielectrics, on the resistance of alloys, and on the phenomena of self-induction and mutual induction. When he was Professor of Physics at Liverpool he conducted a series of experiments on secondary batteries, and later devoted his attention to electrolysis, electrical discharges and the electrical precipitation of particles in the air, a subject which is becoming more and more important. Although we know the very great and valuable work he has done in so many fields, his name is most intimately connected with the subject of wireless telegraphy. The importance of his 1897 invention for adding an inductance in an oscillating radiating system, for the purpose of tuning and increasing the persistence of oscillations, cannot be overestimated. It was an extremely valuable addition to the art in its infancy and has been adopted in every form of succesful radiotelegraph transmitter, whether of the spark, arc or high-frequency alternator type. In 1914 he delivered before the Institution the Fifth Kelvin Lecture on "The Electrification of the Atmosphere, Natural and Artificial." Sir Oliver has received many honours: he is a Fellow of the Royal Society, he has been President of the British Association, and he has been a distinguished teacher both at Liverpool and at Birmingham. I am sure that members will join with the Council in desiring to offer him an additional honour by electing him an Honorary Member of the Institution.

The members present unanimously signified their approval.

A paper by Messrs. J. D. Cockcroft, R. T. Coe, J. A. Tyacke, Students, and Prof. Miles Walker, Member, entitled "An Electric Harmonic Analyser" (see page 69), was read and discussed.

On the motion of the President a hearty vote of thanks was accorded to the authors, and the meeting terminated at 7.45 p.m.

720TH ORDINARY MEETING, 20 NOVEMBER, 1924.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 6th November, 1924, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A paper by Mr. G. Rogers, Associate Member, entitled "Automatic and Semi-Automatic Mercury-Vapour Rectifier Substations" (see page 157), was read and discussed.

On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

41ST MEETING OF THE WIRELESS SECTION, 3 DECEMBER, 1924.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 5th November, 1924, were taken as read and were confirmed and signed.

A paper by Mr. G. Shearing, B.Sc., Member, entitled "Wireless Telegraph Valve Transmitters Employing Rectified Alternating Current" (see page 309), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

721ST ORDINARY MEETING, 4 DECEMBER, 1924.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 20th November, 1924, were taken as read and were confirmed and signed.

A list of donations to the Benevolent Fund (see page 68) was taken as read and the thanks of the meeting were accorded to the donors.

Prof. J. G. Gray, D.Sc., assisted by Mr. J. Gray, then delivered a lecture on "Gyroscopic Pendulums," which was accompanied by a demonstration.

On the motion of the President a vote of thanks to the lecturer was carried with acclamation, and the meeting terminated at 7.30 p.m.

722ND ORDINARY MEETING, 18 DECEMBER, 1924.

(Held in the Institution Lecture Theatre.)

Mr. A. Page, Vice-President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 4th December, 1924, were taken as read and were confirmed and signed.

The following list of donors to the Library was taken as read, and the thanks of the meeting were accorded to the donors :—

Library : Meteorological Office, Air Ministry; American Institute of Electrical Engineers; American Railway Association; Astronomer Royal; Messrs. E. Benn, Ltd.; A. Blanchard; Board of Education; O. Bonazzi; British Empire Exhibition Committee; British Engine Boiler and Electrical Insurance Co., Ltd.; British Engineering Standards Association; British Non-Ferrous Metal Research Association; Messrs. Butterworth and Co.; Dominion Water Power Branch and the Government Trade Commissioner, Canada; Messrs. Chapman and Hall, Ltd.; R. A. Chattock; Chief Inspector of Factories; Comptroller General, Department of Overseas Trade; Messrs. Constable and Co., Ltd.; H. Cotton, M.B.E.; Department of Scientific and Industrial Research; H. M. Dowsett; Dr. C. V. Drysdale, O.B.E.; Electrical Contractors' Association; "Electrical Review"; Electricity Commissioners; C. F. Elwell; Engineering Institute of Canada; E. A. H. French; J. Frith; E. Garcke; Sir Robert Hadfield, Bart., F.R.S.; H. H. Harrison; G. M. Harvey; S. B. Hickin; High Commissioner for Canada; High Commissioner for the Union of South Africa; H. M. Hobart; Hydro-Electric Power Commission of Ontario; Imperial Mineral Research Bureau; Incorporated Municipal Electrical Association; Institution of Engineers, Australia; Institution of Railway Signal Engineers; John Crear Library; A. C. Jolley; Prof. A. E. Kennelly; Kristiania Geofysiske Kommission; Messrs. Marconi's Wireless Telegraph Co., Ltd.; G. Marie; R. E. Neale; Det Norske Meteorologiske Institut; M. Otagawa; Advisory Research Council, Ottawa; E. T. Painton; W. H. Patchell; Messrs. E. F. Phillips's Electrical Works, Ltd.; Messrs. Sir Isaac Pitman and Sons, Ltd.; W. L. Randell; Messrs. S. Rentell and Co., Ltd.; S. R. Roget; Royal Albert Observatory, Mauritius; Dr. A. Russell, F.R.S.; H. M. Sayers; Schweizerischer Elektrotechnischer Verein; J. Scott-Taggart; Signals Experimental Establishment, Woolwich; Messrs. Smith, Kempe and Smith; Société des Ingenieurs Civils de France; Messrs. E. and F. N. Spon, Ltd.; Surveyor-General of India; W. T. Taylor; H. F. Trewman G. E. Tripp, LL.D.; Under-Secretary for Mines; S. Velander; E. B. Wedmore; W. Wilson; The Wireless Press, Ltd.; and Lady Yarrow.

A paper by Mr. Donald Murray, M.A., Member, entitled "Speeding up the Telegraphs: A Forecast of the New Telegraphy" (see page 245), was read and discussed, and a demonstration of printing telegraphs was given.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.45 p.m.

42ND MEETING OF THE WIRELESS SECTION, 7 JANUARY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 3rd December, 1924, were taken as read and were confirmed and signed.

A paper by Professor E. Mallett, M.Sc., Member, and Mr. A. D. Blumlein, Student, entitled "A New Method of High-Frequency Resistance Measurement" (see page 397), was read and discussed.

On the motion of the Chairman a hearty vote of thanks was accorded to the authors for their paper, and the meeting terminated at 7.40 p.m.

723RD ORDINARY MEETING, 8 JANUARY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.
